The extraction conditions can be empirically determined on a small scale (<1 ml) by taking aliquots of washed pellet suspension and microcentrifuging. If preweighed microcentrifuge tubes are used, the extraction conditions can be related to a given wet weight of pellet. A fixed volume of extraction buffer is added plus a reducing agent (5 to 20 mM DTT). Initially, guanidine·HCl (4 to 8 M) or urea (6 to 9 M) should be tried. The pellets are resuspended by vortexing, then incubated for various times at different temperatures. (Suspension of the pellet is aided by brief sonication or by using a tissue homogenizer.) After equilibration, solutions are clarified either by filtration or by centrifugation. For the latter, a benchtop ultracentrifuge such as the Beckman XL-100 or Airfuge is ideal. The comparative effectiveness of extractants can determined by measuring the amount of protein solubilized from the washed pellets using standard protein estimation methods and/or SDS-PAGE (*UNIT 10.1*).

It should be noted that solubilized protein must at some stage be folded into the native conformation; hence, the most effective solubilizing conditions might not necessarily be the best, especially if they cause irreversible denaturation. Irreversible denaturation appears to result from chemical modification of the protein and is induced by such factors as high temperature, extremes of pH, and tight binding of denaturants such as SDS.

The extraction process (Basic Protocol 1) should result in protein that is both monomeric (assumed to be unfolded) and contains cysteine residues in the reduced state. This provides a defined starting point from which to develop a reproducible folding protocol or from which to further purify the protein by, for example, gel filtration under denaturing conditions (Basic Protocol 2). Extraction of inclusion bodies with some denaturants, such as urea, may not completely convert the protein to monomers, resulting in physically heterogeneous mixtures. As pointed out in *UNIT 6.1*, extraction can be accomplished with strong denaturants (e.g., guanidine·HCl) that can then be exchanged by dialysis or gel filtration for weaker ones (e.g., urea). This particular solvent exchange often results in much better yields of folded protein compared to that obtained by the direct removal of guanidine·HCl (e.g., *UNIT 6.5*).

Gel-filtration chromatography (Basic Protocol 2) is not commonly considered a high-resolution separation technique. However, as the recombinant-derived protein content of well-prepared washed pellets will be >50% of the total (see Fig. 6.3.1, lanes h and i), only a 2-fold purification is required to obtain pure protein.

Protein extracted with guanidine·HCl in the presence of reductant will ideally be in a random coil conformation with all sulfhydryl residues in the reduced state. Under such conditions, the order in which proteins elute from a gel-filtration matrix in guanidine·HCl can be directly correlated with molecular size (Mann and Fish, 1972).

Selection of the proper chromatography resin is critical for success (for detailed discussion, see Critical Parameters and Troubleshooting). The main disadvantage of gel filtration in

B. C. U. „... SCU" IAŞI

guanidine·HCl, especially when using some of the (soft) agarose-based resins (e.g., Sepharoses and Bio-Gels), is that flow rates can be very slow due to the high viscosity of the gel-filtration buffer. Basic Protocol 2 uses a Superdex matrix that permits fast flow rates in the presence of high guanidine·HCl (or urea). A column size of 5 × 100 cm allows ~40 to 50 ml guanidine·HCl-containing extract to be processed. For smaller sample sizes, columns with proportionally smaller diameters are used.

Because the proteins separated by gel filtration in the presence of guanidine·HCl are unfolded, they have no biological activity, so the column fractions are usually assayed by SDS-PAGE. Direct addition of SDS to samples containing guanidine·HCl results in the formation of the insoluble guanidinium salt of dodecyl sulfate. The guanidine·HCl must therefore be removed before addition of the sample buffer used for SDS-PAGE analysis (*UNIT 10.1*). The approach used in Support Protocol 1 takes advantage of the fact that guanidine·HCl is soluble in 90% ethanol whereas the protein is not. An alternative is to simply remove the guanidine·HCl by dialysis. Small samples (10 to 100 µl) can be dialyzed using one of various microdialyzing systems commercially available (e.g., the Microdialyzer System 100 from Pierce, which allows simultaneous dialysis of up to 12 samples) or a simple homemade device that uses modified microcentrifuge tubes (Falson, 1992).

Critical Parameters and Troubleshooting

Breaking cells and preextracting inclusion bodies

Once it has been established that the recombinant protein is insoluble (*UNIT 6.1*), extra care should be taken to ensure complete cell lysis. If unbroken cells are present in the low-speed pellets, they will leach contaminants when the pellets are extracted with strong protein denaturants. Proper operation of the French press is described in *UNIT 6.2*. Other major sources of contamination are outer membrane and cell wall material, most of which can be preextracted with detergents such as Triton X-100 (0.5% to 5%) and urea (1 to 4 M).

The proper concentration of urea in the wash buffer is determined empirically in small-scale extractions. It is probably safe to use 2 M urea for most aggregates. The effectiveness of the wash process at removing the cell wall and outer membrane material can be improved by increasing the volume of wash buffer (see Basic Protocol 1, step 6: use 10 ml instead of 6 ml buffer per gram cells). Treatment of the cells with lysozyme prior to homogenization with the French press will also help remove this material (*UNIT 6.5*, Basic Protocols 1 and 2).

Although insoluble proteins are less susceptible than native proteins to proteolysis, inclusion of EDTA and a serine protease inhibitor such as benzamidine·HCl or AEBSF is recommended. The choice of cell lysis buffer is not critical; however, the buffer pH should be >6.5, as many soluble *E. coli* proteins precipitate at slightly acidic pH values.

After preextraction, wash the aggregates with buffer alone to remove excess detergent. When attempting to develop a reproducible folding protocol, note that varying amounts of detergent carryover may influence the outcome. In fact, nonionic detergents can be used as cosolvents to aid folding (*UNIT 6.1*); even so, it is important to know how much detergent is present.

Extracting inclusion bodies with guanidine·HCl

The washed pellets containing the insoluble inclusion body proteins are extracted with guanidine·HCl (see Basic Protocol 1, step 10). To obtain complete dissolution of the pellets, some form of mechanical dispersion is often required. Homogenization at room temperature with a tissue grinder (as described) is often adequate; however, sonication should be used if the pellet is especially recalcitrant. Heating the solution will also aid protein solubilization; 10 to 15 min at 50° to 60°C is usually a good starting point. Excess heating, whether direct or caused by sonication without adequate cooling, should be avoided. It is worth remembering that if extraction involves extremes of heat and or pH, such conditions will favor deamidation of Asn and may also promote cleavage at the labile Asp-Pro bond and other chemical modifications of the protein (Zale and Klibanov, 1986).

It is best to use the extract directly after preparation rather than storing it frozen. In general, an unfolded protein in solution is much more susceptible to proteolytic degradation and chemical modification than its native (folded) counterpart.

Selecting medium and column for gel filtration in guanidine·HCl

Selecting the proper gel-filtration resin is one of the most critical steps. First of all, the

PCU IAS/CENTRAL UNIVERSITY LIBRARY

Table 6.3.1 Gel-Filtration Matrices Suitable for Use with Solutions Containing Guanidine Hydrochloride

Matrix[a]	Mass range (kDa)		Reference
	Native proteins	Unfolded proteins[b]	
Sepharose CL-6B	10-4,000	1-80	Mann and Fish (1972)
Bio-Gel A-5m	10-5,000	1-80	Mann and Fish (1972)
Sepharose CL-4B	60-20,000	10-300	Mann and Fish (1972)

Sephacryl S-200 HR	5-250	1-50	Belew et al. (1978)
Sephacryl S-300 HR	10-1,500	1-100[c]	—
Sephacryl S-400 HR	20-8,000	1->100[c]	—
Superdex 75	3-70	<1-25	I.P. and P.T.W. (unpub. observ.)
Superdex 200	10-600	1-80	I.P. and P.T.W. (unpub. observ.)

[a]All resins are from Pharmacia Biotech except Bio-Gel A-5m, which is from Bio-Rad. The Sepharose and Bio-Gel matrices are normally run under low pressure; all other resins can be run under low or medium pressure. Medium pressure is achieved using one of the chromatography pumps indicated in Basic Protocol 2; the pumps are normally included in the Pharmacia Biotech FPLC or BioPilot systems.

[b]Data on the fractionation range in the unfolded state refer to proteins unfolded with guanidine·HCl; however, the guidelines also apply to proteins unfolded and eluted with urea (assuming they are random coils).

[c]Estimates based on fractionation range for native proteins.

chromatography medium must have high chemical stability that permits prolonged exposure to high concentrations of denaturing solvents such as guanidine·HCl and urea. It must also have high physical strength that allows high flow rates with viscous solvents. Suitable media are listed in Table 6.3.1. The Sepharoses and Bio-Gels are cross-linked agaroses, Sephacryl is dextran cross-linked with bisacrylamide, and Superdex is cross-linked agarose with bonded dextran. All the matrices listed are stable in high concentrations of urea and guanidine·HCl. Details on the properties of various media can be obtained from the manufacturers.

Second, selecting a medium with the proper pore size is important for good separation. Manufacturers provide information about the separation ranges of their products. These ranges are determined for proteins in an aqueous buffer. In guanidine·HCl, denatured proteins (assuming they are random coils) will have a radius 3- to 4-fold greater than an average folded globular protein of the same mass. Thus, the mass range values for unfolded proteins in Table 6.3.1 should be used rather than the native protein values.

Third, the pressure rating of the column must be adequate. Because 4 M guanidine·HCl has a higher viscosity than most aqueous buffers, higher pressures are needed to achieve the same flow rates. The column should be capable of safely withstanding moderate pressures of around 0.5 MPa (5 bar) or ~75 lb/in^2 (the XK columns are rated to 0.5 MPa). The proteins separate as they pass through the column, so column length is important. A column 60 to 100 cm in length will generally be suitable. Some manufacturers offer prepacked columns with a choice of media. If column packing is to be done in the laboratory, then selecting a column with a packing reservoir is helpful.

Prepacked columns (diameters 1.6, 2.6, 3.5, and 6.0 cm and length 60 cm) prepacked with Sephacryl resin (Sephacryl S-100, S-200, or S-300) or Superdex resin (Superdex 200 and 75) are commercially available from Pharmacia Biotech. Superdex 200 and 75 PG (preparative grade) 60/600 columns (6.0 cm i.d. × 60 cm length) are used with the BioPilot system (Pharmacia Biotech) either individually or sequentially to obtain, in many cases, pure protein (for example, see Fig. 6.3.1).

Performing gel filtration in guanidine·HCl

The general guidelines and critical parameters that apply to gel-filtration chromatography in general and are detailed elsewhere (*UNIT 8.3*) also apply here. The main distinction from typical gel filtration is the use of a highly

BOURNEMOUTH UNIVERSITY LIBRARY

viscous solvent, which requires robust matrices to obtain reasonable flow rates. On the other hand, it should be noted that the presence of high concentrations of guanidine·HCl gives higher-resolution separations than those obtained with normal solvents because the high viscosity of the solvent reduces diffusion, which otherwise tends to broaden elution peaks.

It is important to ensure that all connections and tubing are leak-free. Concentrated guanidine·HCl is highly corrosive to metal and electronic components.

The sample derived from extraction of highly aggregated protein must be clarified before being applied to the column. Furthermore, to prevent the sample from precipitating near or at the top of the column, it should be equilibrated to the same temperature as the column matrix and buffer. This is especially important if chromatography is carried out at 4°C and the sample was heated during extraction.

The column must be equilibrated with freshly made buffer before use. The column buffer contains the sulfhydryl reagent DTT, which will oxidize over time, thus lessening its effectiveness and increasing the background UV absorbance of the buffer.

If the recombinant protein has been effectively solubilized, it will be physically homogeneous and its elution position will be proportional to its mass. If the protein elutes anomalously (i.e., is located in more than one peak), there are several possible reasons.

1. *Incomplete protein solubilization.* Try more drastic extraction conditions—in particular, increase the denaturant concentration and temperature during extraction. Use a stronger chemical denaturant, especially if urea was originally used.

2. *Aggregation/precipitation of protein(s) in the column.* Ensure that the concentration of guanidine·HCl in the column buffer will maintain the solubility of all proteins during chromatography. The column can be run at room temperature (as opposed to 4°C), and reasonable flow rates can still be obtained with buffers containing 6 to 7 M guanidine·HCl (4 M is used in Basic Protocol 2).

3. *Conformational heterogeneity.* Related to the above two situations is the case where the protein, although monomeric, contains both unfolded and partially folded species. The folded protein will elute later (appear smaller) than the unfolded protein. Conformational heterogeneity is usually not a major problem in high (>4 M) guanidine·HCl concentrations.

4. *Oxidation of sulfhydryl residues.* The formation of intermolecular disulfide bonds is indicated by the appearance of protein eluting earlier than expected and corresponds to the formation of multimers (dimers, trimers, etc.). Disulfide interchange occurs more readily at high pH; thus, use of a slightly acidic buffer (pH 6.0 to 5.0) and inclusion of fresh reductant in both the sample and column buffer are recommended. For analytical separations, cysteine residues are normally capped by alkylation with iodoacetamide; cysteines can also be reversibility modified by sulfitolysis (Glazer et al., 1975).

5. *Proteolysis.* (a) The sample contains partially proteolyzed protein, with proteolysis by *E. coli* proteases occurring before or after cell breakage: In fully denatured protein, it should be possible to separate clipped protein from unmodified protein if there is sufficient mass difference. Once the protein has been separated by gel filtration, it should be checked by mass spectrometry to confirm its integrity. If the protein is not fully denatured, clipped protein may have similar elution properties as unmodified protein; however, the processing will be revealed when the protein is boiled in SDS and analyzed by gel electrophoresis.

(b) Where the recombinant protein is itself a protease: As pointed out by Fish et al. (1969), "Since denaturation is a kinetic process, the dissolution of proteases in guanidine·HCl might result in a condition where the fraction of the protein not denatured at a given instance may digest the unfolded protein leading to low molecular weight estimate." The converse of this situation is also true: if proteases are extracted under conditions where they are fully denatured and, thus, inactive (e.g., 8 M guanidine·HCl), changes in the solvent conditions (e.g., reducing the guanidine·HCl concentration or exchanging for urea) might lead to a fraction of the protein folding into an active conformation. If autolytic processing is suspected, include an appropriate inhibitor or choose a solvent pH where the enzyme has minimal activity.

Ancipitated Results

Cell lysis and preparation of washed pellets

Pelleted aggregates after washing contain ~30% dry weight, of which 90% is protein. SDS-PAGE of a typical washed pellet preparation (Fig. 6.3.1, lanes h and i) indicates that recombinant bovine growth hormone (21 kDa) makes up >60% of the total protein. The

RCU IASI CENTRAL UNIVERSITY LIBRARY

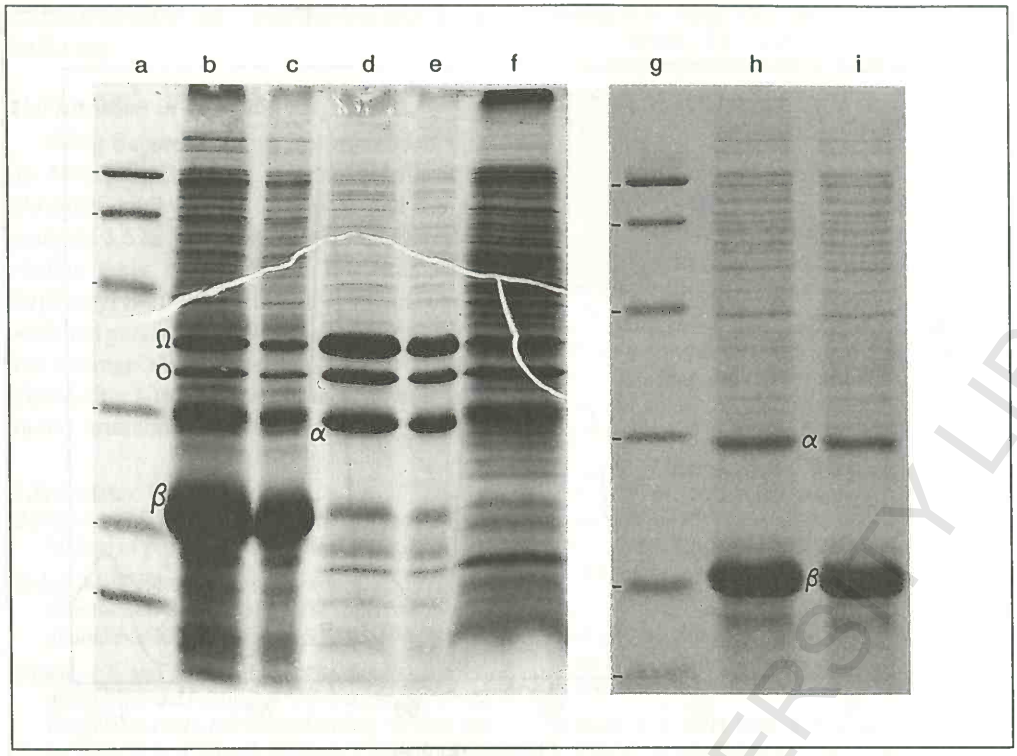

Figure 6.3.1 Analysis by SDS-PAGE of fractions from low-speed centrifugation of *E. coli* cell lysates containing aggregated bovine growth hormone. A 12.5% acrylamide gel of dimensions 12 cm × 16 cm × 1.5 mm was used with the Laemmli buffer system (*UNIT 10.1*). Lanes a and g contain standard proteins (low-range standards, Bio-Rad) in order of increasing migration distance: phosphorylase *b* (97.4 kDa), bovine serum albumin (66.2 kDa), hen egg white ovalbumin (45 kDa), bovine carbonic anhydrase (31 kDa), soybean trypsin inhibitor (21.5 kDa), and hen egg white lysozyme (14.4 kDa). After low-speed centrifugation of the clarified lysate and of the washed pellet homogenate (see Basic Protocol 1, steps 5 and 7), the supernatants will be cloudy (lane f) and the pellets usually consist of two layers (see Fig. 6.1.5). The bottom layer is inclusion body protein plus unbroken cells (lanes b and c) and the top layer consists of outer membrane and peptidoglycan fragments (lanes d and e). The outer membrane proteins OmpA (35 kDa) and OmpF/C (38 kDa) are indicated by ω and o, respectively. After the washing steps, the growth hormone (marked β, 21 kDa) is the major constituent (lanes h and i) together, in this example, with another plasmid-encoded protein, namely kanamycin phosphotransferase (marked α, 30.8 kDa), the product of the gene conferring resistance to the antibiotic kanamycin.

washed pellets analyzed in Figure 6.3.1 are typical starting materials for the protein folding and purification described in *UNIT 6.5* (Basic Protocol 1). The multiple bands in the background are either derived from unbroken cells (most likely) or are *E. coli* cytoplasmic proteins coprecipitated or trapped during aggregate formation. The gel analysis indicates the presence of another plasmid-encoded protein, namely, kanamycin phosphotransferase (30.8 kDa), a product of the gene conferring resistance to the antibiotic kanamycin (Kane and Hartley, 1991). The washing procedure described only partially extracts the phosphotransferase but removes most of the outer membrane proteins. For further details, see the legend to Figure 6.3.1.

Gel filtration in guanidine·HCl

Fractionation of human immunodeficiency virus type 1 (HIV-1) protease illustrates expected results from gel-filtration chromatography. The protein is expressed in *E. coli* as a 17-kDa precursor that at some stage undergoes autolytic processing to form the mature-sized protease (10.7 kDa). The protease and undigested precursor accumulate as insoluble inclusions in the *E. coli* cytoplasm. Washed pellets prepared and extracted with 6 M guanidine·HCl as described (see Basic Protocol 1) were applied to a Superdex 200 column. The protease eluted in a single peak (Fig. 6.3.2, fractions 66 to 72), well separated from unprocessed protein (e.g., fraction 60) and larger molecular mass proteins (e.g., fractions 50 to

BOSTON UNIVERSITY LIBRARY

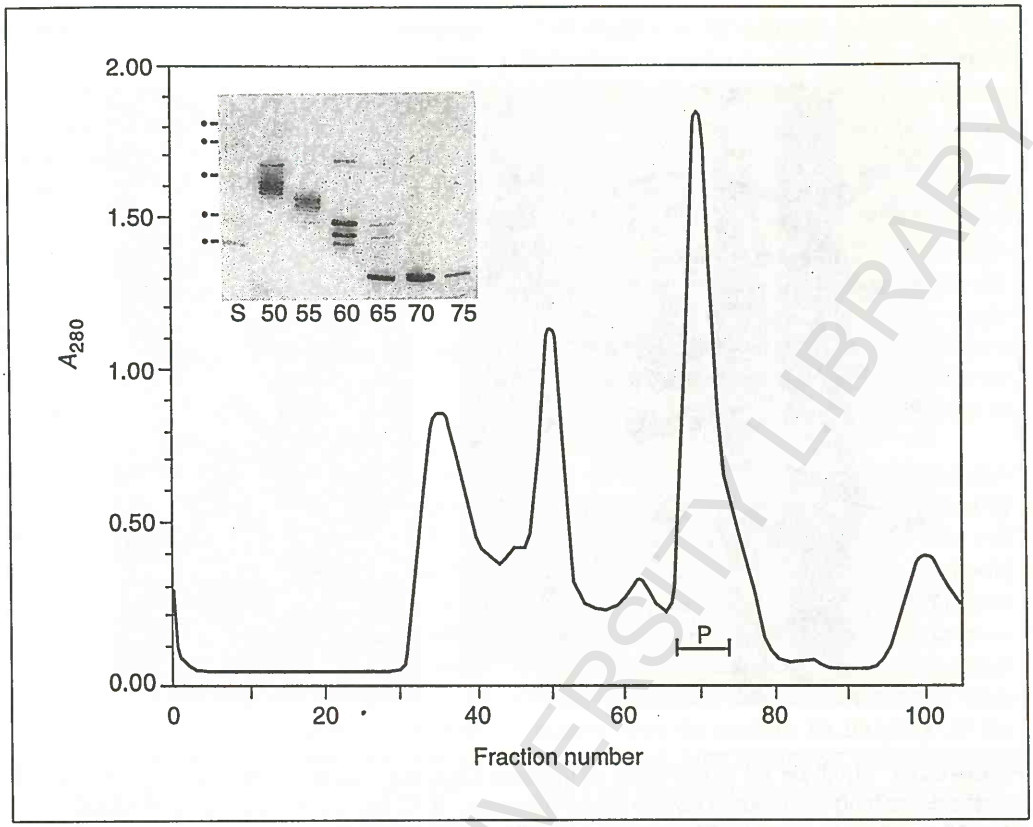

Figure 6.3.2 Gel filtration using Superdex 200 in 4 M guanidine·HCl. Column dimensions, 6 × 60 cm; buffer, 50 mM Tris·Cl (pH 7.5)/4 mM guanidine·Cl/2 mM DTT; flow rate, 5 ml/min (300 ml/hr). The sample was an extract containing HIV-1 protease, which has a mass of 10 kDa. Protein fractions 66 to 72 (pool P) was further purified under the same conditions using a Superdex 75 matrix. The inset shows SDS-PAGE analysis of selected fractions. The protein markers (lane S) correspond to standards with mass values of 66.2, 45, 30, 21.5, and 14.4 kDa, respectively (migration order top to bottom).

55). The fractions indicated in Figure 6.3.2 by P were pooled and the protein further purified by repeat chromatography on a Superdex 75 column under the same conditions. The protein at this stage is >95% pure and after solvent exchange is folded into active protein. (As it happens, the native protease is a 20-kDA homodimer that is very susceptible to autolytic digestion; hence, purification in the denatured, inactive state is highly advantageous).

In the inset of Figure 6.3.2, analysis by SDS-PAGE of fraction 60 illustrates incomplete dissociation of the sample, a problem commonly observed when electrophoresing samples precipitated with ethanol and trichloroacetic acid (TCA). If necessary, repeat the analysis using SDS sample buffer (*UNIT 10.1*; see Support Protocol).

The fractionation of HIV-1 protease is somewhat of a best-case scenario due to the small size of the protein. Usually it is not possible to purify the recombinant protein completely, especially for proteins close in size to the main *E. coli* contaminants (30 to 45 kDa). In general, small proteins (<25 kDa) are best suited for the method; however, any protein will be purified to some extent, and further purification can be attempted using some of the methods discussed in *UNIT 6.1*. Moreover, partial purification may be all that is required to enhance protein folding significantly.

Recovery of recombinant protein from gel-filtration chromatography is close to quantitative, and the purified (or partially purified) protein can be folded or can be stored in aliquots at –80°C. On thawing the protein, add fresh DTT (an additional 1 or 2 mM) and warm the solution at 37° to 40°C for several minutes before use. The protein concentration can be conveniently estimated by UV spectroscopy.

Time Considerations

Cell lysis and preparation of washed pellets

French press lysis of ~150 to 200 ml cell suspension will take ~30 to 35 min. Preparation

RCU IAS CENTRAL UNIVERSITY LIBRARY

and extraction of the washed pellet take about half a day.

Gel filtration in guanidine·HCl

Using Superdex resins in conjunction with an FPLC or BioPilot system, gel-filtration chromatography takes 3 to 6 hr and the gel analysis 1.5 to 2 hr. With low-pressure resins, elution takes much longer. For example, a Sephacryl S-300 column (2.5 × 98 cm) eluted with 6 M guanidine·HCl runs at ~25 to 30 ml/hr. An average-sized protein (15 to 30 kDa) is eluted after 10 to 12 hr. A column can be loaded in late afternoon and run overnight.

Overview of Protein Folding

HOW PROTEINS FOLD

Where proteins are expressed as insoluble aggregates—i.e., bacterial inclusion bodies—the obligatory first step in the recovery of functional protein is to disperse the inclusion bodies in a denaturant such as 6 M guanidine·HCl (guanidinium chloride; GdmCl), which will yield a solution of unfolded and essentially noninteracting polypeptide chains. The next problem is the one that faced Anfinsen in his pioneering work on the mechanism of protein folding—i.e., how to recover the protein in its unique, functional, three-dimensional conformation. The main factors determining the folding of proteins, and hence their three-dimensional conformation, are summarized in the following three sections.

All the Information is in the Sequence

Anfinsen (1973) showed that proteins fold up solely as a result of thermodynamic drive, which leads to the creation of the specific noncovalent interactions and disulfide bonds characteristic of the functional state. In other words, a protein folds because, under folding conditions, its native state is more stable than the unfolded state–the information determining the relative stabilities of the two states resides solely in the primary sequence. No additional energy or information, for example, in the form of a template, is required.

Other factors that may increase the yield and rate of folding such as chaperone proteins, protein disulfide isomerase (PDI), and peptidyl prolyl *cis-trans* isomerase (PPI), all depend on this thermodynamic drive for the intrinsic ability of the intact polypeptide chain to fold.

Proteins Fold Along a Limited Number of Pathways

Like a large river, proteins in the process of folding start from a large number of sources or conformations—i.e., the unfolded state(s). These rapidly condense, reducing the number of paths (intermediate states) available to the flow, until the ocean (the functional, folded state) is finally reached through something like a single pathway. As the protein folds, the number of possible intermediate states becomes increasingly limited, and further folding is thus confined to pathways by which the vast majority of conformational states potentially accessible to the polypeptide chain are precluded. In this way, proteins can fold in vivo at a rate that can keep pace with the rate of synthesis; in vitro, protein molecules can fold with half-times varying from tens to thousands of milliseconds.

Consider first proteins that do not contain disulfide bonds in the native state. Very early in the folding pathway, in less than a few milliseconds, the chain collapses to intermediates in which substantial proportions of the secondary structure and hydrophobic core are assembled. The stabilization of secondary structure elements and the packing of side chains continues until a compact intermediate termed the "molten globule" is formed. This contains essentially all the native secondary structure and, in many proteins, has been shown to accumulate to a significant extent (Ptitsyn et al., 1990). Although the topology of the molten globule is similar to that of the protein in the native state, the specific and persistent tertiary interactions characteristic of the native state are still lacking. This accounts for its ability to bind the hydrophobic probe 8-anilino-1-naphthalene sulfonic acid (ANS) and presumably also for its observed tendency to aggregate. The molten globule finally folds to the native state in a reaction that usually constitutes the rate-limiting step of folding.

Although several proteins have been shown to exhibit multiple kinetic phases and hence small energy barriers during folding, the early stages are fast ($t_{1/2}$ = 1 to 25 msec). Many of the slower steps observed in folding are rate-limited by the slow *cis-trans* isomerization of peptide bonds joining X-Pro residues (Nall, 1994). This isomerization, with half-times on the order of a minute, occurs at later stages of folding, and therefore within rather collapsed forms of the protein. The variable accessibility of the bonds involved in *cis-trans* isomerization, resulting from the collapsed state of the polypeptide chain, explains the somewhat variable success of peptidyl prolyl *cis-trans* isomerase (PPI) in catalyzing the reaction in vitro.

In comparison to these generally fast folding processes, disulfide bond–containing proteins fold somewhat more slowly in vitro. Where the noncovalent interactions are relatively strong and constitute the main factors driving the folding (at least up to a molten globule state), the stages of folding prior to disulfide formation will be similar to those described above. In some disulfide-containing proteins, however, the noncovalent interactions are weaker;

Copyright © 1995 by John Wiley & Sons, Inc.

BOSTON UNIVERSITY LIBRARY

thus the drive to shift the equilibrium toward the compact folded state must come from the formation of the native disulfide bonds. In such cases the intermediate that accumulates during folding will be relatively expanded.

Protein disulfide isomerase (PDI) is located in the lumen of the endoplasmic reticulum and is important in catalyzing formation of disulfide bridges in proteins as they fold in vivo. The isolated enzyme can, in many cases, be used to increase the rate of folding in vitro. This application of PDI has had variable success, which is accounted for (as in the case of PPI, discussed above) by the variable accessibility of the protein thiols. As PDI is a low-efficiency enzyme, large amounts are required to achieve catalysis.

Aggregation is the Main Competitor to Folding

Most proteins tend to exhibit some tendency toward association, reflecting the high proportion (usually ~50%) of their surface that is nonpolar. In the case of folding intermediates, which have somewhat higher proportions of nonpolar groups exposed to the solvent, it is not surprising that aggregation is a frequently experienced hazard. Aggregation during folding in vivo has been well-documented in the cases of phage tail spike protein mutants (Haase-Pettingell and King, 1988) and α-1-antitrypsin (Lomas et al., 1993). It has also been established that a major role of the families of chaperone proteins is to prevent aggregation from competing with folding in the cell (Hlodan and Hartl, 1994). In the case of multimeric proteins, whose subunit chains have evolved to interact strongly with each other—frequently through large nonpolar surfaces—it is not surprising to find that the occurrence of aggregation during folding is a much greater problem.

The dependence of yield on aggregation is illustrated in Figure 6.4.1.

HOW TO FOLD PROTEINS

The three principles outlined in the discussion of How Proteins Fold lead to three sets of conditions necessary for the successful recovery of functional proteins after denaturation: (1) the folded protein should be the most stable state (see All the Information is in the Sequence, above), (2) kinetic barriers that slow down or block the folding pathway should be minimized (see Proteins Fold Along a Limited Number of Pathways), and (3) intermolecular aggregation between folding intermediates should be reduced to acceptable limits (see Aggregation is the Main Competitor to Folding). These three goals will be considered as they bear on the practical problems involved in folding recombinant proteins. They will thus provide a rationale for the protocols in *UNIT 6.5*.

Stabilizing the Native Functional State

The "simple" case

Some proteins—e.g., phosphoglycerate kinase—are composed of a single intact polypeptide chain, constituting the simple case in which all the information required to define the folding and stability of the three-dimensional conformation is present in the sequence. In such a case, the native state will represent the most readily accessible stable state. Where disulfide

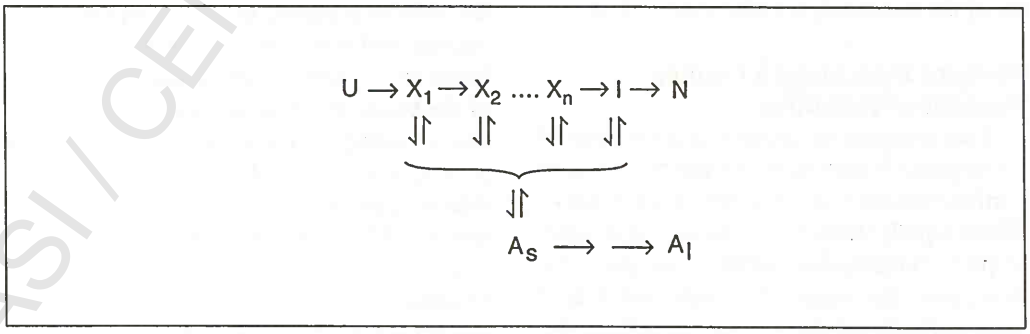

Figure 6.4.1 Illustration of the dependence of yield on aggregation. The unfolded protein (U) folds through the intermediate forms (X_1 to X_n), then through the molten globule (I) to the native state (N). Some or all of the intermediates will be capable of associating, reversibly at first, to form small aggregates (A_s). Subsequently, however, these will associate irreversibly to form larger insoluble aggregates (A_l). The rate of aggregation (r_a) will depend on the concentrations of the intermediates (and hence on the rate constants for the individual steps in the folding pathway) and also on the rate constant ($k_{i,aggr}$) for aggregation of each intermediate (X_i) according to the equation $r_a = k_{i,aggr}[X_i]$. Aggregation will therefore depend on the overall protein concentration as well as the solubility properties of each intermediate.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

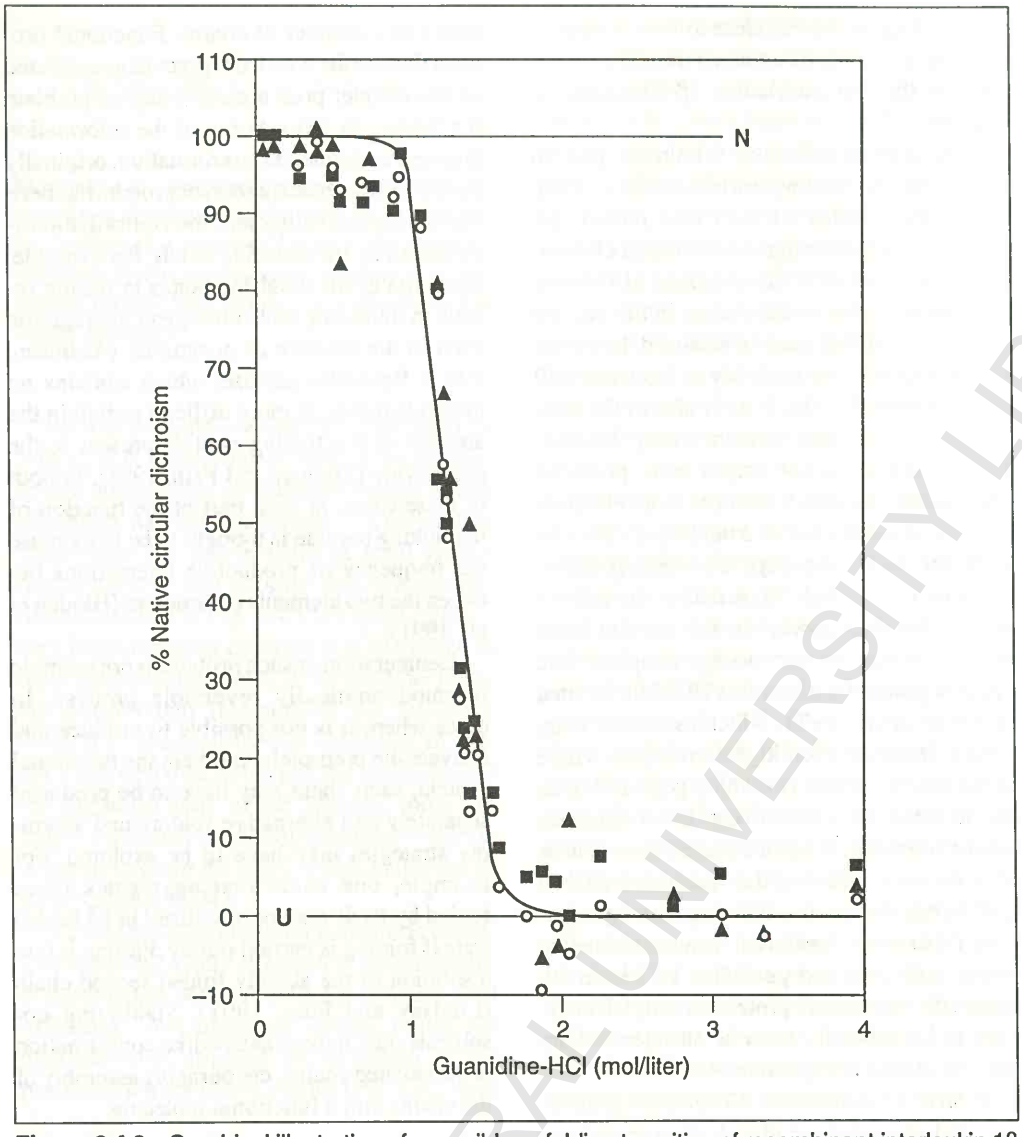

Figure 6.4.2 Graphical illustration of reversible unfolding transition of recombinant interleukin 1β in guanidine·HCl, monitored by circular dichroism (CD). Near-ultraviolet CD, which indicates changes in tertiary structure, was measured at 260 nm (triangles), 287 nm (circles), and 295 nm (squares). The plateau regions are marked for the native (top; N) and unfolded (bottom; U) states respectively, and represent regions of denaturant concentration within which there is no change in protein conformation detectable by CD. CD measurements in the far-ultraviolet range, which reflect changes in secondary structure, resulted in a curve that was coincident with this one, indicating that at equilibrium, this transition is largely two-state—i.e., only the native and unfolded states are significantly populated (Craig et al., 1987).

bonds are involved, they supplement the noncovalent interactions in contributing to the stability and specificity of the native three-dimensional conformation and the folding intermediates (see discussion of Disulfide-bonded proteins, below). Covalently bonded ligands (e.g., heme in cytochrome *c*) may also contribute to the stability of both the native and intermediate forms and therefore play an important role in folding (Roder and Elöve, 1994).

When such proteins are subjected to denaturing agent, such as guanidine·HCl, a reversible unfolding transition is normally observed (Fig. 6.4.2). For the majority of proteins, the equilibrium transition region reflects the varying proportions of the native and unfolded states only, because the concentrations of folding intermediates are rather low at equilibrium.

To fold a protein from inclusion bodies solubilized with 6 M guanidine·HCl, for example, the concentration of denaturant must be reduced to a value within the native plateau

BYU / HARVARD UNIVERSITY LIBRARY

region. It is useful therefore to have access to an experimentally determined transition curve such as that for interleukin 1β illustrated in Figure 6.4.2.

Effects of denaturants. Within the plateau region of the folding transition curve (Fig. 6.4.2), the stability of the native protein decreases with increasing concentration of denaturant. The possible disadvantage of limiting the concentration of denaturant in the interest of protein stability may be balanced, however, by the fact that the tendency to associate will be decreased. This may apply also to the transient intermediates formed during folding. Guanidine·HCl is not only a more powerful denaturant than urea (~2.5-fold more effective on a molar basis), but its solubilizing effect on different chemical groups in proteins is different from that of urea. In particular, the ratio of the solubilizing power for the peptide bond relative to that for the average nonpolar side chain is greater for guanidine·HCl than for urea (Lapanje et al., 1978; Mitchinson and Pain, 1985). Thus, for a folding intermediate, where secondary structure (in which peptide bonds are shielded from the solvent) has formed but where nonpolar groups are more exposed, urea may be more effective than guanidine·HCl in stabilizing the intermediate against aggregation (assuming denaturant concentrations at which both urea and guanidine-HCl have the same effect on overall protein stability). Hence, urea is occasionally used as an intermediate solvent during renaturation.

Effects of cosolvents. Cosolvents such as glycerol and ethylene glycol, glucose and sucrose, certain anions such as phosphate and sulfate, and certain cations such as 2-(*N*-morpholino)ethanesulfonic acid (MES) can stabilize proteins markedly against denaturation by urea or guanidine·HCl. They exhibit little or no effect on the folding rate constant, but dramatically decrease the unfolding rate constant. In certain favorable cases, the unfolded protein can be refolded simply by adding sulfate to the solution containing denaturant (Mitchinson and Pain, 1985). However these cosolvents, which act by stabilizing hydrophobic interactions, also stabilize aggregates; hence their usefulness is likely to be limited, probably to proteins with a relatively high proportion of polar residues.

Proteolytically processed proteins

Other proteins—e.g., chymotrypsin—are derived from precursors that have been processed by proteolytic cleavage and are composed of a number of chains. Functional proteins that are derived from precursors activated in this manner pose a more complex problem for folding in vitro. Some of the information required to define the conformation, originally resident in the intact precursor protein, has been lost during activation and the conformation is stabilized by the disulfide bonds. For example, reduction of the disulfide bonds in insulin results in unfolding and subsequent aggregation even in the absence of denaturant (Anfinsen, 1967). Penicillin acylase, which contains no disulfide bonds, is more difficult to fold in the absence of the linking peptide present in the proenzyme (Lindsay and Pain, 1991). In both of these cases, at least part of the function of the linking peptide is thought to be to increase the frequency of productive interactions between the two elements of structure (Hlodan et al., 1991).

Denaturation of such proteins is not a simple thermodynamically reversible process. In cases where it is not possible to produce and activate the preprotein to obtain the functional protein, each chain may have to be produced separately and alternative folding and assembly strategies may have to be explored. For example, one chain that aggregates when folded by itself may be stabilized in its folded state if folding is carried out by diluting it into a solution of the already folded second chain (Lindsay and Pain, 1991). Stabilizing cosolvents may induce native-like conformation in the isolated chains, encouraging assembly of the chains into a functional molecule.

Disulfide-bonded proteins

Disulfide bonds contribute to the stability of the native conformation to an extent that varies from one protein to another. The overall stability may be expressed thermodynamically in terms of the equilibria for the sidechain and backbone noncovalent interactions (Fig. 6.4.3) and the covalent interaction (Fig. 6.4.4) in which two thiol groups produce a disulfide bond.

$$U(-SH)_{2n} \rightleftharpoons N'(-SH)_{2n}$$

Figure 6.4.3 Equilibrium for noncovalent interactions during protein folding, where *n* is the number of disulfide bonds in the native, functional protein.

BCU IAS KENTERAN UNIVERSITY LIBRARY

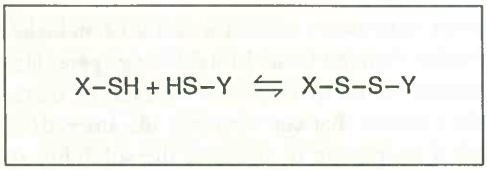

Figure 6.4.4 Equilibrium for the covalent interactions (formation of disulfide bonds) during the folding of a protein, X and Y are cysteine residues in the amino acid sequence of the folding protein that interact specifically in the folded structure.

At one extreme—where the conditions of folding (e.g., denaturant concentration and pH) lead to noncovalent interactions that are strong enough to stabilize the protein in a native-like form, with the native pairs of thiol groups forced close to one another (i.e., the equilibrium illustrated in Fig. 6.4.3 lies to the right)—very little oxidizing pressure will be needed to form the disulfide bonds. If, on the other hand, the noncovalent interactions are relatively weak (i.e., the equilibrium illustrated in Fig. 6.4.3 lies well over to the left and hence toward the expanded state of the protein), more energy—a stronger oxidation potential—will be required to drive the equilibrium to the native state (Gilbert, 1994).

To fold proteins containing disulfide bonds, it is necessary to pay attention to the chemistry of the covalent bonds involved in cysteine thiol oxidation. Two principal folding routes are possible—one utilizing air oxidation in the presence of trace heavy metals (Fig. 6.4.5) and the other involving formation of mixed-disulfide intermediates (Fig. 6.4.6).

The former route (Fig. 6.4.5), although cheaper when using large volumes, is less easy to optimize and control. The latter route (Fig. 6.4.6) utilizes a low-molecular-weight dithiol (R-S-S-R), usually glutathione. In practice, a redox pair of reduced glutathione (GSH) and oxidized glutathione (GSSG) is needed to create the appropriate oxidizing "pressure" that will allow the disulfides in the folding intermediates to make and break, so that the noncovalent interactions can shuffle the protein to its lowest free energy state. Because of the energy balances discussed above, the lowest free energy state will be expected to vary from protein to protein; hence the optimal redox conditions will also differ. However, a GSH:GSSG molar ratio of 10:1 (at a concentration of 2 to 5 mM GSH) gives maximal rates of folding to the native structure for a number of proteins. Because each step in the oxidation involves nucleophilic attack by an S^- group (see Fig. 6.4.6), the rate of disulfide formation is expected to increase within the range of pH 6 to 10. However, pH may also affect the stability of folding intermediates in an unpredictable way. In cases where the noncovalent interactions alone do not lead to a condensed intermediate (i.e., where the equilibrium illustrated in Fig. 6.4.3 lies to the left; see discussion above), addition of a stabilizing cosolvent such as phosphate or sulfate can drive the equilibrium in the direction of condensation, thereby offering the possibility of increasing the rate of disulfide for-

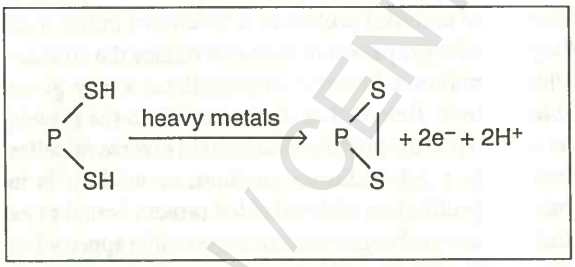

Figure 6.4.5 Formation of disulfide bond by air oxidation of thiol groups in the presence of trace heavy metals.

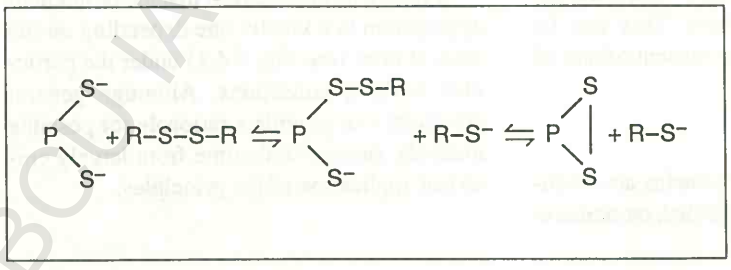

Figure 6.4.6 Formation of disulfide bond through mixed-disulfide intermediates.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

mation and interchange. Other factors (e.g., ionic strength and temperature) that can affect the stability of intermediates will also influence the kinetics and yield of folding.

Achieving an Acceptable Rate of Folding

Within the plateau region of the unfolding transition (see Fig. 6.4.2), the rate of folding will generally be in inverse proportion to the concentration of denaturant. The rate of folding will increase with temperature, up to that of thermal denaturation. For certain proteins whose folding is rate-limited by proline *cis-trans* isomerization (see Proteins Fold Along a Limited Number of Pathways, above), the rate can be increased by the addition of peptidyl prolyl *cis-trans* isomerase (Nall, 1994). However, when working with proteins lacking disulfide bonds, rate is not as important for practical purposes as yield.

The rate of folding for disulfide-bonded proteins in vitro can be very slow, with half-times of the order of minutes or hours, and conditions must be arranged to reduce the time required to realize an acceptable yield. The linkage between noncovalent and disulfide stability (see discussion of disulfide-bonded proteins under Stabilizing the Native Functional State) has important consequences in defining conditions for folding disulfide-bonded proteins. Certain intermediates in some folding pathways have been shown to possess nonnative disulfides (Gilbert, 1994). The energy barriers involved in making and breaking both covalent disulfide links and noncovalent interactions must therefore not be too high if such a pathway is to be followed. If, as a result of the redox conditions, the nonnative disulfides in the intermediates are so strong that they cannot be broken to allow them to shuffle, the native noncovalent interactions will not be able to form. It is necessary therefore to create a redox potential such that the equilibrium illustrated in Figure 6.4.4 is appropriately balanced. The converse of this requirement is that the equilibrium in Figure 6.4.3 must be appropriately balanced to allow the noncovalent interactions to shuffle and thereby allow the native disulfide pairs to form. This can be achieved by adjusting the concentrations of denaturant and cosolvent.

Limiting Aggregation

Aggregates of unfolded proteins are intrinsically more stable than the folded, monomeric state, as is shown by the formation of inclusion bodies. A major factor in stabilizing aggregates appears to be hydrophobic interaction; therefore factors that can decrease the strength of such interaction or increase the solubility of other parts of the protein chain will help relieve problems of low yield stemming from aggregation. The characteristic inverse dependence of stability on temperature in hydrophobic interactions suggests that lower temperatures should lessen aggregation. Nondenaturing concentrations of urea or guanidine·HCl have been also used with considerable success to lessen aggregation. These concentrations have usually been arrived at empirically, by dialyzing denaturant out of the denaturation mixture. Increasing the net charge by moving away from the isoelectric point and/or lowering the ionic strength may also lessen aggregation, other factors being equal.

Chaperone proteins, notably GroEL, have in certain cases been shown to dramatically increase the yield of refolding proteins in vitro (Goloubinoff et al., 1989). This multimeric protein, cylindrical in shape with a cylindrical core, will bind partially folded protein monomers, effectively removing them from free solution, and thereby protecting them against aggregation. The protein is then released with the cooperation of a second chaperone protein, GroES, under the influence of ATP.

The obvious factor governing aggregation is protein concentration (Hlodan et al., 1991; Thatcher and Hitchcock, 1994). Diluting the unfolded protein into larger volumes of buffer should increase the proportion of molecules that fold, although problems of recovery will also increase. Dropwise addition of the solution of unfolded protein to a volume of buffer over a longer period of time can reduce the concentration of "sticky" intermediates at any given time. Removal of denaturant from the protein while the protein is isolated in reverse micelles or a gel-exclusion medium, or while it is in equilibrium with unfolded protein bound to an ion-exchange column, are possible approaches to refolding at higher concentrations of protein (Thatcher and Hitchcock, 1994).

It should be emphasized that the problem of aggregation is a kinetic one depending on the ratio of rates (see Fig. 6.4.1) under the particular working conditions. Although general principles can provide a rationale for possible methods, success will come from largely empirical application of the principles.

Folding and Purification of Insoluble (Inclusion Body) Proteins from *Escherichia coli*

Heterologous expression of recombinant proteins in *E. coli* often results in the formation of insoluble and inactive protein aggregates, commonly referred to as inclusion bodies. To obtain the native (i.e., correctly folded) and hence active form of the protein from such aggregates, four steps are usually followed. In the first step, the bacterial cells are lysed and the aggregates collected by low-speed centrifugation (*UNITS 6.2 & 6.3*). In the second step (which is usually but not always included) the aggregates are preextracted to remove cell wall and outer membrane components, producing washed pellets (*UNIT 6.3*). In the third step, the aggregates are solubilized (or extracted) with strong protein denaturants—e.g., guanidine·HCl, 8 M urea, or organic acids at high concentrations (*UNIT 6.3*). In the fourth step, the solubilized, denatured proteins are folded with concomitant oxidation of reduced cysteine residues into the correct disulfide bonds to obtain the native protein. Basic Protocols 1, 2, and 3 in this unit feature three different approaches to the final step of protein folding and purification.

Basic Protocol 1 describes the extraction of bovine growth hormone (BGH) using guanidine·HCl, after which the solubilized protein is folded (before purification) in an "oxido-shuffling" buffer system to increase the rate of protein oxidation. A nondenaturing concentration of urea (a cosolvent; see *UNIT 6.4*) is added to the buffer used in the folding step to increase the yield of folded protein by minimizing the formation of aggregated, misfolded protein. The folded protein is then purified by chromatography.

Basic Protocol 2 describes folding and purification of the cytokine interleukin 2 (IL-2). This procedure differs from Basic Protocol 1 in that (1) acetic acid is used to solubilize (i.e., extract) the protein, (2) the acid-soluble protein is partially purified by gel filtration before folding, and (3) protein folding and oxidation are carried out with no additives; the protein (in acid solution) is simply dialyzed against water, thereby allowing the pH to slowly increase and air oxidation of the protein to occur. The folded protein is further purified by reversed-phase high-performance liquid chromatography (RP-HPLC). A support protocol is included for rapidly determining the amount of folded protein that contains the correct disulfide linkage pattern.

Basic Protocol 3 describes the folding and purification of a fusion protein containing the catalytic domain of the human immunodeficiency virus 1 (HIV-1) integrase. The fusion partner is a 20-amino-acid peptide containing a track of six histidine residues (a His tag; see *UNIT 5.1*). The protein is extracted with guanidine·HCl (as with BGH), then purified by gel filtration in guanidine·HCl (*UNIT 6.3*). The protein is further purified by metal-chelate affinity chromatography, which takes advantage of the His tag. Next, the purified protein is folded by very slow dilution into a folding buffer containing additives required to maintain the solubility of the folded protein. The His tag is removed by digestion with the protease thrombin, the thrombin is removed by affinity chromatography using an immobilized substrate, and finally the cleaved protein is run through a gel-filtration column to remove any aggregated protein.

BASIC PROTOCOL 1

FOLDING AND PURIFICATION OF BOVINE GROWTH HORMONE

The high-level expression of bovine growth hormone (BGH) in *E. coli* results in the formation of highly aggregated protein (inclusion bodies). To restore the BGH to its native, functional state, the *E. coli* cells are first lysed with the French press and the inclusion bodies are partially purified by selective extraction of soluble and particulate *E. coli* contaminants. The inclusion bodies are solubilized with guanidine·HCl to give protein that is unfolded and reduced (i.e., with four free sulfhydryl residues). The protein is then simultaneously folded and oxidized by the slow removal of protein denaturant, resulting in the formation of two disulfide bonds from the sulfhydryl residues. The solubility of the protein during folding is maintained using a cosolvent (urea) and the oxidation of cysteine residues is catalyzed by a mixture of reduced and oxidized glutathione (GSH/GSSG; see also *APPENDIX 3A*). The folded, oxidized protein is finally purified to homogeneity by anion exchange and gel-filtration chromatography.

Materials

E. coli cells expressing BGH: ~50 g wet weight from a 1.5-liter fermentation (*UNIT 5.3*), and stored as a flattened paste in a sealed polyethylene bag at –80°C
BGH break buffer A (see recipe), 4°C
BGH break buffer B (see recipe), 4°C
BGH wash buffer A (see recipe), 4°C
BGH wash buffer B (see recipe), 4°C
BGH extraction buffer (see recipe), 4°C
BGH folding buffer A (see recipe), 4°C
BGH folding buffer B (see recipe), 4°C
2 M HCl
BGH column buffer A (see recipe), 4°C
DEAE Sepharose CL-4B ion-exchange resin (Pharmacia Biotech)
Sephadex G-100 gel filtration resin (Pharmacia Biotech)
BGH column buffer B (see recipe), 4°C

Blender (e.g., Waring; ≥1 liter capacity)
Tissue homogenizer (e.g., Polytron, Brinkmann)
Beckman J2-21M centrifuge and JA-20 rotor (or equivalent)
Sonicator, ≥400 W, with sound enclosure (Branson or equivalent)
0.7-µm glass-microfiber filters, 4.7-cm diameter (Whatman GF/F) with vacuum filtration apparatus (optional)
Spectra/Por 1 dialysis tubing, 40-mm diameter (MWCO 6000 to 8000; Spectrum)
5 × 50–cm and 5 × 100–cm glass chromatography columns with adjustable flow adaptors (Pharmacia Biotech)
Stirred cell with Diaflo PM 10 ultrafiltration membrane (Amicon)
Millex-GV 0.22-µm filter units (Millipore)

Additional reagents and equipment for cell breakage using a French press (*UNIT 6.2*), dialysis (*APPENDIX 3B*), ion-exchange chromatography (*UNIT 8.2*), gel-filtration chromatography (*UNIT 8.3*), and SDS-PAGE (*UNIT 10.1*)

NOTE: All steps are carried at 4°C unless otherwise stated.

Break cells

1. Resuspend ~ 50 g (wet weight) of *E. coli* cells expressing BGH in 250 ml BGH break buffer A using a blender.

   The lysozyme in BGH break buffer A aids in removal of the peptidoglycan and outer membrane protein contaminants (see UNIT 6.1).

PCU IASI CENTRAL UNIVERSITY LIBRARY

2. Stir cell suspension 30 min at 20° to 25°C using a heavy-duty magnetic stirrer. To reduce viscosity of the suspension, homogenize with tissue homogenizer until no clumps are detected, then centrifuge 35 min at 20,000 × *g* (13,500 rpm in JA-20 rotor), 4°C.

3. Resuspend pellet in 150 ml BGH break buffer B using tissue homogenizer. Break cells using French press as described in *UNIT 6.2*, Basic Protocol 1, steps 1 to 5.

The viscosity can also be reduced by digestion with DNase and RNase as described in UNIT 6.2, in which case the EDTA in BGH break buffer B should be replaced with 5 mM $MgCl_2$.

Prepare and extract washed pellet

4. Centrifuge suspension 40 min at 20,000 × *g*. Resuspend pellet in 250 ml BGH wash buffer A using the tissue homogenizer, then centrifuge 30 min at 20,000 × *g*. Repeat centrifugation and resuspension once using BGH wash buffer A and again using BGH wash buffer B. Discard the cloudy supernatants and save the washed pellet.

If not to be used immediately, the washed pellet may be stored at –80°C.

5. Resuspend washed pellet in 150 ml BGH extraction buffer. Sonicate briefly to completely disperse protein, then clarify solution by centrifuging 30 min at 20,000 × *g* or by filtering through a 0.7-µm glass-microfiber filter under vacuum.

Generally, when protein is extracted with guanidine·HCl, the reductant dithiothreitol is included in the buffer system to ensure that the protein is fully reduced prior to folding. In this procedure it was established that >80% of the protein in the inclusion bodies was already in the reduced state (P.T.W., unpub. observ.). In the extraction buffer used here, therefore, only the relatively weak reductant glutathione is included. This compound serves to maintain thiols in the reduced state, and is a component of the redox buffer that will be used later to oxidize the protein. It cannot, however, be assumed that other inclusion-body proteins contain only free thiols.

Fold protein

6. Dilute the clear amber-colored solution with an equal volume of BGH folding buffer A and pour into prewashed dialysis tubing.

Use two or three pieces of tubing and fill dialysis bags only three-quarters of the way to allow for any volume increase during dialysis.

The BGH concentration from step 5 should be 2 to 4 mg/ml, and after dilution should not exceed 1.0 to 2.0 mg/ml. If higher concentrations are found, the solution must be diluted further with folding buffer A. BGH concentration can be estimated by diluting the sample with 4 M guanidine·HCl in water and measuring the absorbance at 280 nm and 260 nm in a cell with a 1-cm path length. The total protein concentration (mg/ml) is estimated as 1.55 A_{280} – 0.76 A_{260} nm (Stoscheck, 1990). The BGH content may either be assumed to be 60% of the total protein or, more accurately, be estimated by performing SDS-PAGE and densitometry using the washed pellet from step 4.

Urea is included in folding buffer A as a cosolvent to maintain solubility of the protein during refolding. Removal of guanidine·HCl by dialysis or dilution results in precipitation if no cosolvent is used. The urea concentration chosen (in this case 4 M) should be low enough to allow the native structure to form (see UNIT 6.4). Urea unfolding/folding profiles for BGH (i.e., equilibrium-denaturation curves in which protein conformation is measured as a function of denaturant concentration; see UNIT 6.4) were available in the literature prior to development of this method (Edelhoch and Burger, 1966). The urea concentration that induces protein unfolding can be determined rapidly by urea gradient electrophoresis (Goldenberg, 1989).

7. Dialyze solution 12 to 16 hr (or overnight) against 5 liters of BGH folding buffer A, then dialyze an additional 6 to 8 hr against 5 liters of BGH folding buffer B.

The second dialysis can be continued overnight if necessary.

BOURNEMOUTH UNIVERSITY LIBRARY

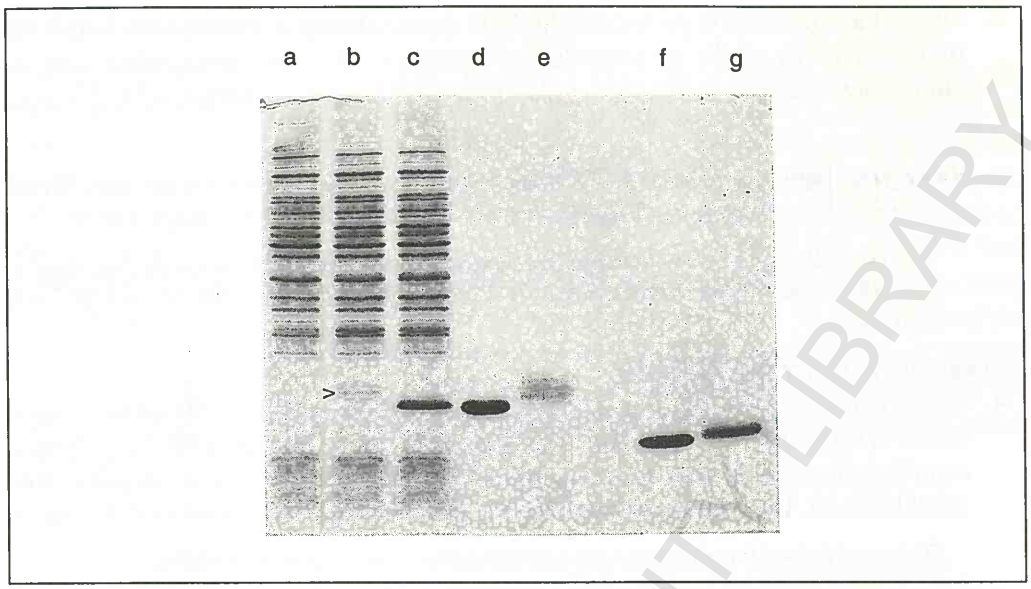

Figure 6.5.1 SDS-PAGE of bovine growth hormones on 12.5% polyacrylamide gel. Lane A, BGH-expressing *E. coli* cells minus the expression vector; lanes B and C, BGH-expressing *E. coli* cells with ΔA-4 and A-9 BGH expression vectors, respectively; lane D, purified recombinant A-9 BGH; lane E, BGH purified from pituitary (supplied by A.F. Parlow, UCLA); lane F, purified recombinant A-9 BGH with no reductant in sample buffer; lane G, BGH purified from pituitary with no reductant in sample buffer. In lane E (pituitary BGH), the two bands correspond to full-length protein and protein truncated at the N-terminus by 4 residues. It can be seen that the bottom band has the same mobility as *E. coli* extracts containing the ΔA-4 BGH construct. In lane G, it it may be noted that the two bands are not resolved under nonreducing conditions.

Oxidation of the protein during dialysis can be monitored by SDS-PAGE (UNIT 10.1). SDS-denatured oxidized BGH is more compact than SDS-denatured reduced BGH and thus migrates faster as a result of the lower apparent molecular weight (i.e., 18 kDa for the oxidized form versus 22 kDa for the reduced form). SDS-PAGE band patterns of oxidized and reduced BGH are shown in Figure 6.5.1. Any free thiol groups in the sample are quenched by addition of 20 mM iodoacetamide. SDS sample buffer (UNIT 10.1) minus reductant is then added. The pH of the SDS-treated sample may have to be readjusted with dilute alkali. The proportion of oxidized versus reduced protein is finally determined by densitometry of the Coomassie blue–stained gel. It should be noted that this approach does not prove whether or not the correct disulfide bond(s) have been formed. The shift in mobility upon reduction occurs because of the formation of the disulfide bond linking Cys-51 to Cys-163. BGH in which the second disulfide bond (linking Cys-180 to Cys-188) has been selectively reduced (Graf et al., 1975) still exhibits the gel shift. Despite these potential pitfalls, the gel method is useful and correlates with other approaches—e.g., direct monitoring of disulfide formation using 2-nitro-5-thiosulfobenzoate in the presence of sodium sulfite after the free sulfhydryls have been quenched and the buffer components removed (Thannhauser et al., 1984). Sulfhydryl groups can be assayed using Ellmans reagent (Riddles et al., 1979).

8. Centrifuge the slightly cloudy solution 30 min at 20,000 × *g*. Discard pellet and adjust supernatant to pH 9.0 with 2 M HCl.

The volume of the supernatant should be 300 to 320 ml.

Purify protein by ion-exchange and gel filtration chromatography

9. Pack a 5 × 50–cm column with DEAE Sepharose CL-4B to give a bed height of ~10 cm and equilibrate with BGH column buffer A. Apply the solution from step 8 at a flow rate of 60 ml/hr and begin collecting 15-ml fractions.

See UNIT 8.2 for further information on preparing an ion-exchange column.

10. Elute with BGH column buffer A at the same flow rate and continue fraction collection until A_{280} or A_{260} of eluant approaches a baseline value. Assay fractions by SDS-PAGE and pool fractions containing BGH.

Under the ion-exchange conditions used, BGH does not bind to the matrix and is located in the flowthrough fractions. The more acidic E. coli contaminants bind tightly to the top portion of the column, which turns brown. Some of the earlier flowthrough fractions may be slightly contaminated with aggregated protein that separates from soluble protein as a result of the gel-filtration effect of the matrix. A BGH concentration of 0.2 to 0.3 mg/ml in ~400 to 450 ml of pooled eluant should be obtained. This should exhibit a single band on the SDS-PAGE gel.

Pooled fractions can be stored 1 to 2 days at 4°C and for longer periods at –80°C.

11. Concentrate pooled BGH-containing fractions to 50 to 60 ml (i.e., to ~2 to 3 mg/ml protein concentration) using a stirred cell with Diaflo PM 10 ultrafiltration membrane. Centrifuge filtrate 15 min at 20,000 × *g* to remove any precipitated protein.

12. Pack a 5 × 100–cm column with Sephadex G-100 to a bed height of 95 cm and equilibrate with BGH column buffer B. Apply the filtrate from step 11 at a flow rate of 40 ml/hr and begin collecting 15-ml fractions.

See UNIT 8.3 for additional information on preparing gel-filtration columns. If a 5 × 100–cm column is not available, a 2.5 × 100–cm column can be used. Depending on the amount of sample, the smaller-diameter column may be run several times, loading 18 to 20 ml of sample per run.

13. Elute with BGH column buffer B at the same flow rate and continue fraction collection until A_{280} or A_{260} of eluant approaches a baseline value. Assay fractions by SDS-PAGE and pool fractions containing BGH.

The protein elutes in a single but slightly asymmetrical peak.

The gel-filtration elution peak has a sharp front edge, whereas the descending portion is more diffuse and trailing. This elution behavior results from the fact that BGH is a rapidly associating/dissociating monomer/dimer system (with a K_d of ~0.8 to 1.0 × 10^{-5} M; see Ackers, 1970, for discussion of theory). The apparent molecular weight estimated by gel filtration is 30 to 35 kDa (with a monomer mass of ~22 kDa).

The slightly alkaline pH of the column buffer and folding buffers is required to maintain solubility of the protein.

14. Repeat step 11, then filter sterilize filtrate using a Millex-GV 0.22-µm filter unit. Store purified BGH in aliquots at –80°C.

For long-term storage the protein can be lyophilized. If this is to be done, the pooled fractions from step 10 should be directly dialyzed (APPENDIX 3B) against 0.1 M ammonium bicarbonate (pH 9.2 to 9.4, adjusted with ammonium hydroxide), and the dialysate filter-sterilized and freeze-dried. If an essentially salt-free protein is required, two cycles of freeze-drying should be performed and the protein reconstituted with water alone after the first drying cycle.

The concentration of the purified BGH can be conveniently determined by UV absorbance measurement—i.e., 1 mg/ml native BGH has an A_{280} of 0.7 in a 1-cm quartz cuvette. Protein concentration may also be estimated in crude extracts using the Bio-Rad Protein Assay Kit (based on the Bradford method) and in partially purified fractions as described in the annotation to step 6. Biological activity of the protein is measured as described in Wingfield et al. (1987a).

BCU LIBRARY - FAITRN - UNIVERSITY LIBRARY

BASIC PROTOCOL 2

FOLDING AND PURIFICATION OF HUMAN INTERLEUKIN 2

Human interleukin 2 (hIL-2) is a hydrophobic, acid-stable polypeptide with a molecular weight of 15 kDa. Recombinant hIL-2 expressed in *E. coli* is deposited in inclusion bodies. Extraction of the inclusion bodies with denaturants followed by folding in aqueous solution often results in formation of insoluble hIL-2 aggregates. In this protocol, inclusion bodies containing recombinant hIL-2 are first extracted with acetic acid and the soluble monomeric hIL-2 is separated from other hIL-2 aggregates by gel-filtration chromatography. The soluble protein is then folded and oxidized by dialysis against water. Correctly folded hIL-2 is finally separated from unfolded hIL-2 and other *E. coli* contaminants by reversed-phase high-performance liquid chromatography (RP-HPLC).

Materials

hIL-2 break buffer (see recipe), 4°C
E. coli cells expressing hIL-2: ~20 g wet weight from a 3-liter fermentation (*UNIT 5.3*), and stored as a flattened paste in a sealed polyethylene bag at –80°C
Sucrose
Lysozyme (Worthington)
hIL-2 wash buffer: 0.75 M guanidine·HCl/1% (w/v) Tween 20 (prepare immediately before use), 4°C
PBS (*APPENDIX 2E*), 4°C
10% and 20% (v/v) acetic acid, 4°C (prepare fresh from glacial acetic acid)
Sephadex G-100 gel-filtration resin (Pharmacia Biotech)
Acetonitrile (HPLC grade)
Trifluoroacetic acid (TFA; HPLC grade)
7 × 250–mm 300-Å octyl Aquapore RP-300 semiprep column (Brownlee column; Thomson Instrument)
RP-HPLC solvent A (see recipe), room temperature
RP-HPLC solvent B (see recipe), room temperature
25 mM acetic acid, 4°C

Tissue homogenizer (e.g., Polytron, Brinkmann)
30°C water bath
Sorvall RC-5C centrifuge with SS-34 rotor (or equivalent)
2.6 × 100–cm glass chromatography column
Spectra/Por 3 dialysis tubing, 11.5- and 45-mm diameters (MWCO 3500; Spectrum)
Sterivex-GS 0.22-μm filter units (Millipore)
HPLC system with pumps, UV detector, and fraction collector (Waters)

Additional reagents and equipment for cell breakage using a French press (*UNIT 6.2*), gel-filtration chromatography (*UNIT 8.3*), and dialysis (*APPENDIX 3B*)

Break cells

1. Add 60 ml hIL-2 break buffer to 20 g (wet weight) of *E. coli* cells expressing hIL-2 in a 250-ml glass beaker. Mix well using tissue homogenizer.

   UNIT6.2 describes use of a tissue homogenizer to resuspend E. coli cells.

2. Add 21 g sucrose and mix well with cell paste using tissue homogenizer. Add 34 mg lysozyme and mix again using tissue homogenizer. Incubate 30 min in a 30°C water bath, then dilute with 100 ml hIL-2 break buffer and cool on ice.

3. Break cells by passing suspension through a French press twice as described in *UNIT 6.2*. Centrifuge 30 min at 13,000 × *g* (10,400 rpm in SS-34 rotor), 4°C. Save pellet.

   The wet weight of the pellet should be ~1.5 g.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

4. Wash pellet by resuspending in 30 ml hIL-2 wash buffer and centrifuging 30 min at 13,000 × *g*. Repeat wash once with hIL-2 wash buffer and again using 30 ml PBS in place of the wash buffer.

Washed pellets should be used immediately or stored at –70°C until required.

Extract protein with acid and prepare gel-filtration column

5. Add 12.5 ml of 20% acetic acid to the washed pellet and mix using tissue homogenizer. Centrifuge 30 min at 13,000 × *g*, 4°C, and save the supernatant.

6. Pack a 2.6 × 100–cm column with Sephadex G-100 to give a bed height of 95 cm and equilibrate with 10% acetic acid.

For convenience the column may be packed the day before use.

7. Repeat step 5 and pool the two clear supernatants (total volume should be ~25 ml).

Isolate hIL-2 monomer from solubilized protein by gel filtration

8. Immediately apply pooled supernatants to column prepared in step 6. Perform gel filtration chromatography at 4°C as described in *UNIT 8.3* and construct a chromatogram, pooling the fractions that make up the third peak.

The solution should be applied to the column immediately after extraction to prevent any covalent modification of the protein.

The column eluate usually shows three major peaks in A_{280}. The first peak (in the void volume) contains aggregates, the second peak contains dimeric hIL-2, and the third peak contains monomeric hIL-2 (S.M.L., unpub. observ.). A T cell proliferation assay shows that the third peak contains the highest biological activity of hIL-2 (Liang et al., 1986; Bottomly et al., 1991).

9. Using 45-mm diameter Spectra/Por 3 dialysis tubing (MWCO 3500), dialyze the pooled fractions (~60 ml) making up the third peak at 4°C overnight against 5 liters of Milli-Q water, then for an additional 3 to 4 hr against 5 liters of fresh Milli-Q water.

The pooled eluate fractions should be extensively dialyzed against water to remove acetic acid. The dialysate should have a volume of ~60 ml with an hIL-2 concentration of 0.2 mg/ml. After dialysis, the hIL-2 monomer can be stored at –20°C until required.

As the acetic acid is removed; sample pH slowly increases, thereby allowing hIL-2 thiols to form disulfide bonds.

Purify protein by RP-HPLC

10. Filter the dialysate through a 0.22-µm filter unit, then add 30 ml acetonitrile (33% v/v final) and 0.09 ml TFA (0.1% v/v final).

11. Prepare and test the HPLC system according to manufacturer's instructions. Place a 300-Å octyl Aquapore RP-300 reversed-phase chromatography column in line.

Other reversed-phase columns; e.g., the 2.2 × 15–cm TMS-250 (TosoHaas) can also be used (Kato, 1985).

12. Fill the reservoirs of the HPLC system gradient maker with RP-HPLC solvent A and RP-HPLC solvent B. Carry out a blank run (at room temperature) with the following gradient program:

0 min: 0% solvent B/100% solvent A
10 min: 0% solvent B/100% solvent A
60 min: 50% solvent B/50% solvent A
90 min: 50% solvent B/50% solvent A
150 min: 70% solvent B/30% solvent A

BCU/ASU/CENTRAL UNIVERSITY LIBRARY

160 min: 70% solvent B/30% solvent A
170 min: 100% solvent B/0% solvent A
180 min: 100% solvent B/0% solvent A
190 min: 0% solvent B/100% solvent A
210 min: 0% solvent B/100% solvent A.

Repeat blank run as necessary to ensure that the baseline profile has stabilized.

13. Pump sample from step 10 into column at a flow rate of 4 ml/min. Run the gradient program described in step 12 at a flow rate of 1 ml/min at room temperature. Collect 8-ml fractions at a rate of 1 ml/min and pool the fractions making up the correctly folded hIL-2 peak, which elutes at ~70 min.

Care should be taken to avoid introducing air bubbles while pumping the sample into the column, as these will generate false peaks in the chromatogram. If the peaks in the HPLC profile are too broad, the gradient program should be varied to improve the separation (see Chapter 8).

14. Using 11.5-mm diameter Spectra/Por 3 dialysis tubing (MWCO 3500), dialyze the pooled hIL-2 fractions against Milli-Q water or 25 mM acetic acid at 4°C. Filter the purified protein solution using a 0.22-μm filter unit and store at –20°C or below.

SUPPORT PROTOCOL

RESOLUTION OF NATIVE AND MISFOLDED FORMS OF hIL-2 BY RP-HPLC

Human interleukin 2 (hIL-2) contains three cysteine residues—at positions 58, 105, and 125. In the correctly folded (native) protein, the cysteines at positions 58 and 105 form a disulfide bond that is important for biological activity of the protein (Robb et al., 1984; Wang et al., 1984; Liang et al., 1985).

As hIL-2 contains three cysteines, three possible intramolecular disulfide–linked forms can exist, only one of which is the native form. RP-HPLC can separate these isomers, and is used to verify that the purified IL-2 contains the native disulfide.

Additional Materials (also see Basic Protocol 2)

0.46 × 10–cm SynChropak RP-P C18 column (Thomson Instrument)
RP-HPLC solvent C (see recipe)
25 mM acetic acid
Purified folded hIL-2 solution (see Basic Protocol 2)

1. Prepare and test HPLC system according to manufacturer's instructions. Place a 0.46 × 10–cm SynChropak RP-P C18 column in line.
2. Fill the reservoirs of the HPLC system gradient maker with RP-HPLC solvent A and RP-HPLC solvent C. Apply 20 μl of 25 mM acetic acid as a blank sample. Perform a blank run at room temperature using a gradient program starting with 100% solvent A for 5 min, followed by a linear gradient starting at 100% solvent A/0% solvent C and ending at 0% solvent A/100% solvent C, at a flow rate of 1 ml/min. Repeat as necessary to check that the baseline profile is reproducible.
3. Prepare a solution of ~5 mg/ml purified folded hIL-2 solution in 25 mM acetic acid and filter through a 0.22-μm filter.
4. Apply 20 μl of purified folded hIL-2 solution in 25 mM acetic acid to the column and carry out RP-HPLC at room temperature using the gradient program described in step 2. Collect the fractions containing the properly folded hIL-2.

PCU IASI CENTRAL UNIVERSITY LIBRARY

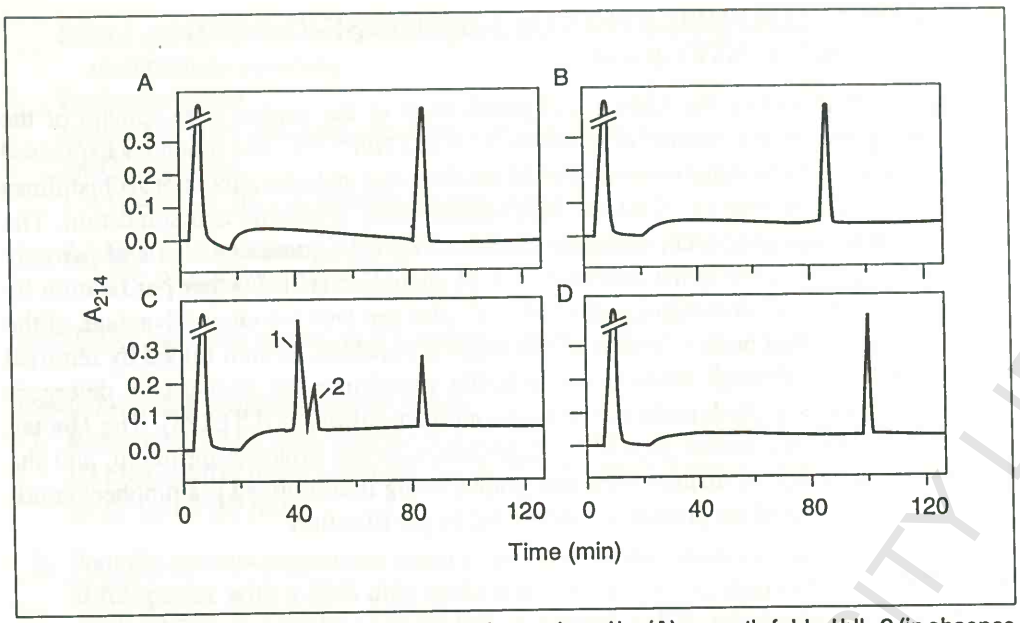

Figure 6.5.2 Chromatograms illustrating peaks produced by (**A**) correctly folded hIL-2 (in absence of denaturant); (**B**) correctly folded hIL-2 (in presence of denaturant but at pH 3.5, which is too low for disulfide-bond exchange); (**C**) scrambled hIL-2 isomers (resulting from denaturant treatment at pH 8.5); (**D**) unfolded hIL-2 (resulting from denaturant/reductant treatment).

Properly folded hIL-2 usually elutes at ~54% acetonitrile and unfolded hIL-2, which has no intramolecular disulfide bond, elutes at 57% acetonitrile.

In the presence of denaturants such as guanidine·HCl, hIL-2 rapidly scrambles into a mixture of three disulfide-linked isomers. The incorrectly folded hIL-2 elutes at a lower acetonitrile concentration (<54%) as shown in Figure 6.5.2. For each separation in Figure 6.5.2, two Vydac C4 columns were connected in series and run at 40°C with a 1 ml/min flow rate. The sample was eluted with an acetonitrile gradient that increased from 0% to 44% in 15 min, and then to 64% in 120 min. In the separation represented by the chromatogram in panel A, 100 µg hIL-2 in 40 µl of 50 mM acetic acid was dissolved in 400 µl of 20% formic acid and chromatographed. The elution peak (at ~57.3% acetonitrile) represents native hIL-2. In panel B, hIL-2 was added to 300 µl of 6 M guanidine·HCl/0.2 M acetic acid, pH 3.5, and incubated 10 min at room temperature. 200 µl of 20% formic acid was added and the sample was chromatographed. Note that the chromatogram has not changed, as the pH is below the point where isomerization (disulfide-bond exchange) occurs. In panel C, hIL-2 was added to 300 µl of 6 M guanidine·HCl/0.05 M Tris·Cl, pH 8.5, incubated 5 min at room temperature, then quenched with formic acid as in the separation represented by panel B. Peak 1 represents the scrambled isomer with a disulfide bond between Cys-105 and Cys-125, whereas peak 2 is probably the scrambled isomer with a disulfide bond between Cys-58 and Cys-125. Finally, in panel D, hIL-2 was added to 6 M guanidine·Cl as in panel C. 50 mM DTT was then added and the sample was incubated 40 min at room temperature, then quenched with formic acid as in panel B. The peak (at ~59.4% acetonitrile) represents completely reduced (unfolded) hIL-2. (see also Browning et al., 1986).

IMPORTANT NOTE: *If the pressure in the HPLC column exceeds 4000 psi, the column should be cleaned.*

BCU IAŞI - CENTRAL UNIVERSITY LIBRARY

FOLDING AND PURIFICATION OF A HISTIDINE-TAGGED PROTEIN: HIV-1 INTEGRASE

This protocol describes the folding and purification of the central core domain of the HIV-1 integrase, which consists of residues 50 to 212 (IN^{50-212}). The protein is expressed in *E. coli* with an N-terminal extension of 20 residues that includes a track of six histidines (i.e., a His tag; see *UNIT 5.1*). Cell are first broken using lysozyme and sonication. The protein is then extracted from inclusion bodies using 8 M guanidine·HCl and partially purified by gel filtration in the presence of 4 M guanidine·HCl. Further purification by metal-chelate affinity chromatography (MCAC; also see *UNIT 9.4*) takes advantage of the His tag. The purified protein, which at this stage is unfolded, is then folded by removal of guanidine·HCl through dilution into a buffer containing the zwitterionic detergent 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS). The His tag is removed from the folded protein by digestion with the protease thrombin, and the thrombin is removed by affinity chromatography using immobilized *p*-aminobenzamidine. A final cleanup of the protein is carried out by gel filtration.

Materials

E. coli cells expressing HIV-1 integrase: 100 g wet weight from a 3.5-liter fermentation (*UNIT 5.3*), stored as a flattened paste in a sealed polyethylene bag at −80°C
IN break buffer (see recipe), 4°C
Suspension buffer: IN break buffer (see recipe) prepared without lysozyme, 4°C
IN extraction buffer (see recipe), 4°C
6 × 60–cm Superdex 200 prep grade prepacked gel-filtration column (Pharmacia Biotech)
IN column buffer A (see recipe), 4°C
Ni-NTA-Sepharose CL-6B MCAC resin (Qiagen)
IN column buffer B (see recipe), 4°C
IN column buffer C (see recipe), 4°C
IN column buffer D (see recipe), 4°C
6 × 60–cm Superdex 75 prep grade prepacked gel-filtration column (Pharmacia Biotech)
IN column buffer E (see recipe), 4°C
4 M guanidine·HCl/5 mM DTT (4°C)
IN folding buffer (see recipe), 4°C
50 mM Tris·Cl (pH 7.5 at 4°C)/10 mM CHAPS, 4°C
2000 NIH unit/ml thrombin (see recipe)
IN column buffer F (see recipe), 4°C
9 M urea, 4°C
IN column buffer G (see recipe), 4°C
p-aminobenzamidine immobilized on Sepharose 6B (Pierce, Pharmacia Biotech, or Sigma)
0.1 mM 4-(2-aminoethyl)benzenesulfonyl fluoride (AEBSF; Boehringer Mannheim or ICN Biomedicals)

Blender (e.g., Waring; ≥1 liter capacity)
1-liter steel beaker
Sonicator, ≥400 W, with sound enclosure (Branson or equivalent)
Centrifuge with Beckman J-14 rotor (or equivalent)
Tissue homogenizer (e.g., Polytron, Brinkmann)
Ultracentrifuge with Beckman 45Ti rotor (or eqivalent)
5 × 50–cm chromatography column with adjustable flow adaptors

PCU IASI / CENTRAL UNIVERSITY LIBRARY

Stirred cells (400-ml and 2-liter capacities) with Diaflo PM 10 ultrafiltration membranes (Amicon)
Peristaltic pump
Millex-GV 0.22-μm pore size filter units (Millipore)
28°C water bath
1 × 10– to 1 × 20–cm chromatography column

Additional reagents and equipment for gel-filtration chromatography (*UNIT 8.3*) and SDS-PAGE (*UNIT 10.1*)

NOTE: All steps are carried at 4°C unless otherwise stated.

Break cells and prepare washed pellets

1. Resuspend 100 g (wet weight) of *E. coli* cells expressing HIV-1 integrase in 400 ml IN break buffer using a blender. Stir with a magnetic stirrer at room temperature (20° to 25°C) for 30 min.

2. Pour the viscous suspension into a 1-liter steel beaker in an ice bath. Sonicate 20 min at full power with a 60% duty cycle (i.e., on for 0.6 sec, then off for 0.4 sec), with stirring.

   Be sure that the temperature does not rise above 20°C.

3. Centrifuge 1 hr at 30,000 × *g* (14,000 rpm in J-14 rotor), 4°C. Resuspend pellet with 500 ml suspension buffer and centrifuge 1 hr at 30,000 × *g*.

Extract washed pellet and purify by gel filtration

4. Dissolve pellet in 40 ml IN extraction buffer using tissue homogenizer. Centrifuge 45 min at 100,000 × *g* (35,000 rpm in 45Ti rotor), 4°C.

5. Apply the clear supernatant to a 6 × 60–cm Superdex 200 gel-filtration column (*UNIT 8.3*) equilibrated with IN column buffer A. Elute at 300 ml/hr using IN column buffer A, collecting 15-ml fractions. Assay fractions by SDS-PAGE (*UNIT 10.1*) and pool those containing $IN^{50\text{-}212}$.

   $IN^{50\text{-}212}$ should be the major band visible on SDS-PAGE after gel filtration, representing 20% to 50% of the total protein.

Purify $IN^{50\text{-}212}$ by MCAC

6. Apply the $IN^{50\text{-}212}$ sample to a 5 × 50–cm column that has been packed with Ni-NTA-Sepharose CL-6B MCAC resin to a bed height of 5 cm and equilibrated with IN column buffer B at a flow rate of 300 ml/hr. Continue washing column with buffer until absorbance approaches the baseline.

7. Continue washing the column with 5 to 10 column volumes (490 to 980 ml) of IN column buffer C.

   The absorbance of the column eluate should be close to baseline before the sample is applied.

   Histidine is bound to the Ni-NTA resin by coordination bonding of the nonprotonated nitrogen atom of the imidazole side chain to Ni^{2+} ions. Because the pH of the IN column buffer C (6.4) is close to the average pK_a of histidine (6.0 to 7.0), only proteins that contain a track of six histidines (i.e., the His tag) are bound strongly enough to be retained. The sample applied to the column should not contain EDTA, and if reductant is required 1 mM 2-mercaptoethanol should be used rather than dithiothreitol.

   The Ni-NTA matrix is reported to have a binding capacity of ~5 to 10 mg protein per ml resin.

BOSTON COLLEGE CENTRAL UNIVERSITY LIBRARY

8. Elute bound protein with a linear pH gradient in a total volume of 980 ml (10 column volumes) beginning at pH 6.4 and ending at pH 4.5: make the gradient by placing 490 ml IN column buffer C (pH 6.4) and 490 ml of IN column buffer D (pH 4.5) in the appropriate reservoirs of the gradient maker. Elute column at ~300 ml/hr, collect 10-ml fractions and pool those making up the major peak (containing $IN^{50\text{-}212}$; eluted at ~pH 5.5).

   After elution, the column can be cleaned by washing with 0.2 M acetic acid/6 M guanidine·HCl, then reequilibrated with IN column buffer B. Under the conditions described, the column can be used two or three times before it turns from light blue-green to brownish-gray, indicating that regeneration is required. The column can be regenerated by passing 2 column volumes of 100 mM EDTA to strip Ni from the resin, washing the column sequentially with 2 column volumes each of 0.1 M NaOH and 6 M guanidine·HCl, and finally passing 2 column volumes of 10 mM $NiSO_4$ through the column to charge the resin with Ni. The column is then washed with water and equilibrated with IN column buffer B. Further details on use of the Ni-NTA resin are given in the manufacturer's literature (Qiagen, 1992) and in UNIT 9.2.

9. Concentrate pooled $IN^{50\text{-}212}$-containing fractions to ~40 ml (i.e., ~8 to 10 mg/ml protein) using a stirred cell with Diaflo PM 10 ultrafiltration membrane.

10. Apply concentrated sample to a 6 × 60–cm Superdex 75 gel-filtration column equilibrated with IN column buffer E. Pool the peak fractions.

    Reductants (either dithiothreitol or 2-mercaptoethanol) are included in the buffers to maintain the $IN^{50\text{-}212}$ cysteine thiol groups in the reduced state. It should be noted that $IN^{50\text{-}212}$ contains three cysteine residues that do not participate in disulfide bond formation.

    Pooled fractions may be stored in 10 to 20 ml aliquots at –80°C until ready to use.

    *This gel-filtration step removes minor protein contaminants and metal ions leached from the MCAC column. It also exchanges the protein into fresh buffer containing DTT. Alternatively, the pooled fractions from step 8 can be concentrated by ultrafiltration to ≤1 mg/ml protein, then dialyzed (*APPENDIX 3B*) against IN column buffer E.*

Fold protein by dilution

11. Dilute pooled fractions from step 10 to ~1 mg/ml protein using 4 M guanidine·HCl/5 mM DTT. Pump 30 ml (or other volume as required) of the diluted solution into 1 liter IN folding buffer using a peristaltic pump at a flow rate of ~3 ml/hr while stirring gently with a magnetic stirrer (see Fig. 6.5.3).

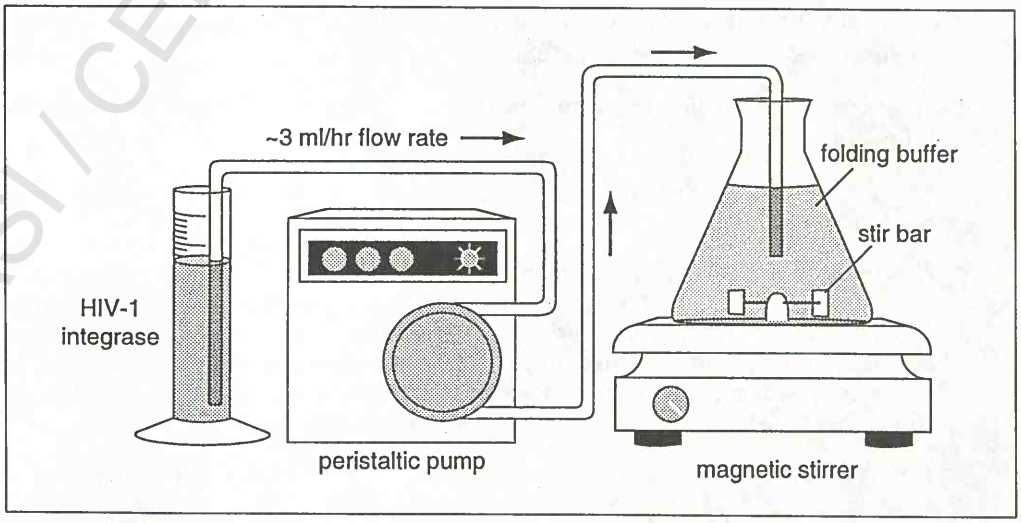

Figure 6.5.3 Setup for folding of HIV-1 integrase by dilution into buffer.

ECU IAST / CENTRAL UNIVERSITY LIBRARY

After dilution, the final protein concentration will be ~30 μg/ml.

Protein concentration can be estimated using A_{280} = 1.46 for 1 mg/ml folded IN^{50-212} (still containing the His tag) measured in a cuvette with a 1-cm path length.. If A_{280} is >2.0, dilute with 4 M guanidine·HCl in water.

The scale of operation at this step is limited by the large dilution of the protein. This step can be scaled up if equipment suitable for concentration of large volumes is available (see annotation to step 12). Otherwise, the step can be repeated if more protein is needed.

Protein folding is usually carried out at a low concentration to avoid aggregation, which is thought to arise from partially folded protein in the folding pathway (i.e., folding intermediates; Goldberg et al., 1991; Jaenicke, 1991; also see UNIT 6.4). Because aggregation is an intermolecular event, it is concentration-dependent. In this step the protein concentration is increased very slowly, allowing the protein already in solution to fold before additional unfolded protein is added. It is assumed that folded protein does not participate in aggregation.

12. Concentrate solution to ~1 mg/ml protein using a stirred cell with Diaflo PM 10 ultrafiltration membrane. Filter concentrated solution (25 to 30 ml volume) through a Millex-GV 0.22-μm filter.

    If it is not be be used immediately, the concentrated solution can be stored at −80°C for several months.

    The largest stirred cell produced by Amicon has a 2-liter maximum capacity (i.e., the Model 2000). This cell can be used to concentrate the solution to ~100 ml, and this must be further concentrated using a smaller cell (e.g., with a 200- or 400-ml capacity). For volumes >2 liters, or for a more rapid process, the Minitan tangential-flow membrane system (Millipore) can be used. This system allows a concentration rate of 0.5 to 1.0 liter/hr.

Cleave histidine tag with thrombin

13. Dilute folded protein from step 12 1:1 with 50 mM Tris·Cl (pH 7.5)/10 mM CHAPS (~0.5 mg/ml final protein concentration).

    This dilution is carried out because thrombin digestion (in step 14) works best at NaCl concentrations <200 mM.

14. Add 300 μl of 2000 NIH unit/ml thrombin (600 NIH units) to 60 ml of diluted protein from step 13 (30 mg IN^{50-212}). Incubate 30 min at 28°C with occasional mixing. Add an additional 300 μl of 2000 NIH unit/ml thrombin and incubate another 30 min. Cool solution on ice to 4°C and proceed immediately to step 15.

    Digestion conditions are optimized by conducting small-scale digestions (using <1.0 ml of protein solution from step 13). See Critical Parameters and Troubleshooting for details. The substrate/enzyme ratio used here is ~0.02% (w/w).

    Thrombin digestions are more reproducible when carried out on a relatively small scale—e.g., ~20 to 30 mg protein per batch. If more cleaved protein is required, several batches can be processed concurrently.

Remove excess thrombin by affinity chromatography

15. Pack a 1 × 10–cm column with *p*-aminobenzamidine immobilized on Sepharose 6B. Equilibrate with IN column buffer F.

16. Add 7.5 ml of 9 M urea (final concentration 1 M) to the 60-ml thrombin digest prepared in step 14.

17. Apply digest to equilibrated column from step 15 at a flow rate of 2 ml/min. Collect

BOOTH/CENTRAL UNIVERSITY LIBRARY

the column flowthrough, then wash with IN column buffer F until A_{280} is close to the baseline (this usually requires 1 to 2 column volumes).

$IN^{50\text{-}212}$ cannot be separated from thrombin by gel filtration because the $IN_{50\text{-}212}$ (mol. wt. 18,200) undegoes self-association (Hickman et al., 1994), and therefore elutes with a molecular weight close to that of thrombin (36,000). Affinity chromatography using the thrombin inhibitor p-aminobenzamidine is therefore employed.

The 1 M urea is added to the sample and column buffers to prevent nonspecific binding of $IN^{50\text{-}212}$ to the column.

The affinity column may be regenerated by washing with several column volumes of 6 M guanidine·HCl in water to remove the bound thrombin; alternatively, the thrombin can be eluted under native conditions with 50 mM Tris·Cl (pH 7.8)/10 mM benzamidine·HCl.

18. Pool flowthrough and wash fractions, add 0.1 mM AEBSF, then concentrate to ~ 2 mg/ml (in ~10 ml) using a stirred cell with Diaflo PM 10 ultrafiltration membrane.

Peform final purification and assay protein

19. Purify protein by gel filtration as in step 10, using IN column buffer G in place of IN column buffer E for equilibration and elution.

The column size can be reduced to 2.6 × 60 cm for fractionation of smaller (~30 mg) quantities of protein; the sample volume should be 5 to 10 ml.

20. Pool $IN^{50\text{-}212}$-containing fractions and filter sterilize with Millex-GV 0.22-μm filter.

The final protein solution can be concentrated if required. However, it should be noted that when CHAPS-containing solutions are concentrated by ultrafiltration, the detergent will also be concentrated. The excess detergent can be slowly removed by dialysis (APPENDIX 3B; the critical micellar concentration of CHAPS is 8 mM and its micellar size is ~8 kDa). Unfortunately, radiolabeled CHAPS is not available for monitoring the removal of that detergent; however, an enzymatic assay is available (Talalay, 1960; Coleman et al., 1979).

21. Measure A_{280} of protein solution in a cuvette with a 1-cm path length.

Native $IN^{50\text{-}212}$ (after the His tag has been cleaved) at a concentration of 1 mg/ml will have an A_{280} = 1.54.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

BGH break buffer A

100 mM Tris·Cl, pH 7.8 (pH as determined at 4°C)
20 mM EDTA (from 0.5 M stock)
10% (w/v) sucrose (100 g/liter)
200 μg/ml lysozyme (200 mg/liter)
Prepare immediately before use

BGH break buffer B

100 mM Tris·Cl, pH 7.8 (pH as determined at 4°C)
10 mM EDTA (from 0.5 M stock)
0.5 mM phenylmethylsulfonyl fluoride (PMSF)
5 mM benzamidine·HCl (780 mg/liter)
Prepare immediately before use

PMSF can be added as 2.5 ml/liter of 0.2 M PMSF stock solution.

PCU IASI CENTRAL UNIVERSITY LIBRARY

BGH column buffer A

60 mM ethanolamine·HCl, pH 9.0
5% (w/v) sucrose (50 g/liter)
Prepare immediately before use

Ethanolamine (molecular weight 61.08; density 1.02) is a strong base (pK_a = 9.4). The pH 9.6 buffer can made by dissolving 3.7 ml liquid ethanolamine free base or 5.9 g ethanolamine·HCl salt (molecular weight 97.5) per liter, and adjusting the pH to 9.6 with HCl or NaOH.

BGH column buffer B

Solution A: 0.5 M (62 g/liter) anhydrous Na_2HCO_3 (mol. wt. 84)
Solution B: 0.5 M (53 g/liter) anhydrous Na_2CO_3 (mol. wt. 106)
Mix 52 ml solution A and 148 ml solution B and dilute to 1 liter with water.

The solution may also be made directly by dissolving 7.8 g $NaHCO_3$ and 2.2 g Na_2CO_3. The 0.5 M stock solutions may be stored at least 1 month at 4°C.

BGH extraction buffer

To 420 ml H_2O add (in the order indicated):
17.2 ml 150 g/liter (2 M) glycine stock (50 mM final; store stock at 4°C)
7.8 ml 2 M NaOH
7.7 g reduced glutathione (GSH) *or* 50 ml 0.1 M GSH stock (see recipe; 5 mM final)
764 g guanidine·HCl (8 M final)
H_2O to 1 liter
Prepare immediately before use

Because of the volume increase on addition of guanidine·HCl (i.e., 1 g increases the volume 0.76 ml), buffer components must be added to 420 ml water and total volume adjusted to 1 liter at the end.

The buffer should be pH 9.6 as determined at 4°C; if it is not, it can be adjusted with 2 M NaOH or 2 M HCl. If solid glutathione (which is acidic) is added, pH will require adjustment.

If high-quality guanidine·HCl is used, the solution will be colorless and clear (see APPENDIX 3A).

BGH folding buffer A

To ~500 ml H_2O add (in the order indicated):
17.2 ml of 150 g/liter (2 M) glycine stock (50 mM glycine final; store stock at 4°C)
7.8 ml 2 M NaOH
100 g sucrose (10% w/v final)
2 ml 0.5 M EDTA (1 mM final)
310 mg reduced glutathione (GSH) *or* 10 ml of 0.1 M GSH stock (see recipe; 1 mM final)
60 mg oxidized glutathione (GSSG) *or* 1 ml of 0.1 M GSSG stock (see recipe; 0.1 mM final)
240 g urea (4 M final)
Add 4°C H_2O to 1 liter
Prepare immediately before use

The buffer should be pH 9.6 as determined at 4°C; if it is not it can be adjusted with either 2 M NaOH or 2 M HCl.

Because of the volume increase on addition of urea (i.e., 1 g increases the volume 0.76 ml), buffer components must be added to ~500 ml and total volume adjusted to 1 liter at the end. There is no need to deionize urea if ultrapure-grade material is used.

BOWMAN / CENTRAL UNIVERSITY LIBRARY

BGH folding buffer B

60 mM ethanolamine·HCl, pH 9.6 (pH as determined at 4°C)
10% (w/v) sucrose (100 g/liter)
1 mM EDTA (from 0.5 M stock)
0.1 mM reduced glutathione (GSH)
0.01 mM oxidized glutathione (GSSG)
Prepare immediately before use

GSH and GSSG can be added from stock solutions (1 ml of 0.1 M GSH and 0.1 ml of 0.1 M GSSG per liter) or as solids. If solid glutathione (which is acidic) is added, pH may require adjustment.

Ethanolamine (molecular weight 61.08; density 1.02) is a strong base (pK_a = 9.4). The pH 9.6 buffer can made by dissolving 3.7 ml liquid ethanolamine free base per liter or 5.9 g ethanolamine·HCl salt (molecular weight 97.5) per liter, and adjusting the pH to 9.6 with HCl or NaOH. It can be stored several days at 4°C.

BGH wash buffer A

100 mM Tris·Cl, pH 7.8 (pH as determined at 4°C)
2% (w/v) Triton X-100 (20 g/liter)
4 M urea (240 g/liter)
5 mM EDTA (from 0.5 M stock)
0.5 M DTT (77 mg/liter)
Prepare immediately before use

When preparing solution, allow for volume increase on addition of urea; 1 g urea will increase solution volume by 0.76 ml. There is no need to deionize urea if ultrapure-grade material is used.

Triton X-100 is a viscous liquid at 20° to 25°C; for the use intended here, there is no need for highly purified Triton.

BGH wash buffer B

100 mM Tris·Cl, pH 7.8 (pH as determined at 4°C)
0.5 mM DTT (77 mg/liter)
Prepare immediately before use

It is preferable to add DTT as a solid, but it may also be added as 0.2 M stock in water (30.8 g/liter; store at or below –20°C; stable ≥1 month).

Glutathione stock solutions, 0.1 M

Reduced glutathione: Dissolve 30.73 mg/ml reduced glutathione (GSH) in water and adjust pH to 7 with NaOH. Store at or below –20°C (stable ≥1 month).

Oxidized glutathione: Dissolve 61.3 mg/ml oxidized glutathione (GSSG) in water and adjust pH to 7 with NaOH. Store at or below –20°C (stable ≥1 month).

hIL-2 break buffer

0.1 M Tris·Cl, pH 7.5 (pH as determined at 4°C)
50 mM EDTA (from 0.5 M stock; *APPENDIX 2E*)
Prepare immediately before use

IN break buffer

50 mM Tris·Cl, pH 7.5 (pH as determined at 4°C)
5 mM EDTA (from 0.5 M stock)
5 mM benzamidine·HCl (780 mg/liter)
5 mM DTT (770 mg/liter)
0.1 mg/ml lysozyme (100 mg/liter)
Prepare immediately before use

It is preferable that DTT be added as a solid, but it may also be added as 0.2 M stock in water (30.8 g/liter; store at or below –20°C; stable ≥1 month).

BGU IASI / CENTRAL UNIVERSITY LIBRARY

IN column buffer A

10 mM Tris·Cl, pH 7.5 (pH as determined at 4°C)
4 M guanidine·HCl (382 g/liter)
1 mM 2-mercaptoethanol (2-ME; 0.070 ml/liter)

Because of the volume increase on addition of guanidine·HCl (i.e., 1 g increases the volume 0.76 ml), buffer components must be added to 420 ml water and total volume adjusted to 1 liter at the end.

Concentrated 2-ME (14.3 M) should be stored at 4°C and opened bottles replaced every 2 or 3 months.

IN column buffer B

To 500 ml H_2O add:
10 ml 1 M Tris·Cl, pH 8.0 (pH as determined at 4°C; 10 mM final)
0.73 g $NaH_2PO_4·H_2O$ (monobasic; mol. wt. 137.99)
13.44 g Na_2HPO_4 (dibasic; mol. wt. 141.96)
0.07 ml 2-mercaptoethanol (2-ME; 1 mM final)
After salts have dissolved add:
573.2 g guanidine·HCl (6 M final)
Bring temperature to 4°C and add 4°C H_2O to 1 liter
Adjust pH to 8.0 (as determined at 4°C) if necessary with 2 M NaOH or 2 M HCl
Prepare immediately before use

Because of the volume increase on addition of guanidine·HCl (i.e., 1 g increases the volume 0.76 ml), buffer components must be added to ~500 ml and total volume adjusted to 1 liter at the end.

Concentrated 2-ME (14.3 M) should be stored at 4°C and opened bottles replaced every 2 or 3 months.

IN column buffer C

Titrate IN column buffer B (see recipe) to pH 6.4 (as determined at 4°C) with HCl.
Prepare immediately before use.

IN column buffer D

Prepare 100 mM (13.8 g/liter) $NaH_2PO_4·H_2O$. If necessary adjust to pH 4.5 with 2 M NaOH or 2 M HCl.

IN column buffer E

Immediately before use, prepare IN column buffer B (see recipe), replacing the 2-ME with 5 mM DTT.

It is preferable that DTT be added as a solid, but it may also be added as 0.2 M stock in water (30.8 g/liter; store at or below –20°C; stable ≥1 month).

IN column buffer F

50 mM Tris·Cl, pH 7.5 (pH as determined at 4°C)
0.25 M NaCl (14.6 g/liter)
10 mM 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS; mol. wt. 614.9; 6.2 g/liter)
1 mM DTT (154 mg/liter)
1 mM EDTA (prepare from 0.5 M stock)
1 M urea (60 g/liter)
Prepare immediately before use

It is preferable that DTT be added as a solid, but it may also be added as 0.2 M stock in water (30.8 g/liter; store at or below –20°C; stable ≥1 month).

IN column buffer G

Prepare IN column buffer F (see recipe), but omit urea.

BOSTON CENTRAL UNIVERSITY LIBRARY

IN extraction buffer

10 mM Tris·Cl, pH 7.5 (pH as determined at 4°C)
8 M guanidine·HCl (764 g/liter)
5 mM DTT (770 mg/liter)
Prepare immediately before use

Because of the volume increase on addition of guanidine·HCl (i.e., 1 g increases the volume 0.76 ml), buffer components must be added to 420 ml and total volume adjusted to 1 liter at the end.

If high-quality guanidine·HCl is used, the solution will be colorless and clear (see APPENDIX 3A).

It is preferable that DTT be added as a solid, but it may also be added as 0.2 M stock in water (30.8 g/liter; store at or below –20°C; stable ≥1 month).

IN folding buffer

50 mM Tris·Cl. pH 7.5 (pH as determined at 4°C)
0.5 M NaCl (29.2 g/liter)
10 mM 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS; mol. wt. 614.9; 6.2 g/liter)
2 mM DTT (308 mg/liter)
Prepare immediately before use

It is preferable that DTT be added as a solid, but it may also be added as 0.2 M stock in water (30.8 g/liter; store at or below –20°C; stable ≥1 month).

RP-HPLC solvents A, B, and C

Solvent A: Prepare 0.1% (v/v) acetonitrile in water (both HPLC grade; e.g., Sigma).

Solvent B: Prepare 0.1% (v/v) TFA in acetonitrile (both HPLC grade)

Solvent C: Mix 800 ml acteonitrile and 1 ml TFA (both HPLC grade). Dilute with HPLC-grade water to 1 liter.

Prepare all solutions fresh; filter and degas before use.

Thrombin, 2000 NIH units/ml

Immediately before use reconstitute contents of a 1030 NIH-unit vial (2100 NIH units/mg) of thrombin from human plasma (Sigma) with 0.5 ml water to give a solution containing 50 mM sodium citrate, pH 6.5, 0.15 M NaCl, and 2000 NIH units/ml thrombin.

The A_{280} of 1 mg/ml thrombin is 1.83 in a cuvette with a 1-cm path length. Store the lyophized powder at or below –20°C.

COMMENTARY

Background Information

Bovine growth hormone (BGH)

There has been much commercial interest over the past fourteen years in producing large quantities of recombinant growth hormones. Human growth hormone is used as a pharmaceutical agent for treating dwarfism. Nonhuman growth hormones, including bovine and porcine growth hormones, are used in agriculture for stimulating growth and lactation in animals. These hormones were among the first group of proteins pursued by the biotechnology industry; they had been investigated decades before by protein chemists.

Bovine growth hormone (BGH; also known as bovine somatotropin) is a pituitary hormone, and the mature protein contains 191 residues (mol. wt. 21,876) with two disulfide bonds—one between residues 51 and 163 and another between residues 180 and 188. The closely related porcine growth hormone (pGH) was the first growth hormone for which the three-dimensional structure was determined (Abdel-Meguid et al., 1987). Since then, the structure of the human growth hormone (hGH) as a complex with its receptor has also been determined (deVos et al., 1992). It should be noted that hGH and pGH share 68% and 91% sequence similarity, respectively, with BGH.

FGU IASI/CENTRAL UNIVERSITY LIBRARY

In Basic Protocol 1, conditions are chosen that allow the unfolded, reduced protein to be folded and oxidized at relatively high protein concentrations (~1 to 2 mg/ml). The procedure is based on the original work of Goldberg (Orsini and Goldberg, 1978; see also references therein), who pioneered the use of cosolvents (e.g., urea in Basic Protocol 1; also see UNIT 6.4 and Maeda et al., 1994) to help maintain solubility during refolding. The use of redox buffer systems containing low-molecular-weight thiol-disulfide pairs (e.g., reduced and oxidized glutathione) to enhance the rate of disulfide-bond formation during the folding of reduced protein is based on Wetlaufer's work (Wetlaufer, 1984; see also references therein).

Although the methodology of Basic Protocol 1 was developed in 1982-1983, it remains a fairly typical example of a technique for preparative protein folding. Details of BGH expression in *E. coli* can be found in Wingfield et al. (1987a).

BGH folding and thiol oxidation

The structure of both porcine and human growth hormone consists of four antiparallel α-helices (Abdel-Meguid et al., 1987). The topology of BGH is almost certainly similar to that of pGH, due to the high degree of sequence and functional similarity. In pGH, one disulfide bond is formed between Cys-53 (found in the middle of the region connecting helices 1 and 2) and Cys-164 (located in helix 4). The other disulfide bond links the C-terminal region (at Cys-189) to helix 4 (at Cys-181).

Examination of the solution conditions for folding and oxidation of the reduced pituitary-derived BGH has shown that reduced and unfolded protein—in 6 M guanidine·HCl diluted into 4.5 M urea—can be air-oxidized with a high (90%) yield (Holzman et al., 1986). These conditions are similar to those used in Basic Protocol 1, except that in the latter, the protein concentration is >5-fold higher (>1 mg ml) and a redox buffer is used.

For further information on in vitro folding of BGH and the closely related pGH, consult Brems and Havel (1989) and Bastiras and Wallace (1992). Havel et al. (1989) present a concise and useful review of the some of the spectroscopic methods used to monitor protein conformation and structure (e.g., UV absorption, circular dichroism, and fluorescence) with examples of studies on BGH.

Comparison of authentic and recombinant BGH

Natural BGH is purified from bovine pituitaries, and examples of purifications leading to crystallizable protein are described by Bell et al. (1985) and Spitsberg (1987). The method that appears to give the most homogeneous product (Wood et al., 1989) involves extraction of pituitaries with 4.5 M urea (pH 8.8) followed by purifications employing anion- and cation-exchange chromatography in the presence of urea. The urea maintains solubility of the protein during purification; at the concentration used (4.5 M) it does not perturb or unfold the protein. The urea is finally removed from the purified protein by dialysis at pH 10. A single bovine pituitary yields ~16 mg of pure protein by this method.

Preparations of the natural protein often show varying degrees of N-terminal heterogeneity, depending on the method of purification. This may involve truncations of either one (ΔA-1) or four (A-4) residues—e.g., **(Ala)PheProAla**MetSerLeuSerGlyLeuCys AlaPhe...—where the residue in parentheses is lost in a Δ A-1 truncation and the four boldface residues are lost in a A-4 truncation. An example of a A-4 truncation is shown in Figure 6.5.1, lane E, where the two closely migrating bands at 23 and 22 kDa correspond to full-length and N-terminal-deleted (A-4) protein, respectively (for further details see Wingfield et al., 1987b, and references therein; also see Langley et al., 1987a). The two forms can be resolved under native conditions by chromatofocusing, which takes advantage of the small difference in their isoelectric points; full-length and A-4 BGH have pI values of 8.2 and 8.0, respectively (Wingfield et al., 1987b). Protein purified by the method of Wood et al. (1989) has a single and correct N-terminus.

Recombinant hormones have been expressed that contain the full BGH sequence (e.g., Langley et al., 1987a), as well as others with the ΔA-1 deletion (e.g., Wingfield et al., 1987a; Bogosian et al., 1989) and the A-9 deletion (Wingfield et al., 1987a). Purified A-1 BGH retains the initiating Met at the N-terminus (MetPhePro...), but when the initiating Met is placed in front of the Ala, the Met is removed to give the authentic sequence (AlaPhePro...). Deletion of at least the first nine N-terminal residues does not appear to effect the biological activity of BGH.

Another source of chemical heterogeneity in both authentic and recombinant growth hor-

BOSTON UNIVERSITY LIBRARY

mones is the deamidation of specific Asn and Gln residues (Secchi et al., 1986). This is partly responsible for the multiple band patterns observed in isoelectric focusing gels (Wingfield et al., 1987a; 1987a). In typical authentic and recombinant BGH preparations, ~20% of the protein is deamidated. However, because these modified forms have lower pIs than unmodified protein, they can be separated by chromatofocusing (Wingfield et al., 1987a). The cation-exchange chromatography step (at pH 6.9 in 4.5 M urea) used by Wood et al. (1989) for purification of pituitary BGH also appears to separate deamidated from unmodified protein. Deamidated protein is more positively charged than unmodified protein, and will therefore bind more tightly to a negatively charged cation-exchange matrix.

Authentic and recombinant BGH both exhibit self-association with the characteristics of a rapid monomer-dimer equilibrium. The dissociation constant (K_d) for authentic BGH is 6.6 × 10–6 M (Fernandez and Delfino, 1983), which is similar to that determined for both the A-1 and A-9 recombinant forms of BGH (P.T.W., unpub. observ.). At concentrations of 1.0 and 0.1 mg/ml, ~76% and 42% of the protein will be dimeric, respectively. Under physiological conditions, the monomer appears to be the active species. Monomeric protein binds to two molecules of the extracellular domain of the cell-surface receptor, forming a 1:2 molar complex analogous to the human growth hormone (Staten et al., 1993).

Other approaches used to extract and fold recombinant BGH

Langley et al. (1987a) extracted protein from inclusion bodies using 6 M guanidine·HCl (pH 8.0) as the denaturant. The extract was allowed to oxidize in air >72 hr at room temperature in the presence of the denaturant. Oxidized protein was fractionated by gel filtration in guanidine·HCl, the fractions making up the monomer peak pooled, and the protein folded by removal of denaturant using dialysis. The rationale for this method is that, in a protein with four cysteine residues that form two disulfide bonds (such as BGH), there are three possible intramolecular disulfide linkage combinations. Hence, even if the oxidation proceeds in a random manner as expected for unfolded protein, at least 33% of the protein produced will have the correct pattern. In practice, the recovery of correctly folded oxidized protein was significantly higher than 33%—suggesting that even in 6 M guanidine·HCl, BGH may contain some elements of native-like structure. This method is geared toward large-scale protein production and gives good protein recovery. However, the long incubation period in guanidine·HCl appears to result in ~50% of the protein being deamidated (Langley et al., 1987b).

Bogosian et al. (1989) used 4.5 M urea at pH 10.7 to extract BGH from inclusion bodies. The extract was then stirred for 48 hr, allowing the protein to oxidize in air. This method is mentioned because it results in formation of a novel concatenated dimer, formed by the interlocking of disulfide loops (Violand et al., 1989). It is most likely that under the conditions used for extraction, the protein folding and oxidation is initiated from partially folded associated protein.

Ovine growth hormone (which is closely related to BGH) was folded and purified with an overall recovery of 30% by a procedure similar in approach to Basic Protocol 1 (Wallis and Wallis, 1989). This method, however, used 2 M guanidine·HCl instead of urea as the co-solvent to maintain solubility during folding. It also employed air oxidation for 24 hr instead of the redox buffer system.

Interleukin 2

Interleukin 2 (IL-2) is a member of the cytokine family. It is composed of a compact core bundle of four antiparallel α-helices (Bazan, 1992; McKay, 1992). IL-2 plays important roles in the proliferation and differentiation of T lymphocytes as well as in regulation of the immune system. The biological effects of IL-2 are mediated via binding to IL-2 receptors (Minami et al., 1993).

The human IL-2 (hIL-2) gene has been cloned and expressed in *E. coli* as insoluble inclusion bodies (Devos et al., 1983). The purification of recombinant hIL-2 has been described and the protein thoroughly characterized (Liang et al., 1985; Kato et al., 1985; Weir and Sparks, 1987). Basic Protocol 2 details the solubilization, refolding, and purification of recombinant hIL-2. This procedure can be scaled up to yield hIL-2 on the scale of hundreds of milligrams.

hIL-2 has three cysteines; hence, three possible disulfide-linked forms can exist. The native isomer consists primarily of one form—i.e., the one that contains a disulfide linkage between Cys-58 and Cys-105 (Robb et al., 1984; Wang et al., 1984; Liang et al., 1985).

PCU IASWER TRAI UNIVERSITY LIBRARY

Reversed-phase-HPLC has been used to separate these isomers (Browning et al., 1987; also see Fig. 6.5.3).

HIV-1 integrase

An early part of the life cycle of all retroviruses (including the human immunodeficiency virus, HIV) is the integration of a DNA copy of the viral genome into the host chromosome. This step is essential for viral replication. Retroviral DNA integration is carried out by a defined set of DNA cutting and joining reactions, catalyzed by integrase protein (Katz and Skalka, 1994).

The HIV-1 integrase is a 288-residue protein (mol. wt. 32,200) which has been expressed in *E. coli* (Sherman and Fyfe, 1990). The protein is located in the pellet obtained by low-speed centrifugation following cell breakage, but is apparently not highly aggregated into inclusion bodies, as it can be extracted into high-ionic-strength solution (e.g., 1 M NaCl) without a denaturant. The insolubility of the protein is probably a result of nonspecific binding to *E. coli* nucleic acid. The salt-extraction procedure was originally used by Terry et al. (1988) for extraction of avian sarcoma-leukosis virus integrase expressed in *E. coli*.

Dissection of the HIV-1 integrase by preparation of a series of deletion mutants (Bushman et al., 1993; see also references therein) demonstrated that a central core region of residues 50 to 212 was enzymatically active, carrying out a subset of the reactions catalyzed by the full-length enzyme. This deletion mutant is interesting for structural studies as it has better solubility than the full-length enzyme, which is notoriously difficult to handle as a result of limited solubility in the usual aqueous solvents.

The HIV-1 integrase deletion mutant ($IN^{50\text{-}212}$) is expressed in *E. coli* as a fusion protein with the N-terminal extension sequence GlySerSerGlyHisHisHisHisHisHisSerSer GlyLeuVal**ProArgGly**SerHisMet. This sequence (a His tag) contains a six-residue histidine repeat which is responsible for the selective high-affinity binding of the fusion protein to a nickel-chelate column. The boldface portion of the His tag sequence indicates the location of the specific thrombin-cleavage site between Arg-16 and Gly-17, which is exploited in removal of the tag using thrombin.

In Basic Protocol 3 the His-tagged $IN^{50\text{-}212}$ is expressed as an insoluble (i.e., inclusion-body-type) protein, and is purified under denaturing conditions, taking advantage of the fact that metal-chelate affinity chromatography (MCAC) can be carried out in the presence of protein denaturants such as guanidine·HCl. Following purification, the protein is folded and the His tag removed by exploiting the specific thrombin-cleavage site of the tag sequence (underlined above). The cleaved protein has the N-terminal sequence GlySerHisMetHisGlyGln.... The Met at position 4 corresponds to Met 50 of the wild-type integrase and residues 1 to 3 (GlySerHis) are derived from the tag. Excess thrombin is removed by affinity chromatography using an immobilized inhibitor (*p*-aminobenzamidine). In the last step of the purification, the $IN^{50\text{-}212}$ is subjected to gel-filtration to remove any aggregated multimers. The protein produced is 166 residues long, the molecular weight estimated from the DNA coding sequence is 18,200, and the calculated isoelectric point is ~7.

Although the folded deletion mutant has enhanced solubility as compared with the wild-type enzyme, the zwitterionic detergent CHAPS is included in buffers to maintain solubility, especially during protein folding. Following protein purification the detergent can be removed or exchanged for other buffer additives.

Substitution of Phe-185 for a Lys residue appears to increase the solubility of $IN^{50\text{-}212}$. This mutant protein, expressed in *E. coli* with the N-terminal His tag, was extracted with 1 M salt and purified by MCAC. The extraction with high-ionic-strength salt solution in the absence of denaturant is analogous to the procedure used with the full-length protein, discussed above. The crystal structure of this protein has been determined at 2.5-Å resolution. The overall topology consists of five β-sheets flanked by helical regions, showing that the integrase domain belongs to a superfamily of polynucleotidyl transferases that includes ribonuclease H (Dyda et al., 1994).

Critical Parameters

Bovine growth hormone (BGH)

Protein extraction. The protein should be extracted from the inclusion bodies in a monomeric and fully reduced state. This provides a defined starting point from which to develop a reproducible folding protocol. Based on pilot-scale experiments in which washed pellets (from step 4 of Basic Protocol 1) were extracted with various protein denaturants (P.T.W., unpub. observ.; also see *UNIT 6.3*), 8 M guanidine·HCl was chosen for solubilization of aggregated BGH. The most effective ones were

PRINCETON UNIVERSITY LIBRARY

urea and guanidine·HCl at 6 M to 8 M concentrations, each of which solubilized >80% of the protein. The extracts were further analyzed by gel filtration on Sephacryl S-300 in the presence of the same concentration of the particular denaturant used for the initial extraction. The results indicated that guanidine·HCl at concentrations >6 M yielded solubilized protein of which >80% was monomeric. Although 8 M urea also solubilized >80% of the protein, only ~20% of this protein was monomeric, the remainder consisting of dimers and higher-order aggregates.

Protein folding and oxidation. Basic Protocol 1 describes an empirical approach based on some of the principles discussed in *UNITS 6.1 & 6.4*. The determination of basic physicochemical/conformational properties for a particular protein will take some of the guesswork out of developing a suitable folding protocol. For BGH, purified authentic protein from bovine pituitary glands was available, and had been fairly well characterized before recombinant proteins were produced. This situation is not common, as the natural counterparts of many recombinant proteins are rare and may never have been purified. The optimal ratio of reduced to oxidized glutathione in the folding buffers used in Basic Protocol 1 was empirically determined. However, it is commonly observed that the highest folding yields are obtained when the ratio of GSH/GSSG is between 5 and 10 and the total reduced and oxidized glutathione concentration is in the range of 1 to 10 mM.

Deamidation. As mentioned above, BGH is susceptible to deamidation. Although deamidated forms (charge isomers) can be resolved by ion-exchange methods (Wingfield et al., 1987a), their formation should be minimized. This is achieved by limiting the amount of time the protein spends in the fully unfolded state, especially at pH 9.5. For example, the guanidine·HCl extract should be processed immediately and diluted as described in step 6 of Basic Protocol 1. The dialysis steps (at pH 9.5) should be performed for the times indicated, not longer. The folded protein is stable and does not appear to deamidate spontaneously on storage.

Scaleup. For larger-scale production, a Manton-Gaulin-APV homogenizer (*UNIT 6.1*) is used to break cells instead of the French press. In addition, a larger Sephadex G-100 column (e.g., 5.0 × 90–cm) is used in step 12 of Basic Protocol 1.

Interleukin-2

Protein purification. Recombinant hIL-2 should be extracted as a monomer (see Basic Protocol 2, step 5). The extraction has been tested with various concentrations of acetic to determine the optimal condition; 20% acetic acid has been found to extract the maximum amount of monomeric hIL-2 from inclusion bodies. However, in the gel-filtration step (see Basic Protocol 2, step 8), 20% acetic acid is too corrosive for the metal parts of the chromatography system (e.g., the stands, pump, and fraction collector); thus 10% acetic acid is recommended.

Protein folding. The hIL-2 monomer that elutes from the Sephadex G-100 column (see Basic Protocol 2, step 8) yields two peaks upon analytical reversed-phased chromatography (see Support Protocol). These two peaks represent the refolded, oxidized hIL-2 and unfolded, reduced hIL-2. The proportion of the oxidized form is increased by the dialysis step (see Basic Protocol 2, step 9). The time and volume recommended in the dialysis step have been determined empirically to produce the best yield of oxidized hIL-2. Longer periods of dialysis (e.g. 48 hr) causes do not increase the yield of oxidized hIL-2.

Scaleup. The parameters for larger-scale production are the same as those for BGH (see above).

HIV-1 integrase

MCAC. It is important to use low concentrations of 2-mercaptoethanol in the sample and column buffer (1 mM is safe) and to completely avoid dithiothreitol, as either reductant will strip Ni^{2+} from the MCAC matrix (see *UNIT 9.4*).

Protein folding. Because HIV-1 integrase is not a very soluble protein and has a high tendency toward self-association and aggregation (Hickman et al., 1994), the solubility and stability of the folded protein must be maintained by including a relatively high salt concentration as well as the detergent CHAPS in the folding buffer and in all subsequent column buffers. The buffer additives indicated for HIV-1 integrase are usually not required for folding of the average protein.

Thrombin cleavage. It is necessary to perform pilot-scale experiments to optimize the conditions for removing the His tag using thrombin. The usual parameters to vary are enzyme/substrate ratios and incubation time and temperature. Thrombin is a serine protease, and can be irreversibly inhibited with either PMSF or AEBSF. Removal of the tag can be

FGU IASI CENTRAL UNIVERSITY LIBRARY

monitored by SDS-PAGE (*UNIT 10.1*), in which case the thrombin should be quenched with 1 mM PMSF or AEBSF prior to addition of SDS and heating. There is an ~2-kDa mass difference between tagged and nontagged protein (see Fig. 6.5.2). The digestion should be as complete as possible at the specific cleavage site (see Background Information); overdigestion may result in nonspecific cleavage at other sites. It is also important to avoid denaturation of the (thrombin) (e.g., by vigorous stirring or overheating), as partially denatured proteases often exhibit some loss of specificity, cleaving at unpredictable sites.

Troubleshooting

Bovine growth hormone (BGH)

Most precautions and guidelines for folding and oxidation are given in annotations to the individual steps of Basic Protocol 1. It should be cautioned that, when using a mixture of oxidized and reduced glutathione for oxidizing proteins that contain both free and disulfide-linked cysteines in the native state (e.g., IL-2), the potential exists for glutathionylation, in which the unpaired cysteine(s) form a mixed disulfide with glutathione. This modification will cause charge heterogeneity, and can be readily detected by electrospray ionization mass spectrometry (ESI-MS), which will indicate a mass increase of 305.3 for each GSH moiety incorporated.

Interleukin-2

Low-molecular-weight impurities extracted together with monomeric hIL-2 in acetic acid (see Basic Protocol 2, step 5) are usually eluted earlier than the oxidized form of hIL-2 in RP-HPLC (see Basic Protocol, step 12) and can thus be removed. If the RP-HPLC peak containing the oxidized form of hIL-2 is contaminated by low-molecular-weight impurities, SDS-PAGE analysis of each fraction composing the peak is recommended to avoid pooling fractions containing impurities. Additional information regarding troubleshooting is given in annotations to individual steps of Basic Protocol 2.

HIV-1 integrase

MCAC. Protein will not bind to the column if the His tag has been nonspecifically degraded or removed by *E. coli* proteases. SDS-PAGE (*UNIT 10.1*) of the cell extracts and fractions during the purification should indicate if the tag is present. The His tag adds ~2 kDa to the apparent mass of the protein. The denaturant concentration should be high enough to maintain solubility of the protein during chromatography. Insoluble or aggregated protein will not bind to the column and will be located in the column flowthrough or will clog the top of the matrix. If protein aggregates on the column, a higher concentration of denaturant should be tried, although aggregation should not happen using 6 M guanidine·HCl in column buffer A. Further details on troubleshooting the use of the Ni-NTA resin are given in the manufacturer's literature (Qiagen, 1992) and in *UNIT 9.4*.

Thrombin cleavage. If undigested (His-tagged) protein still remains after digestion, the standard procedure is to reapply the mixture to an MCAC column, whereupon the matrix will specifically bind the unprocessed protein containing the His tag. The processed (cleaved) protein is not bound and elutes in the column flowthrough. This approach, although satisfactory for monomeric proteins, is complicated with multimeric proteins and those that exhibit reversible self-association—e.g., HIV-1 integrase. For example, in a partially digested dimeric protein, the subunits can be arranged in three possible configurations—TT, TM, and MM—where T is still tagged and M has had the tag cleaved. It may be possible to separate TT and TM by gradient elution from the MCAC column, as the former might be expected to bind more tightly than the latter. A simpler approach is to use solvent conditions that dissociate the protein subunits without denaturing them. For HIV-1-integrase, this can be achieved with 2 to 3 M urea.

Anticipated Results

BGH

The purification of Δ A-9 BGH is summarized in Table 6.5.1. About 90 to 100 mg of protein are obtained from 50 g (wet weight) of cells with an overall yield in the range 15% to 25%. For larger and/or multidomain proteins, much lower yields (1% to 5%) may be more typical. Gel analysis of the BGH in cell extracts and in purified protein is shown in Figure 6.5.1.

Interleukin-2

If the expression of hIL-2 in *E. coli* is ~10%, 20 g of cell pellet will yield 4 to 5 mg of purified protein, with a specific activity of 5×10^6 U/mg. The purity of the hIL-2 should be >98% as indicated by analytical C18 column chromatography (see Support Protocol).

JONAS SALK INSTITUTE LIBRARY

Table 6.5.1 Purification of a Recombinant Bovine Growth Hormone Analog[a]

Stage of Purification[b]	Total Protein[c] (mg)	Specific BGH content[d] (%)	Total BGH (mg)	Yield (%)
Cells	5000	7.5	375	100
Washed pellet (step 4)	375	60	225	60
Dialysis supernatant (step 8)	200	75	150	40
DEAE-Sepharose pool (step 11)	131	95	125	33
Sephadex G-100 pool (step 14)	95	99	94	25

[a]The summary refers specifically to a biologically active analog of BGH (δ-9 BGH) in which the full-length sequence is truncated at the *N*-terminus by eight residues and serine is substituted for glycine at the first position. Similar relative yields were obtained with a δ-1 analog in which the *N*-terminal Ala of the native sequence was replaced by Met, but the amount of this protein expressed in *E. coli* was several-fold lower than that obtained for δ-9 BGH (Wingfield et al., 1987a)

[b]The numbers in parentheses refer to Basic Protocol 1 steps.

[c]Determinations were made using the Bio-Rad Protein Assay Kit, except those for the DEAE and Sephadex pools, which were made by UV absorbance measurements.

[d]Percentage of total protein that is BGH. Estimates made by densitometric scanning of Coomassie blue stained SDS-polyacrylamide gels.

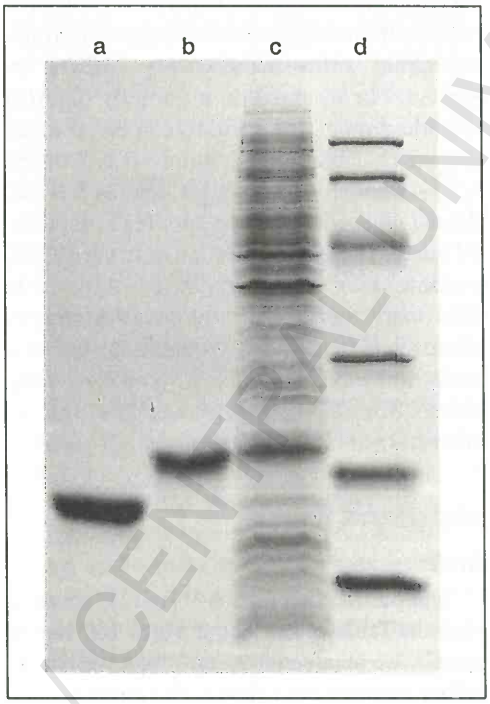

Figure 6.5.4 Results of SDS-PAGE of H1V-1 integrase$^{50\text{-}212}$ on a 12.5% polyacrylamide gel stained with Coomassie blue. Lane A, recombinant HIV-1 integrase$^{50\text{-}212}$; lane B, recombinant HIV-1 integrase$^{50\text{-}212}$ with N-terminal His tag; lane C, extract of HIV-1 integrase–expressing *E. coli* cells used for purification.

In a scaled-up process (see Critical Parameters), 25 to 30 mg of purified hIL-2 may be obtained from 200 g of *E. coli* cell pellet.

HIV-1 integrase

Figure 6.5.4 shows results of SDS-PAGE of the purified IN$^{50\text{-}212}$ before (lane B) and after (lane A) removal of the His tag by thrombin digestion. The molecular weight difference of ~2000 kDa corresponds to the removal of the 16 amino acid residues comprising the N-terminal His tag.

The overall recovery of purified protein is ~30%. For example, from 1 g (wet weight) of cells (containing ~5% IN$^{50\text{-}212}$) ~1.5 mg of purified protein are obtained (see Figure 6.5.4, lane C, for SDS-PAGE analysis of whole IN$^{50\text{-}212}$–expressing *E. coli*). Most of the steps, including protein folding, have high recoveries (80% to 95%). The yield of thrombin-digested

BGU IASI CENTRAL UNIVERSITY LIBRARY

protein from purified tagged protein is between 60% to 70%.

The enzymatic and biophysical properties of the protein are detailed in Hickman et al. (1994).

Time Considerations

BGH

Basic Protocol 1 for the purification of BGH takes 5 days. Protein can be stored at –80°C at the end of step 4 (as washed pellets) or step 10 (as pooled fractions from ion-exchange).

Day 1: Cell breakage, preparation of washed pellets and extraction with guanidine·HCl (steps 1 to 5) requires ½ day of work. The protein extract is then dialyzed overnight (step 5).

Day 2: After changing the dialysis buffer (step 7), dialysis is continued at least 6 hr. At this step the dialysis can be left overnight or directly processed by ion-exchange chromatography (steps 8 to 10), which takes 6 to 8 hr and can be run overnight.

Day 3: Ion-exchange chromatography is run, or if ion-exchange was performed on day 2, the pooled fractions are concentrated for several hours (step 11), then applied to the gel-filtration column and chromatographed for several hours (steps 12 and 13). The gel-filtration column is run is overnight if a low-pressure matrix (e.g., Sephadex G-100) is used or on the same day if a medium-pressure matrix (e.g., Superdex 200) is used.

Day 4: The protein is analyzed (e.g., by SDS-PAGE or isoelectric focusing), concentrated if required (step 14), and frozen or prepared for lypohilization.

Interleukin-2

In Basic Protocol 2, preparation and lysis of the cells (steps 1 and 2) will take 1 hr, cell breakage and preparation of washed pellets (steps 3 and 4) will take 3 hr, acid extraction (steps 5 and 6) will take 1 hr, Sephadex G-100 column chromatography (step 7) will take 12 hr, dialysis of the pooled fractions will be carried out overnight, and RP-HPLC (steps 9 to 12) will require 7.5 hr. The final dialysis is run overnight. In the Support Protocol for resolution of native and misfolded forms of hIL-2, it will take ~1 hr to run a sample after the blank runs to establish the baseline profile have been completed.

HIV-1 integrase

Basic Protocol 3 is usually carried in two stages. In stage 1, purification of the unfolded protein that still contains the His tag (steps 1 to 8) is usually carried out on a relatively large scale (using 100 g of cells). If the Superdex 200 column used in step 5 and the MCAC column used in step 6 are run using the Pharmacia Biotech Biopilot system, this stage will take 3 to 4 days to complete. It will take longer if low-pressure columns are used. In stage 2, protein folding (steps 11 and 12), removal of the His tag by thrombin cleavage (steps 13 and 14), affinity chromatography (steps 15 to 17), and gel filtration (step 19) are performed. This stage is carried out repeatedly with relatively small amounts of protein (i.e., 30 mg; this represents <10% of the protein produced in the Stage 1). Using the Pharmacia Biotech FPLC system for the chromatography steps, stage 2 takes 2 days.

Expression and Purification of GST Fusion Proteins

This unit describes how pGEX vectors (available from Pharmacia Biotech) can be used for high-level inducible intracellular expression of polypeptides as fusions with glutathione-*S*-transferase (GST) in *Escherichia coli*. GST fusion proteins are easily purified under nondenaturing conditions by affinity chromatography (Chapter 9) using a glutathione–Sepharose 4B conjugate. The amino-terminal GST moiety can then be cleaved from the protein of interest using a specific protease cleavage site located between the GST moiety and the recombinant polypeptide. Finally, the GST moiety can be removed by rechromatographing the sample on the glutathione-Sepharose column.

Potential applications of the system include the expression and purification of large quantities of individual polypeptides for use in structural determinations using either nuclear magnetic resonance (NMR) or crystallography, immunological studies, vaccine production, and structure-function studies involving protein-protein and DNA-protein interactions.

The basic protocols are chromatography-based adaptations of the manufacturer's recommendations and include batch and column purification methods. The experience of this laboratory is that, although batch purifications may be slightly faster, column-based purification steps usually provide higher protein yields and higher purity of the final product.

GST fusion proteins can be expressed at high levels in *E. coli* grown using an environmental shaker (see Basic Protocol 1). The soluble fusion protein is purified using a single-step glutathione–Sepharose 4B affinity column (see Basic Protocol 2). Fusion proteins that are found in inclusion bodies can be extracted using denaturants and then refolded before affinity chromatography using a glutathione–Sepharose 4B column (see Alternate Protocol 1). Soluble fusion proteins can also be purified batchwise using glutathione–Sepharose 4B affinity matrix (see Alternate Protocol 2). The fusion protein can be cleaved with either thrombin or factor Xa in solution to separate the protein of interest from glutathione (see Basic Protocol 3). The protein of interest can also be released by protease digestion of the fusion protein immobilized on a glutathione–Sepharose 4B column (see Alternate Protocol 3), or by batchwise protease cleavage and separation from the resin (see Alternate Protocol 4). Affinity purification using glutathione–Sepharose 4B can be used to remove the GST moiety after enzymatic cleavage (see Support Protocol 1). HPLC gel filtration is used as a final purification step to obtain >98% pure protein (see Support Protocol 2). The relationships between the protocols are shown in Figure 6.6.1.

STRATEGIC PLANNING

A variety of pGEX expression vectors are commercially available (Pharmacia Biotech) that contain a *tac* promoter for chemically inducible, high-level protein expression. The available pGEX vectors have an open reading frame encoding glutathione-*S*-transferase (GST) followed by multiple cloning sites. These are followed by termination codons in each reading frame (Figs. 6.6.2 and 6.6.3). A fragment of DNA containing the genetic sequence for the polypeptide of interest is ligated into an appropriate pGEX vector and transformed into *E. coli*. It should be noted that although expression in *E. coli* is efficient, there is no post-translational modification machinery. Successful expression of GST

fusion proteins using baculovirus systems (Davies et al., 1993) and yeast (Mitchell et al., 1993) have also been reported.

One factor that influences which pGEX vector to choose is whether or not the GST moiety will ultimately be cleaved away from the protein of interest. The pGEX-2T and pGEX-4T series of vectors contain a protease cleavage site for thrombin, and the pGEX-3X and pGEX-5X series of vectors contain protease cleavage sites for factor Xa. A more recently developed expression vector is the pGEX-6P series, which contains a cleavage site for PreScission protease (Pharmacia Biotech). PreScission protease has the advantage that it is effective at low temperatures (5°C). It is also a GST fusion protein, a feature that facilitates removal of the protease from the target protein after cleavage. Fusion proteins with a thrombin recognition site have the advantage that relatively small amounts of thrombin and short digestion times at 37°C will often cleave the fusion protein with high efficiency. Thrombin digestions are often the most cost effective on a per milligram of cleaved target polypeptide basis. Factor Xa is more expensive and typically requires use of much higher enzyme-to-substrate ratios for efficient cleavage. Solutions of factor Xa also have a more limited shelf life since freezing and thawing inactivates this enzyme.

For preparation of cDNA inserts encoding the desired polypeptide, see Ausubel et al. (1994) or Sambrook et al. (1989). Briefly, a set of oligonucleotides is designed for polymerase chain reaction (PCR) amplification of the region of interest of a pertinent cDNA. These oligonucleotides should also contain appropriate restriction sites adjacent to the desired coding region that are compatible with a restriction site in the cloning site of the selected pGEX vector (see Figs. 6.6.2 and 6.6.3). PCR amplification is performed,

ECU IAS/CERTAR UNIVERSITY LIBRARY

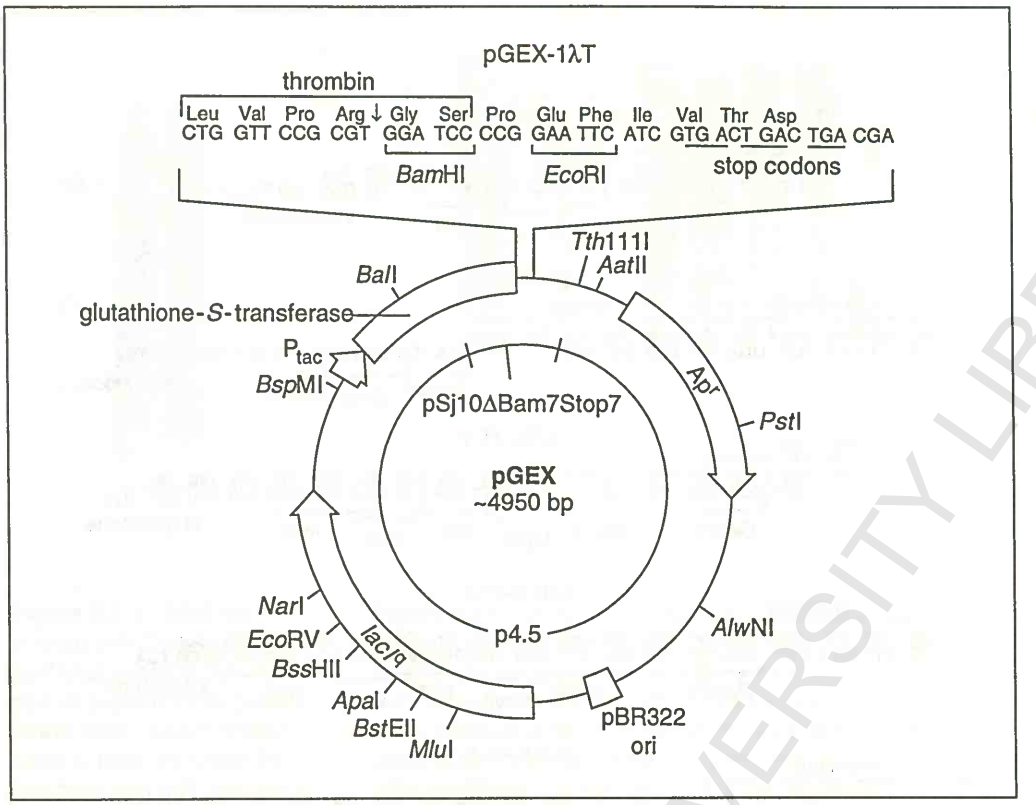

Figure 6.6.2 pGEX vectors are plasmid expression vectors that express a cloned gene as a fusion protein with glutathione-*S*-transferase (GST). The *lac* repressor gene binds to the *lac* promoter (p_{tac}) and represses expression of the GST fusion protein until induction with isopropyl-1-thio-β-D-galactopyranoside (IPTG). The polypeptide of interest can be inserted immediately after the GST gene using the polylinker site shown in brackets (pGEX-1λT, shown here, is the most common; see Fig. 6.6.3 for other PGEX polylinkers). Protease cleavage sites (brackets above the polylinker sequences) are located between the GST carrier protein and the protein of interest so that the GST moiety can be removed. Restriction endonuclease sites are indicated below the sequence of the polylinker and on the plasmid. An important consideration in selecting a vector and appropriate cloning sites is to minimize the number of extraneous residues introduced into the N-terminal of the target polypeptide. Vector map courtesy of Pharmacia Biotech.

followed by digestion of the PCR product and the pGEX vector with the appropriate restriction enzymes. The PCR product is then ligated into the pGEX vector and transfected into a suitable *E. coli* host. Several transformants should be grown in minicultures and induced with isopropyl-1-thio-β-D-galactopyranoside (IPTG) to check for expression of the desired fusion protein. Fusion protein expression can be monitored by SDS-PAGE (*UNIT 10.1*) or by Western blot (*UNIT 10.10*) detection of the GST fusion protein using an antibody specific for either the target protein or the GST moiety. Once successful expression is achieved, the integrity of the DNA should be verified by sequencing to ensure that no errors were introduced during PCR.

Before conducting a large-scale purification, it is worthwhile to perform a small pilot purification (~10-fold less than protocol descriptions) to determine optimal conditions. The purification can then easily be scaled up. All stages of purification should be monitored using SDS-PAGE (*UNIT 10.1*). In most cases, GST fusion protein expression is very high and a major band at the expected molecular weight (the GST moiety contributes 26 kDa to the molecular weight) is obvious when uninduced and induced cells are compared on SDS gels (Fig. 6.6.4). This band can then be monitored at each step of the purification. However, as noted above, if the level of protein expression obtained is low or band identification is ambiguous, the fusion protein can be monitored by Western blot

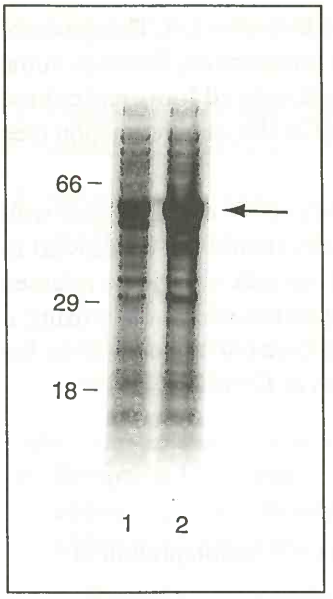

Figure 6.6.4 SDS gel stained with Coomassie brilliant blue showing the expression of a glutathione-*S*-transferase (GST) fusion protein. Lane 1, total cell lysate before induction with isopropyl-1-thio-β-D-galactopyranoside (IPTG). Lane 2, total cell lysate after 3-hr induction with IPTG. The position of the fusion protein is indicated by the arrow.

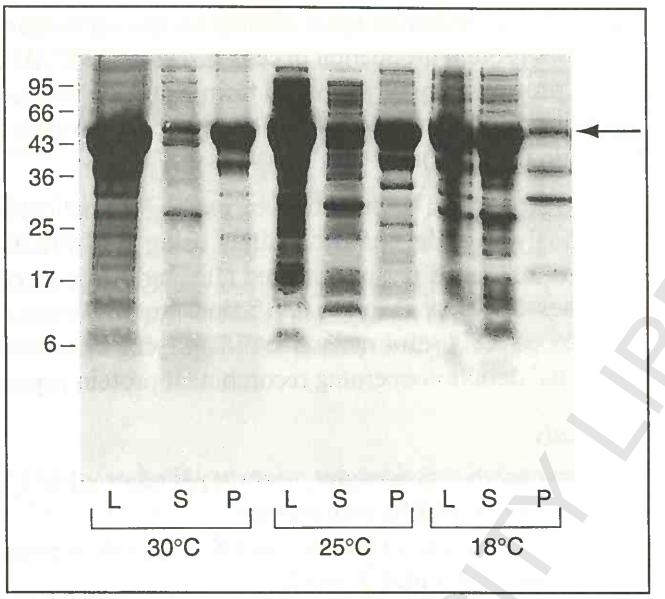

Figure 6.6.5 SDS gel stained with Coomassie brilliant blue showing the effects of different growth temperatures on solubility of an expressed glutathione-*S*-transferase (GST) fusion protein. *E. coli* transfected with a recombinant pGEX-2T vector were grown at different temperatures as indicated. Proportional aliquots of whole-cell lysate after sonication (L), the supernatant after centrifuging the lysate (S), and the remaining pellet (P) are shown. This recombinant was primarily in inclusion bodies (P) at 37°C (not shown), 30°C, and 25°C. At 18°C, however, nearly all of the expressed protein was in a soluble native form.

analysis (*UNIT 10.10*) using a GST-specific antibody (Pharmacia Biotech). It is recommended that the lysed cell extract, extracted pellet, and all other collected fractions from the purification be saved on ice until after careful analysis of the entire purification by SDS-PAGE and/or immunoblotting to ensure that fractions containing the fusion protein are not mistakenly discarded.

Basic Protocol 1 describes protein production in cells grown at 37°C; however, at this temperature some fusion proteins may be found in inclusion bodies in a denatured form. As an alternative to attempting to renature the protein after extraction from inclusion bodies (*UNIT 6.1*), expression at lower temperatures, such as 30°, 25°, 20°, or 15°C, can be evaluated to determine whether the protein can be obtained in good yield in the soluble fraction (Fig. 6.6.5). When expressing fusion proteins at lower temperatures, the initial overnight culture can be grown at 37°C followed by growth at a lower temperature prior to induction.

EXPRESSION OF GLUTATHIONE-*S*-TRANSFERASE FUSION PROTEIN

BASIC PROTOCOL 1

Transformed *E. coli* cells expressing the glutathione-*S*-tranferase (GST) fusion protein of interest are grown in culture in the presence of isopropyl-1-thio-β-D-galactopyranoside (IPTG) at the desired preparative scale. Since the expression level of GST fusion proteins is usually very high, adequate amounts of protein can usually be conveniently obtained by preparing a few liters of cells grown in shaker cultures. This protocol describes the preparation of 1.8 liters of transfected *E. coli* in three 600-ml units using 2-liter flasks in a shaker incubator. Moderate further scale-up is feasible by using more or larger flasks.

BOSTON UNIVERSITY LIBRARY

Further scale-up can be accomplished using a fermentor (see *UNITS 5.3 & 5.4*). This protocol describes protein production in cells grown at 37°C. At this temperature, however, some fusion proteins may be recovered from inclusion bodies in a denatured form, and culture conditions may need to be modified to improve protein yield in the soluble fraction (see Strategic Planning).

Culture growth can be monitored by reading the optical density at 550 nm (OD_{550}) as well as by analysis of the bacterial culture using SDS-PAGE. Cells should not be allowed to grow for extended periods of time after induction as cell lysis can occur; this releases proteases that may degrade the fusion protein. Visual inspection of the cells using a microscope is a useful method for identifying cell breakage (see *UNITS 5.1-5.3 & 6.1-6.5* for additional details concerning recombinant protein expression in *E. coli*).

Materials

Luria broth (LB medium; *UNIT 5.2*; pH adjusted to 7.2)
5 mg/ml ampicillin (see recipe)
Glycerol culture of transformed *E. coli* cells expressing GST fusion protein of interest in a pGEX vector
100 mM isopropyl-1-thio-β-D-galactopyranoside (IPTG; see recipe)

2-liter culture flasks
500-ml culture flasks
Large centrifuge bottles (e.g., 1-liter capacity)
Low-speed refrigerated centrifuge (e.g., Beckman J6-B and JS-4.2 rotor or equivalent), 4°C

Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 10.1*)

Grow bacterial cells

1. Prepare LB medium and add 600 ml to each of three 2-liter flasks and 100 ml to each of two 500-ml flasks. Autoclave 20 to 30 min at a slow exhaust (liquid) setting.

   Flasks should be filled to only 20% to 30% of their capacity to ensure adequate aeration of the medium during cell growth. Autoclave LB medium immediately after preparing it to prevent any incidental bacterial growth from occurring. It can then be stored up to 1 month at room temperature under sterile conditions.

2. Allow medium to cool to room temperature. Add 1 ml of 5 mg/ml ampicillin to one flask containing 100 ml LB medium.

   It is important to allow medium to cool before proceeding, because ampicillin is inactivated at temperatures >50°C. Flame the opening of all bottles and flasks to reduce the risk of contamination.

3. Using an inoculating loop, transfer some of the glycerol culture containing the transfected *E. coli* expressing the GST fusion protein of interest to the flask containing 100 ml LB medium with ampicillin.

   Sterile flame the inoculating loop as well as the opening of all bottles. Allow the loop to cool before transferring the inoculating culture. If the loop temperature is too high, all the cells could be killed during the transfer.

4. Incubate the inoculated culture on an environmental shaker set at 250 to 300 rpm overnight at 37°C.

5. The next morning, remove the culture from the shaker and read the optical density at 550 nm (OD_{550}) using a UV/visible light spectrophotometer.

   The OD_{550} of the overnight culture should be ~1.0. Use medium from the second 500-ml flask that did not receive ampicillin as a reference to zero the spectrophotometer.

ECU IASHC CENTRAL UNIVERSITY LIBRARY

6. Using sterile technique, add 6 ml of 5 mg/ml ampicillin to each 2-liter flask containing 600 ml LB medium (0.1 mM final concentration).

7. Dilute the overnight culture 1:20 by adding 30 ml to each of the three 2-liter flasks containing 600 ml LB medium.

8. Incubate the 600-ml cultures on a shaker at 37°C at 250 to 300 rpm until the OD_{550} is 0.5 to 0.7.

It should take ~2 hr for the culture to reach this early log stage of growth at 37°C. If cells are grown at lower temperatures to shift the expressed protein from inclusion bodies into the soluble fraction, this time must be increased, since the cells will grow more slowly at lower temperatures.

Induce expression of fusion protein

9. Remove a 1-ml sample from each flask and save for gel analysis. Induce cells by adding 6 ml of 100 mM IPTG per flask (1.0 mM final). Incubate at 37°C for an additional 2.5 to 3 hr.

Optimal growth conditions (OD_{550} at time of induction, growth temperature, and growth time after induction) for each recombinant protein should be empirically determined. The conditions given here will generally be suitable for growth at either 37° or 30°C. At lower temperatures (≤25°C), longer growth times will definitely be needed, and the best protein yields will usually be obtained if the OD_{550} prior to induction is 0.65 to 0.85.

10. Remove cultures from the shaker 2.5 to 3 hr after induction. Remove 1 ml from each culture and save for gel analysis. Check final OD_{550}.

Culture growth can be monitored at OD_{550}. When the cells reach saturation, they will stop dividing. A typical SDS-PAGE gel of an uninduced control culture and an induced culture after 3 hr growth is shown in Figure 6.6.4.

Recover bacterial cells

11. Pour each culture into a large centrifuge bottle and centrifuge 20 min at 4000 × *g*, 4°C.

Medium from the second 500-ml flask without ampicillin can be used to balance the centrifuge bottles.

12. Carefully decant the supernatant, leaving 15 to 50 ml in the centrifuge bottle. Resuspend the pelleted cells in the remaining supernatant. Transfer the cell suspension to a 50-ml centrifuge tube.

13. Centrifuge 20 min at 4000 × *g*, 4°C. Decant the supernatant.

14. Freeze cell pellet by placing in a –80°C freezer.

15. Analyze saved 1-ml samples from before and after induction using SDS-PAGE (*UNIT 10.1*) to check for protein expression.

As noted above, a 1-ml aliquot of culture is removed prior to induction and a second 1-ml sample is removed after the 3-hr induction. These aliquots can be centrifuged for 2 min and the supernatants carefully removed with a pipet. These samples can be stored at 0° to 4°C overnight prior to running a gel; for longer-term storage prior to gel analysis, store frozen (–20°C) to prevent proteolysis. The cell pellet can be directly resuspended in SDS sample buffer (200 µl) and heated 3 to 5 min at 90°C. Typical results are shown in Figure 6.6.4.

BCU LASCI CENTRAL UNIVERSITY LIBRARY

AFFINITY CHROMATOGRAPHY PURIFICATION OF A SOLUBLE GST FUSION PROTEIN

Soluble glutathione-*S*-transferase (GST) fusion proteins can easily be purified from cell lysate supernatants by affinity chromatography on glutathione–Sepharose 4B using either batch or column loading of the sample. Protease inhibitors should be added to the lysis buffer to minimize potential proteolysis. As an aid for cell lysis, 1% (v/v) Triton X-100 may be added to the lysis buffer. After cells are lysed, centrifugation is used to pellet any unlysed cells and inclusion bodies. Location of the fusion protein can usually easily be determined by analyzing a small aliquot of both the supernatant and the pellet by SDS-PAGE (*UNIT 10.1*). The glutathione–Sepharose 4B can be regenerated and reused for subsequent purifications. To avoid potential cross-contamination of different proteins or mutant forms of a single protein, however, it is recommended that a given column or batch of resin be reserved for use with a single protein. Preequilibration of the glutathione column (steps 1 to 4) can be performed either prior to or in parallel with cell lysis. All steps except SDS-PAGE (room temperature) should be performed in a cold room at 4°C, unless otherwise noted.

Materials

Glutathione–Sepharose 4B resin (Pharmacia Biotech)
PBS (*APPENDIX 2E*)
Glutathione buffer (see recipe)
PBS/EDTA/PMSF buffer (see recipe)
Pelleted *E. coli* culture expressing fusion protein (see Basic Protocol 1, step 14)
Lysis buffer (see recipe), ice cold
Wash buffer (see recipe), ice cold
PBS/EDTA (see recipe)

2.5 × 8–cm glutathione–Sepharose 4B column (e.g., Bio-Rad Econo)
Peristaltic pump
Sonicator equipped with microtip probe (e.g., Branson)
Dounce homogenizer
60-ml centrifuge bottles (capable of handling force of 48,000 × *g*)
High-speed refrigerated centrifuge (e.g., Beckman JZ-21M centrifuge and JA-18 rotor or equivalent), 4°C

Additional reagents and equipment for pouring chromatographic columns (*UNIT 8.3*) and for SDS-PAGE (*UNIT 10.1*)

Preequilibrate glutathione column

1. Pour 20 ml glutathione–Sepharose 4B resin into 2.5 × 8–cm column (glutathione column; see *UNIT 8.3* for details of pouring procedure).

   This amount of resin should be adequate for purification of fusion protein from three 600-ml cultures that contain ~20 to 40 mg fusion protein per culture. Although glutathione–Sepharose 4B has an advertised minimum binding capacity of 8 mg/ml resin, the actual capacity may be substantially different and should be empirically determined. The actual amount of resin used and column size can be increased or decreased depending on the amount of fusion protein to be purified.

2. Wash the glutathione column with 5 to 10 bed volumes PBS at a flow rate of 1.5 ml/min to remove the ethanol storage solution.

   A bed volume is one-half the amount of glutathione–Sepharose 4B that was added to the column as a 50% slurry.

DCU IASC CENTRAL UNIVERSITY LIBRARY

New columns should be prepared as described in steps 1 to 4. Previously used columns should be preequilibrated using steps 3 to 4 only, to ensure that the column is completely reduced and has maximal binding capacity.

Use of a peristaltic pump is recommended for convenient control of flow rates. Compression of the resin bed indicates that the column pressure is too high and that the flow rate should be lowered.

3. Wash the glutathione column with 3 to 5 bed volumes glutathione buffer at 1.5 ml/min.

Previously used columns may become partially oxidized on storage and should be preequilibrated (steps 3 to 4) within 24 hr before use.

4. Wash the glutathione column with 10 bed volumes PBS/EDTA/PMSF at 1.5 ml/min.

Lyse cells

5. Resuspend each pelleted 600-ml culture in 15 ml ice-cold lysis buffer.

Pellets should be resuspended in 25 to 50 µl buffer per milliliter of culture.

6. Sonicate the suspension using a probe-tip sonicator ten times for 10 sec each, with 1-min rests between sonications to lyse the cells. Save a sample (~100 µl) of the lysate for gel analysis and transfer remainder to a 60-ml centrifuge tube.

The cells are usually adequately lysed at the point when the suspension turns a slightly darker color and becomes clearer. To minimize proteolysis in the sample, it is essential to keep the cells on ice throughout the sonication procedure, and sonication should be performed in short bursts to minimize sample heating. Avoid excessive sonication, as this can lead to co-purification of E. coli host proteins along with the fusion protein of interest. Avoid frothing during sonication, which can denature the fusion protein.

7. Centrifuge the lysate 20 min at 48,000 × *g*, 4°C.

Unbroken cells, large cellular debris, and inclusion-body protein will be pelleted.

8. Decant the supernatant containing the soluble fusion protein into a clean 50-ml centrifuge tube.

9. Add a volume of ice-cold wash buffer equal to the volume of lysis buffer used in step 5 to the pellet. Use a dounce homogenizer to resuspend the pellet.

Pellets should be resuspended in 25 to 50 µl buffer per milliliter of culture.

10. Analyze the lysate, supernatant, and resuspended pellet using SDS-PAGE (*UNIT 10.1*) to verify that the fusion protein is in the supernatant.

If the fusion protein is in the supernatant, proceed to the next step. If the protein is in the pellet, it is necessary to purify the GST fusion proteins from inclusion bodies (see Alternate Protocol 2) or to start over, shifting the protein into the supernatant by growing the cultures at a lower temperature (see Troubleshooting and Fig. 6.6.5).

Load the column

11. Load the supernatant onto a preequilibrated glutathione column (see step 4). Collect fractions and analyze multiple fractions across the unbound peak by SDS-PAGE (*UNIT 10.1*) to verify that the fusion protein has bound and that column capacity was not exceeded.

For a 2.5-cm diameter column, a sample-loading flow rate of ≤0.1 ml/min is recommended to permit complete binding of the fusion protein to the resin. Faster flow rates may decrease the yield of bound fusion protein due to slow kinetics of association at 4°C, unless a large excess of resin is used. This step is most conveniently performed overnight; the flow rate

B. C. U. „M. Eminescu" IAŞI
CHIMIE

BCU IASI CENTRAL UNIVERSITY LIBRARY

can be adjusted so that most of the supernatant will be loaded by the next morning. Do not allow the column to run dry.

SDS-PAGE analysis of fractions collected during sample loading will reveal whether the fusion protein is bound to the column or is present in the unbound fractions. Absence of fusion protein in early unbound fractions combined with its appearance in late unbound fractions indicates that column capacity has been exceeded. If this condition is observed, reduce the protein load or increase the column size.

12. Wash the column with 5 to 10 bed volumes PBS/EDTA/PMSF at 1.5 ml/min.

13. Wash the column with 10 bed volumes PBS/EDTA at 1.5 ml/min to remove the PMSF.

If samples are to be cleaved with thrombin or factor Xa, any serine protease inhibitor (e.g., PMSF) must be removed from the sample before cleavage.

Elute the fusion protein

14. Elute the fusion protein from the column by washing the column with 5 bed volumes glutathione buffer.

A flow rate of 0.3 ml/min for a 2.5-cm column is recommended to elute the fusion protein in a minimal volume. Elution of the fusion protein can be monitored at A_{280} either with an online UV monitor or by reading the absorption of individual fractions.

15. Analyze the fractions by SDS-PAGE (*UNIT 10.1*) and pool fractions containing the GST fusion protein. Store at 0° to 4°C.

Fusion protein should typically be >90% pure at this point.

ALTERNATE PROTOCOL 1

AFFINITY CHROMATOGRAPHY PURIFICATION OF GST FUSION PROTEIN FROM INCLUSION BODIES

In some cases, fusion proteins are entirely or primarily located in a denatured, aggregated form in inclusion bodies. Glutathione-*S*-transferase (GST) fusion proteins can often be purified from inclusion bodies after solubilization in urea or another denaturant followed by renaturation by dialysis (*UNIT 6.3*). Other methods of solubilization include addition of detergents such as Sarkosyl (*N*-laurylsarosine; Grieco et al., 1992; Frangioni, 1992). After denaturation and renaturation, it is important to ensure that the protein has regained its native conformation and function (*UNITS 6.4 & 6.5*). Although denatured GST will not bind to the glutathione column and hence will not be recovered by this method, the possibility that the GST moiety has refolded when the fusion partner has not folded properly should also be considered. As an alternative to purifying proteins from inclusion bodies, growing the cells at a lower temperature will often shift the fusion protein into the supernatant while still producing ≥10 mg of fusion protein per liter of culture when pGEX vectors are used (see Strategic Planning and see Troubleshooting). All steps should be performed in a cold room at 4°C unless otherwise noted.

Additional Materials (also see Basic Protocol 2)

U buffer (see recipe)
Triton X-100
PBS/glycerol buffer (see recipe)
Low-speed refrigerated centrifuge (e.g., Beckman J6-B and JS-4.2 rotor or equivalent), 4°C

Additional reagents and equipment for dialysis (*APPENDIX 3B*)

1. Preequilibrate the glutathione column, lyse the cells, and separate the lysate pellet, which includes the inclusion bodies, and supernatant (see Basic Protocol 2, steps 1 to 9).

DCU IASC CENTRAL UNIVERSITY LIBRARY

2. Centrifuge washed pellet (see Basic Protocol 2, step 9) 20 min at 48,000 × *g*, 4°C. Decant the supernatant and resuspend the pellet in 12 ml freshly prepared U buffer per 600 ml original culture. Incubate 2 hr on ice.

   Pellets should be resuspended in 20 µl U buffer per ml of culture.

3. Centrifuge 20 min at 48,000 × *g*, 4°C. Carefully transfer the supernatant to a clean 50-ml centrifuge tube.

   The extracted fusion protein should now be in the supernatant.

4. Add Triton X-100 to the supernatant to give a final concentration of 1% (v/v).

5. Dialyze the sample (*APPENDIX 3B*) 2 to 3 hr in PBS/glycerol buffer.

   Dialysis buffer volume should be 20 times the sample volume.

6. Dialyze sample overnight in PBS/EDTA/PMSF.

   Dialysis buffer volume should be >100 times the sample volume.

7. Remove the sample from the dialysis bag and centrifuge 20 min at 4000 × *g*, 4°C.

8. Column purify the fusion protein (see Basic Protocol 2, steps 11 to 15).

BATCH PURIFICATION OF GST FUSION PROTEIN

ALTERNATE PROTOCOL 2

Soluble glutathione-*S*-transferase (GST) fusion proteins in cell lysate supernatants or renatured proteins extracted from inclusion bodies can be batch purified on glutathione–Sepharose 4B as an alternative to column-based purification (see Basic Protocol 2 and see Alternate Protocol 1). Batch purification requires less equipment and is relatively quick and easy, but resulting protein yield and sample purity are lower than in a chromatographic separation. In addition, the room temperature incubations recommended by the resin manufacturer (Pharmacia Biotech), especially the batch incubation of *E. coli* lysate supernatant or inclusion body extract with glutathione-Sepharose, increase the risk of proteolytic degradation of the fusion protein.

Prepare fusion protein

1. Extract soluble fusion proteins (see Basic Protocol 2, steps 5 to 10).

   If the fusion protein is in inclusion bodies, lyse the cells and collect the pellet (Basic Protocol 2, steps 5 to 9, followed by Alternate Protocol 1, steps 2 to 7).

Prepare resin slurry

2. Prepare a 50% slurry of glutathione–Sepharose 4B in PBS: For each milliliter of bed volume, centrifuge 1.33 ml of a 75% slurry of glutathione–Sepharose 4B for 5 min at 500 × *g*, room temperature. Discard the supernatant. Wash with 10 bed volumes PBS. Invert tube containing resin several times to mix, then centrifuge 5 min at 500 × *g*, room temperature, and remove supernatant. Add 1 ml PBS for each 1.33 ml of original slurry. Mix well before using.

Bind fusion protein to resin

3. Add 2 ml of 50% slurry of equilibrated glutathione-Sepharose to each 100 ml bacterial lysate supernatant. Incubate 30 min at room temperature with gentle agitation on a platform or orbital shaker.

4. Centrifuge the suspension 5 min at 500 × *g*, room temperature. Remove supernatant and save at 0° to 4°C for later analysis by SDS-PAGE (*UNIT 10.1*) to determine the efficiency of binding of the fusion protein to the resin.

BCU ASTON CENTRAL UNIVERSITY LIBRARY

5. Wash the pellet with 10 bed vol PBS.

   A bed volume is one-half the volume of the 50% slurry that was added to the column.

6. Centrifuge the suspension 5 min at 500 × *g*, room temperature. Discard the supernatant.

7. Repeat the wash and centrifugation steps for a total of three washes with 10 bed volumes each of PBS.

Elute fusion protein

8. Elute the bound fusion protein by gently resuspending the sedimented resin in 1.0 ml glutathione buffer per milliliter resin bed volume. Incubate 10 min at room temperature with gentle agitation.

9. Centrifuge the suspension 5 min at 500 × *g*, room temperature. Transfer supernatant to a separate tube.

10. Repeat the elution and centrifugation (steps 8 to 9) a total of three times. Store at 0° and 4°C.

    The supernatants may be pooled into one tube or analyzed separately by SDS-PAGE (UNIT 10.1) to monitor for fusion protein content.

    The yield of fusion protein can be monitored by measuring the absorbance at 280 nm (A_{280}). The extinction coefficient will partially depend on the absorbance characteristics of the experimental component of the fusion protein. For the GST moiety alone, the concentration can be estimated using 1 A_{280} = ~0.6 mg/ml protein.

    As noted above, batch purification at room temperature increases the risk of proteolytic digestion of the target protein. To minimize such degradation, this procedure can alternatively be performed in a cold room at 4°C with incubation times in steps 3 and 8 increased 2- to 4-fold.

BASIC PROTOCOL 3

PROTEASE CLEAVAGE OF FUSION PROTEIN IN SOLUTION TO REMOVE GST AFFINITY TAG

The glutathione-*S*-transferase (GST) affinity tag is removed by cleaving with thrombin (pGEX-T vectors) or factor Xa (pGEX-X vectors). Conditions for optimal cleavage of each recombinant fusion protein must be empirically determined. Some of the parameters that can be varied include temperature, enzyme-to-substrate ratio, length of incubation, and buffer conditions. Proteolysis can usually be performed in the glutathione buffer used to elute the fusion protein from the column, either with or without addition of NaCl or Ca^{2+}. After proteolysis, the glutathione must be removed by dialysis prior to rechromatography on the glutathione column to separate the cleaved target protein from the GST moiety and uncleaved fusion protein.

Materials

Solution of affinity-purified fusion protein (see Basic Protocol 2, step 15, or Alternate Protocol 2, step 10)
Thrombin (Sigma) reconstituted in water at 0.5 U/µl or 1 µg/µl factor Xa (Boehringer Mannheim)
0.15 M PMSF in isopropanol
PBS/EDTA/PMSF buffer (see recipe)
Beckman J6-B centrifuge and JS-4.2 rotor (or equivalent), 4°C
Additional reagents and equipment for dialysis (*APPENDIX 3B*) and SDS-PAGE (*UNIT 10.1*)

ECU IAS / CENTRAL UNIVERSITY LIBRARY

1. To the solution of affinity-purified fusion protein, add an appropriate amount of thrombin (when using pGEX-T vectors) or factor Xa (when using pGEX-X vectors) per microgram of purified fusion protein and digest protein 2 to 8 hr in a shaking water bath at 37°C (thrombin) or 25°C (factor Xa).

   The appropriate amount of enzyme must first be empirically determined for each fusion protein by surveying a range of conditions in a pilot analytical proteolysis experiment. A convenient method is to digest 100 µg fusion protein per condition over a range of enzyme-to-substrate ratios and for differing incubation times. Typical digestion times range from 2 to 8 hr and typical enzyme-to-substrate-ratios are 1:100, 1:350, 1:1000, and 1:3000 (in units of enzyme per microgram fusion protein) at 37°C for bovine plasma thrombin, or 1:10, 1:25, 1:50, 1:100, 1:300 (microgram enzyme per microgram fusion protein) at 25°C for bovine plasma factor Xa. At the desired times, proteolysis is stopped by adding an aliquot of the sample to boiling SDS sample buffer, and samples are analyzed on an SDS minigel (UNIT 10.1; 2 µg/lane) to determine the best digestion conditions. If digestion is incomplete at the highest enzyme-to-substrate ratio tested with digestion times of 6 to 8 hr, consider reengineering the protease cleavage site by introducing a linker between the GST moiety and target polypeptide to decrease steric hindrance. In some cases, >10-fold improvement in cleavage efficiency can be achieved by adding as few as two glycines next to the thrombin site. The SDS gel in Figure 6.6.6 shows a typical thrombin digestion optimization experiment where the amount of enzyme has been varied.

2. Stop preparative digestion by adding a 1:500 dilution of 0.15 M PMSF stock solution. Incubate sample an additional 15 min at 37°C for thrombin or 30 min at 25°C for factor Xa to covalently inhibit the enzyme with the PMSF.

3. Dialyze the sample (APPENDIX 3B) twice versus 2 liters PBS/EDTA/PMSF for a minimum of 4 hr per buffer change at 4°C.

   Complete removal of glutathione is important if samples are to be rechromatographed on glutathione-Sepharose to remove the GST moiety and uncleaved fusion protein. Larger volumes of dialysate may be necessary depending on sample volume: e.g., if the sample volume is >40 ml, increase the dialysis buffer volume to 4 liters per change or use three changes of buffer. In addition, since glutathione equilibrates slowly during dialysis, when

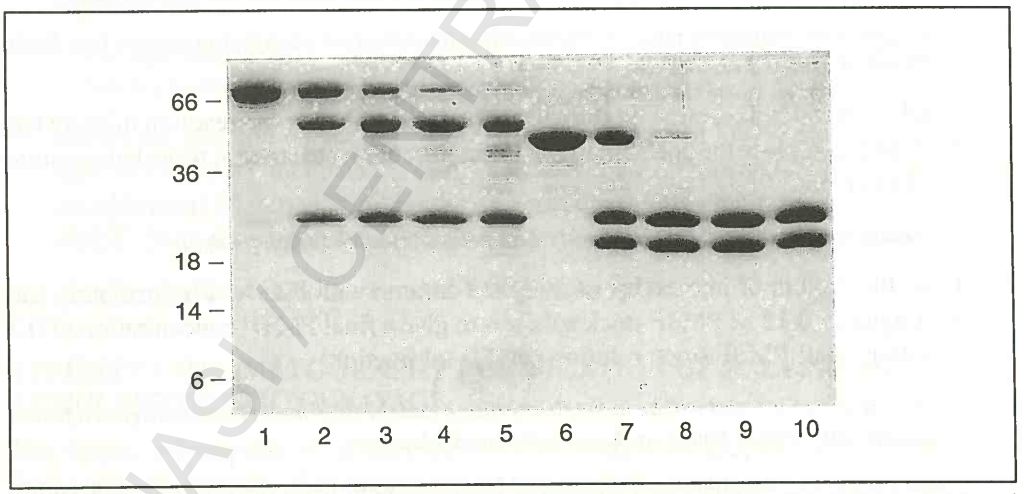

Figure 6.6.6 SDS gel stained with Coomassie brilliant blue showing pilot thrombin digestions of two recombinant glutathione-*S*-transferase (GST) fusion proteins. Samples were digested 3 hr at 37°C in buffer with varying enzyme-to-substrate ratios. Lane 1, a 78-kDa fusion protein. Lanes 2 to 5, thrombin digestion of the 78-kDa fusion protein using enzyme-to-substrate ratios of 1:3000, 1:1000, 1:350 and 1:100, respectively. Lane 6, a 45-kDa fusion protein. Lanes 7 to 10, thrombin digestion of the 45-kDa fusion protein using substrate ratios of 1:3000, 1:1000, 1:350, and 1:100, respectively. In each case, an enzyme-to-substrate ratio of 1:1000 was chosen as the optimal digestion condition

PGDIASI / CENTRAL UNIVERSITY LIBRARY

dialysis tubing with a MWCO <12,000 is used, the dialysis conditions should be increased to at least three changes with 2 liters dialysis buffer per change.

4. Centrifuge the dialyzed sample 20 min at 4000 × *g*, 4°C, to remove any precipitated material. Transfer the supernatant to a clean tube at 0° to 4°C and analyze by SDS-PAGE (*UNIT 10.1*).

The cleaved protein of interest can be separated from the GST moiety and uncleaved fusion protein by rechromatographing it on the glutathione column (see Support Protocol 1).

ALTERNATE PROTOCOL 3

PROTEASE CLEAVAGE OF FUSION PROTEIN BOUND TO A GLUTATHIONE-SEPHAROSE COLUMN

The target polypeptide can be cleaved from the glutathione-*S*-transferase (GST) moiety while the fusion protein is immobilized on the affinity matrix as described by Gearing et al. (1989). The fusion protein is loaded onto the glutathione column after cell lysis in the normal manner. Rather than elute the fusion protein with glutathione buffer, a solution of thrombin (or factor Xa) is loaded onto the column and allowed to incubate at room temperature for several hours. The cleaved protein is then eluted from the column by washing with PBS. This method is much faster and can yield higher purity products than batch protease digestions and in some cases, secondary cleavages can be avoided or minimized using the on-column method. Disadvantages of this method include much less effective protease cleavage, much lower final polypeptide yields, decreased control of digestion conditions, and inability to easily monitor the extent of cleavage using on column digestion.

Additional Materials (also see Basic Protocol 3)

PBS (*APPENDIX 2E*)
Glutathione–Sepharose 4B column containing bound fusion protein (see Basic Protocol 2, step 13)
Glutathione buffer (see recipe)

1. For each milliliter of glutathione–Sepharose 4B column containing bound fusion protein, dilute desired amount of reconstituted thrombin to 1.0 ml using PBS.

Enzyme concentrations must be empirically determined for each fusion protein (see Basic Protocol 3, step 1 annotation).

2. Load the thrombin reaction mixture onto the column. When the reaction mixture has been added, replace the bottom cap and allow the column to stand at room temperature for 2 to 16 hr.

Incubation times must be empirically determined for each fusion protein.

3. Elute the protein of interest by washing the column with PBS and immediately add an aliquot of 0.15 M PMSF stock solution to give a final PMSF concentration of 0.3 mM (e.g., 6 µl PMSF stock solution per 3.0-ml fraction).

The protein of interest will be in the flowthrough and the GST moiety and undigested fusion protein will remain bound to the glutathione-Sepharose.

4. Remove the GST moiety and uncleaved fusion protein from the column by washing with 5 bed volumes glutathione buffer at 0.3 ml/min.

5. Immediately after collecting fractions, store all fractions at 0° to 4°C.

6. Evaluate unbound and bound peaks using SDS-PAGE (*UNIT 10.1*).

A large proportion of the fusion protein is usually not cleaved by this method.

ECU IASI CENTRAL UNIVERSITY LIBRARY

BATCH PROTEASE CLEAVAGE AND SEPARATION OF FUSION PROTEIN ON GLUTATHIONE RESIN

ALTERNATE PROTOCOL 4

As a subsequent step to batch purification of soluble glutathione-*S*-transferase (GST) fusion proteins (see Alternate Protocol 2), the GST affinity tag can be cleaved from the protein of interest using thrombin (pGEX-2T) or factor Xa (pGEX-3X) before elution from the glutathione–Sepharose 4B resin in a manner analogous to the on-column cleavage described in Alternate Protocol 3. In this protocol, the fusion protein on the glutathione-Sepharose resin is incubated in the presence of protease, and the cleaved protein is released into the supernatant and collected by centrifugation.

Additional Materials (also see Basic Protocol 3)

Glutathione–Sepharose 4B resin with bound fusion protein (see Alternate Protocol 2, step 7)
PBS (*APPENDIX 2E*)

1. For each milliliter of glutathione–Sepharose 4B resin with bound fusion protein, dilute the desired amount of reconstituted thrombin to 1.0 ml with PBS.

   Enzyme concentrations must be empirically determined for each fusion protein (see Basic Protocol 3, step 1 annotation).

2. Add the reconstituted thrombin reaction mixture to the pelleted glutathione-Sepharose resin containing the bound fusion protein (from Alternate Protocol 2, step 7).

3. Gently resuspend the glutathione-Sepharose and agitate on an orbital shaker 2 to 16 hr at room temperature.

   Incubation times must be empirically determined for each fusion protein.

   Cleavage may be monitored by removing an aliquot of the slurry from the incubation mixture at different time points, centrifuging the slurry to separate the resin and supernatant, and analyzing the fractions by SDS-PAGE (UNIT 10.1).

4. Centrifuge the slurry 5 min at 500 × *g*, room temperature. Transfer supernatant to a separate tube.

   The supernatant will contain the protein of interest, while the GST moiety and uncleaved fusion protein will remain bound to the resin.

5. Inhibit the reaction by adding a 1:500 dilution of 0.15 M PMSF stock solution (0.3 mM PMSF final). Incubate the sample an additional 15 min at 37°C for thrombin or an additional 30 min at 25°C for factor Xa to covalently inhibit the enzyme with the PMSF. Store the samples at 0° to 4°C.

6. Analyze the final fractions by SDS-PAGE (*UNIT 10.1*).

AFFINITY CHROMATOGRAPHY PURIFICATION OF POLYPEPTIDES AFTER ENZYMATIC CLEAVAGE

SUPPORT PROTOCOL 1

The target polypeptide is affinity purified by rechromatography on a glutathione–Sepharose 4B column after enzymatic cleavage of the fusion protein and dialysis to remove glutathione present in the buffer from the initial column eluate. Uncleaved fusion protein and the glutathione-*S*-transferase (GST) moiety both bind to the column, and the protein of interest is in the column flowthrough. All steps should be performed in a cold room at 4°C unless otherwise indicated.

BOSTON / CENTRAL UNIVERSITY LIBRARY

Materials

Solution of fusion protein that has been cleaved with thrombin or factor Xa and dialyzed into PBS/EDTA/PMSF buffer (see Basic Protocol 3, step 4)
Glutathione buffer (see recipe)
PBS/EDTA/PMSF buffer (see recipe)
2.5 × 8–cm glutathione–Sepharose 4B column (e.g., Bio-Rad Econo)

Additional reagents and equipment for SDS-PAGE (*UNIT 10.1*)

1. Wash the glutathione–Sepharose 4B column with >3 bed volumes glutathione buffer at 1.5 ml/min.

   A bed volume is one-half the amount of glutathione-Sepharose that was added to the column.

   The same 2.5 × 8–cm column used for initial purification of a given fusion protein can be used for repurification of the same target polypeptide after protease cleavage. Glutathione-Sepharose must be fully reduced in order for the GST moiety to bind efficiently. If the column was washed with glutathione buffer <48 hr before, this step may be skipped.

2. Wash the glutathione column with 10 bed vol PBS/EDTA/PMSF at 1.5 ml/min.

3. Load the solution of fusion protein that has been cleaved onto the column using a flow rate of 0.1 ml/min. Collect fractions for later analysis by SDS-PAGE (*UNIT 10.1*) and store at 0° to 4° C.

   The protein of interest will be in the unbound or column flowthrough peak, and the GST moiety will bind to the glutathione-Sepharose. A low flow rate for sample application, such as 0.1 ml/min, should be used to ensure complete binding of GST to the column. Faster flow rates are likely to result in elution of excessive amounts of the GST moiety in the unbound fraction.

4. Wash the column with 2 to 3 bed volumes PBS/EDTA/PMSF at 1.5 ml/min.

5. Elute the bound GST moiety from the resin by washing with 5 bed volumes glutathione buffer at 0.3 ml/min.

6. Analyze bound and unbound peaks by SDS-PAGE (*UNIT 10.1*), pool the fractions containing the cleaved target polypeptide, and store at 0° to 4°C.

SUPPORT PROTOCOL 2

FURTHER PURIFICATION OF CLEAVED RECOMBINANT PROTEIN USING HPLC GEL FILTRATION

Cleaved proteins after rechromatography on glutathione columns (see Support Protocol 1) or eluted after on-column protease cleavage (see Alternate Protocol 3) contain the inactivated protease used to cleave the protein. These samples also typically contain small amounts of aggregates, a small amount of glutathione-*S*-transferase (GST) moiety that did not rebind to the column, and possibly other minor contaminants, including proteolytic cleavage products or host cell proteins. Although the protein is typically ~90% pure at this stage, a further purification step may be desirable for many applications. HPLC gel filtration is a fairly rapid high-resolution purification step that usually separates properly folded polypeptides from aggregates and incorrectly folded chains. Selection of appropriate matrices and column dimensions for particular applications is discussed in *UNIT 8.3*. Alternatively, ion-exchange chromatography (*UNIT 8.2*) can be used as a further purification strategy, either instead of or in addition to HPLC gel filtration. This protocol describes the HPLC gel filtration purification of cleaved polypeptides after rechromatography. All steps, including HPLC, should be performed at 4°C unless otherwise indicated.

ECU IAS / CENTRAL UNIVERSITY LIBRARY

Materials

Cleaved fusion protein (see Support Protocol 1, step 6, or Alternate Protocol 3, step 5)
PBS (*APPENDIX 2E*)

Centriprep concentrator with appropriate MWCO (Amicon)
Low-speed refrigerated centrifuge (e.g., Beckman J6-B and JS-4.2 rotor or equivalent, 4°C), *or* 0.22-µm low-protein-binding filter (Costar)
Gel-filtration columns (see *UNIT 8.3*)

Additional reagents and equipment for SDS-PAGE (*UNIT 10.1*)

1. Concentrate the unbound cleaved fusion protein using a Centriprep concentrator.

   Samples should be concentrated to a volume of no greater than 0.5% to 1% of the column volume to be used for the separation.

2. Centrifuge the concentrated sample 20 min at 4000 × *g*, 4°C. Remove the supernatant, being careful not to disturb any pellet that may have formed (precipitated material formed during concentration).

   Alternatively, a 0.22-µm low-protein-binding filter may be used to remove particulates. It is especially important to remove particulates to avoid clogging of the HPLC column end frits.

3. Inject the concentrated sample onto gel filtration column(s) equilibrated in PBS.
4. Monitor the absorbance at 280 nm (A_{280}) using an online HPLC detector and collect fractions.
5. Analyze the fractions by SDS-PAGE (*UNIT 10.1*) to determine fractions of interest and to evaluate the purity of the target polypeptide, which should be in the major peak.
6. Pool the desired fractions and store at 0° to 4°C.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or its equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Ampicillin, 5 mg/ml

500 mg ampicillin
100 ml H_2O
Filter sterilize using 0.22-µm filter
Store up to several months at 4°C

Do not autoclave the solution; ampicillin is inactivated above 50°C.

Glutathione buffer

50 mM Tris base
10 mM reduced glutathione (Sigma)
Adjust pH to 8.0 with 6 M HCl
Bring to final volume with cold H_2O
Prepare fresh daily and store at 4°C until needed

Isopropyl-1-thio-β-D-galactopyranoside (IPTG), 100 mM

1 g IPTG
42 ml sterile H_2O
Divide into 6-ml aliquots in sterile tubes
Store up to 1 year at –20°C

BCU IALH / CENTRAL UNIVERSITY LIBRARY

Lysis buffer

50 mM NaCl
50 mM Tris base
5 mM EDTA
1 µg/ml leupeptin
1 µg/ml pepstatin
0.15 mM phenylmethylsulfonyl fluoride (PMSF) in isopropanol
1 mM diisopropyl fluorophosphate (DFP)
Adjust pH to 8.0 with 6 M HCl
Bring to final volume with cold H_2O
Prepare fresh daily

CAUTION: *DFP is a dangerous neurotoxin. Handle the neat reagent with double gloves in a chemical fume hood only. Carefully follow all precautions supplied by the manufacturer for this chemical.*

PBS/EDTA

1× PBS (*APPENDIX 2E*)
5 mM EDTA
Adjust pH to 7.4 with 1 M NaOH
Bring to final volume with cold H_2O
Store up to 1 month at 4°C

PBS/EDTA/PMSF buffer

1× PBS (*APPENDIX 2E*)
5 mM EDTA
0.15 mM phenylmethylsulfonyl fluoride (PMSF) in isopropanol
Adjust pH to 7.4 with 1 M NaOH
Bring to final volume with cold H_2O
Store up to 1 week at 4°C

PBS/glycerol buffer

1× PBS (*APPENDIX 2E*)
20% (v/v) glycerol
1% (v/v) Triton X-100
5 mM 2-mercaptoethanol (2-ME)
5 mM EDTA
0.1 µg/ml leupeptin
0.1 µg/ml pepstatin
0.15 mM phenylmethylsulfonyl fluoride (PMSF) in isopropanol
0.1 mM diisopropyl fluorophosphate (DFP)
Adjust pH to 7.4 with 1 M NaOH
Bring to final volume with cold H_2O
Prepare fresh daily

CAUTION: *DFP is a dangerous neurotoxin. Handle the neat reagent with double gloves in a chemical fume hood only. Carefully follow all precautions supplied by the manufacturer for this chemical.*

U buffer

5 M urea
50 mM Tris base
5 mM EDTA
5 mM 2-mercaptoethanol (2-ME)
1 µg/ml leupeptin
1 µg/ml pepstatin

continued

DCU IASL/CENTRAL UNIVERSITY LIBRARY

0.15 mM phenylmethylsulfonyl fluoride (PMSF) in isopropanol

Adjust pH to 8.0 with 6 M HCl
Bring to final volume with cold H_2O
Prepare fresh daily

COMMENTARY

Background Information

The pGEX vectors were designed for high-level, inducible, intracellular expression of glutathione-*S*-transferase (GST) fusion proteins produced in *Escherichia coli*. GST is a common 26-kDa protein of eukaryotes. The GST gene used in the development of the pGEX vectors was originally cloned from the parasitic helminth *Schistosoma japonicum* (Smith and Johnson, 1988).

Purification of fusion proteins from a whole-cell lysate is readily achieved through the strong affinity of the GST moiety for glutathione, which is immobilized on Sepharose beads. The fusion protein can be displaced under mild conditions from the glutathione-Sepharose beads using neutral-pH buffers containing free reduced glutathione.

The main advantages of this system are the very high level of fusion protein expression (often >10 to 50 mg/liter of *E. coli* culture grown on an environmental shaker) and the facile purification methods for both initial isolation and subsequent separation of cleaved polypeptide and GST moiety. Since nondenaturing purification conditions are employed, polypeptides that do not normally contain post-translational modifications usually retain their functional and antigenic properties. Other advantages of this system include availability of several alternative protease cleavage sites and the large number of bacterial hosts that can be used.

Purification of most soluble GST fusion proteins is straightforward, and success in the purification of insoluble products is determined largely by the ability to refold the fusion protein after extracting it from inclusion bodies. Since the GST moiety refolds fairly readily after urea solubilization, the presence of this moiety may facilitate refolding of the adjacent polypeptide. However, the high protein expression level of the vector, even at lower growth temperatures means that the preferred strategy for solubilizing proteins that are initially expressed in inclusion bodies is to attempt to grow the transfected cells at lower temperatures, where the protein often remains in the soluble fraction (see Fig. 6.6.5 and Troubleshooting). Difficulties with vector construction, protein expression, and protease cleavage may be greater when the molecular weight of the desired polypeptide is >100 kDa.

The GST moiety can usually be easily removed from the protein of interest by cleavage with thrombin or factor Xa. For some studies, such as some immunological or functional assays, removal of the GST moiety may not be required. An important consideration is that the GST moiety is a dimer; hence, steric hindrance effects and nonequivalence of functional sites on the associated fusion partner within this dimeric structure must be considered.

Troubleshooting

Contamination of the glutathione-*S*-transferase (GST) fusion protein after affinity purification with *E. coli* host cell proteins is usually an indication that sonication has been too severe. Other contaminants may represent de-

BOSTON UNIVERSITY LIBRARY

graded fragments of the fusion protein that might be eliminated by the addition of protease inhibitors and/or carefully keeping all samples, buffers, and sample tubes as cold as possible (i.e., keeping the materials at 0°C, on ice, often results in noticeably lower proteolysis than occurs where samples are kept at 4°C in a refrigerator). Degradation of fusion proteins during expression can sometimes be minimized by adding isopropyl-1-thio-β-D-galactopyranoside (IPTG) later in the bacterial culture growth with cells at higher OD at time of induction and by decreasing the duration of the induction period.

If the fusion protein does not completely bind to the glutathione-Sepharose resin, several options may be tried: increasing the quantity of glutathione-Sepharose, decreasing the protein loading flow rate, ensuring that the column is completely reduced by pretreating it with a freshly prepared glutathione buffer within 24 hr prior to using the column for purification, and ensuring that any denaturants or reducing reagents used to treat the sample have been completely removed through exhaustive dialysis.

Expression of GST fusion protein in inclusion bodies can be addressed in several ways. The preferred method is to lower the growth temperature from 37° to 30°, 25°, 20°, or 15°C. The optimal growth temperature is that temperature where >50% of the expressed protein is in the supernatant. This strategy is efficient even if the expressed fusion protein yield decreases somewhat at the lower growth temperatures. It is usually more time and cost effective to grow a larger quantity of cells than to attempt to renature fusion protein extracted from inclusion bodies since the latter method nearly doubles the time required to purify the fusion protein. In one study, when the authors' laboratory expressed eleven GST fusion proteins at 37°C, four proteins were primarily in inclusion bodies and the remaining seven proteins were partially in the supernatant, although a substantial amount of fusion protein was also in inclusion bodies. When these eleven fusion proteins were expressed at 30°C, ten were primarily (>80%) in the soluble fraction. The remaining recombinant protein was primarily in inclusion bodies at either 30° or 25°C, but could be switched to the soluble fraction and produced in high yield by growing the cells at 18°C, as shown in Figure 6.6.5. If lowering the growth temperature does not result in expression of a soluble protein, renaturing the protein after extracting inclusion bodies with a chaotropic reagent such as urea can be attempted (see Alternate Protocol 1). Finally, even when most of a protein is primarily in inclusion bodies, there may be enough protein in the soluble fraction that it can be purified in low milligram yields per liter of culture.

In some cases, using high enzyme-to-substrate ratios and prolonged incubation times is not sufficient to cleave the fusion protein in good yield. To minimize steric hindrance at the thrombin cleavage site, modified pGEX vectors that contain a glycine-rich, nine-amino-acid "kinker" region immediately before or after the thrombin cleavage site (Guan and Dixon, 1991; Hakes and Dixon, 1991) can be tried. Sometimes introduction of as few as one or two extra glycines immediately after to the thrombin site may substantially improve the rate of protease cleavage.

The probability that extraneous residues on the N-termini of cleaved polypeptides could significantly affect structural and functional properties of expressed polypeptides is very likely to increase as the length of the extraneous sequence increases. Hence, the number of extra residues remaining on the target polypeptide after protease cleavage should be minimized. Although thrombin cleavage is usually more cost effective than factor Xa cleavage, a minimum of two extra residues from the thrombin recognition site (GS) are left on the cleaved peptide. Although no residues from the factor Xa recognition site are left on the cleaved polypeptide, at least several extraneous amino acids are introduced onto the N-terminal of all pGEX-X vectors from the sequence remaining at the cloning site (see Figs. 6.6.2 and 6.6.3). Depending upon the pGEX vector and cloning site utilized, as few as two and as many as thirteen extra amino acids may remain on the cleaved N-terminal end of the target protein.

The yield of GST fusion proteins is typically quite high, i.e., 10 to 50 mg of fusion protein per liter of culture when cells are grown on an environmental shaker. When low protein expression does occur, it can often be improved by optimizing the bacterial culture growth conditions: for example, growing the cells to a somewhat higher OD_{550} at the time of induction, increasing the length of the induction period, using another strain of *E. coli* such as a protease-negative strain, or growing the cells at higher temperatures (although proteins are more likely to be in inclusion bodies at higher temperatures; see Background Information). Caution should be taken when using higher cell ODs and longer growth times after induction,

ECU IAS/CERIAS UNIVERSITY LIBRARY

since the cells may start to lyse under these conditions.

For additional information concerning GST fusion protein expression, Pharmacia Biotech publishes a reference list, bulletin number 18-1117-27, that classifies related publications into several useful categories to assist in troubleshooting a variety of parameters.

Anticipated Results

Yields of fusion protein can vary widely. Typical yields are 10 to 50 mg/liter, but can occasionally be much lower, especially if the fusion protein is toxic to the cells or is unstable. In some cases, >50 mg/liter can be obtained when expression conditions have been well optimized. A single-step affinity purification should yield fusion protein that is >90% pure in most cases. The relationship between yield of fusion protein and yield of cleaved, repurified recombinant target polypeptide is in part due to the mass of the target polypeptide. A good final yield of a cleaved protein after repurification on a glutathione column followed by HPLC gel filtration might be ~2 mg/liter for a 10-kDa protein and ~10 mg/liter for a 50-kDa protein.

Time Considerations

Protein expression takes 1.5 days of intermittent work requiring approximately 3 to 4 hr of operator time. Longer induction periods may be required at temperatures lower than 30°C, but total operator time remains the same. A small-scale batch purification can be completed in 1 day. A large-scale column purification, cleavage of fusion protein, and repurification of the cleaved peptide by affinity and gel filtration chromatography will take ~5 to 8 days of intermittent work requiring several hours of operator time per day. The purification should be completed in as short a time as practical to minimize proteolysis, aggregation, and precipitation of impure fractions.

Expression and Purification of Thioredoxin Fusion Proteins

This unit describes a gene fusion expression system that uses thioredoxin, the product of the *Escherichia coli trxA* gene, as the fusion partner. The system is particularly useful for high-level production of soluble fusion proteins in the *E. coli* cytoplasm; in many cases heterologous proteins produced as thioredoxin fusion proteins are correctly folded and display full biological activity. Although the thioredoxin gene fusion system is routinely used for protein production, high-level production of peptides—i.e., for use as antigens—is also possible because the prominent thioredoxin active-site loop is a very permissive site for the introduction of short amino acid sequences (10 to 30 residues in length). The inherent thermal stability of thioredoxin and its susceptibility to quantitative release from the *E. coli* cytoplasm by osmotic shock can also be exploited as useful tools for thioredoxin fusion protein purification. In addition, a more generic method for purification of any soluble thioredoxin fusion employs a modified form of thioredoxin (called "His-patch Trx"), which has been designed to bind to metal chelate resins. Protein fusions to His-patch Trx can usually be purified in a single step from cell lysates (see Strategic Planning).

The first step is construction of a fusion of *trxA* to any desired gene and expression of the fusion protein in an appropriate host strain at 37°C (see Basic Protocol). Additional protocols describe *E. coli* cell lysis using a French pressure cell and fractionation (see Support Protocol 1), osmotic release of thioredoxin fusion proteins from the *E. coli* cytoplasm (see Support Protocol 2), and heat treatment to purify some thioredoxin fusion proteins (see Support Protocol 3).

STRATEGIC PLANNING

The thioredoxin gene fusion expression vectors pTRXFUS and hpTRXFUS, both of which carry the *E. coli trxA* gene (Fig. 6.7.1), are used for high-level production of C-terminal fusions to thioredoxin. The vector hpTRXFUS differs from pTRXFUS in that it contains a modified *E. coli trxA* gene which produces a mutant protein ("His-patch" thioredoxin) that can specifically bind to metal chelate matrices charged with nickel or cobalt, otherwise known as native metal-chelate affinity chromatography (MCAC; *UNIT 9.4*). The *trxA* translation-termination codon has been replaced in both vectors by DNA encoding a ten-residue peptide linker sequence that includes an enterokinase (enteropeptidase; LaVallie et al., 1993a) cleavage site. This highly specific site can be cleaved with enterokinase following purification of the fusion protein to release the protein of interest from its thioredoxin fusion partner. Immediately downstream of the DNA encoding the enterokinase site in pTRXFUS and hpTRXFUS lies a DNA polylinker sequence containing a number of unique restriction endonuclease sites that can be used for forming in-frame translational fusions of any desired gene to *trxA*. Downstream of the DNA polylinker lies the *E. coli aspA* transcription terminator. Replication of these vectors is controlled by a modified colE1 replication origin similar to that found in pUC vectors (Norrander et al., 1983). Plasmid selection and maintenance is ensured by the presence of the β-lactamase gene on the vector. The vector pALtrxA-781 (Fig. 6.7.1) is very similar to pTRXFUS. However in this plasmid the *trxA* gene is followed by a translation termination codon, and the sequences encoding the enterokinase-site peptide linker are absent. A unique *Rsr*II site, present in both pALtrxA-781 and pTRXFUS, allows for the easy insertion of short peptide-encoding DNA sequences into *trxA* within the region that encodes the active-site loop.

BRADFORD UNIVERSITY LIBRARY

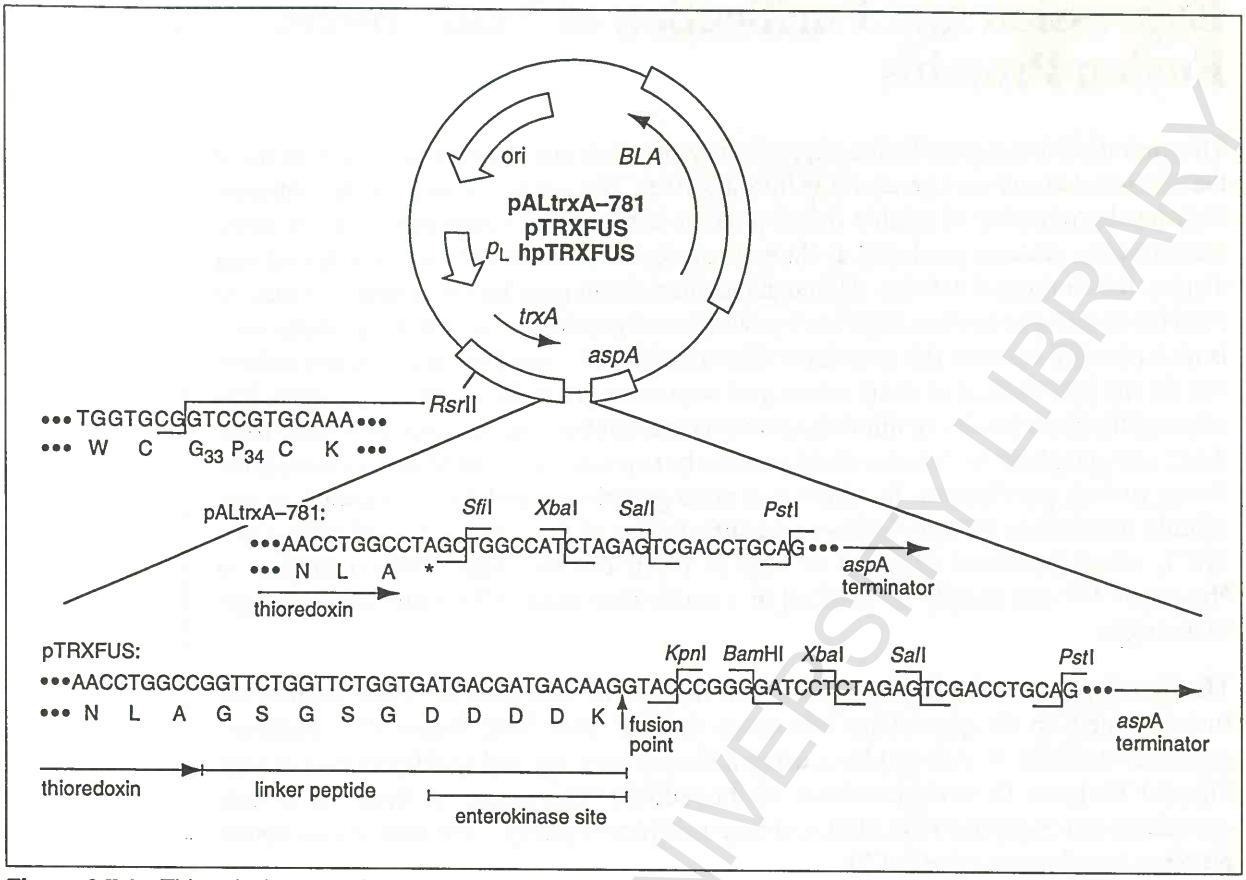

Figure 6.7.1 Thioredoxin gene fusion expression vectors pTRXFUS, hpTRXFUS, and pALtrxA-781. pALtrxA-781 contains a polylinker sequence at the 3′ end of the *trxA* gene. pTRXFUS and hpTRXFUS contain a linker region encoding a peptide that includes the enterokinase cleavage site between the *trxA* gene and the polylinker. The sequence surrounding the active site loop of thioredoxin has a single *Rsr*II site that can be used to insert peptide coding sequence. The asterisk indicates a translational stop codon. Abbreviations: *trxA*, *E. coli* thioredoxin gene; *BLA*, β-lactamase gene; ori, colE1 replication origin; pL, bacteriophage λ major leftward promoter; *aspA* terminator, *E. coli* aspartate amino-transferase transcription terminator.

pTRXFUS, hpTRXFUS, and pALtrxA-781 carry the strong bacteriophage λ promoter pL (Shimatake and Rosenberg, 1981) positioned upstream of the *trxA* gene. Transcription initiation at the pL promoter is controlled by the intracellular concentration of λ repressor protein (cI). cI^{857}-containing strains (Shatzman et al., 1990) can be used for heat inductions of pL at 42°C; alternatively, in the strains carrying the wild-type repressor, pL can be induced by a prior induction of the *E. coli* SOS stress response. However, it is often desirable to express heterologous genes in *E. coli* at temperatures considerably lower than 42°C, or under conditions where cells are not undergoing a physiological stress. Strains GI698, GI724 and GI723 were designed to allow the growth and induction of pL expression vectors, including pTRXFUS, hpTRXFUS, and pALtrxA-781, under mild conditions over a wide range of temperatures (see Table 6.7.1; Mieschendahl et al., 1986). Each of these strains carries a wild-type allele of cI stably integrated into the *E. coli* chromosome at the nonessential *ampC* locus. A synthetic *trp* promoter integrated into *ampC* upstream of the cI gene in each strain directs the synthesis of cI repressor only when intracellular tryptophan levels are low. When tryptophan levels are high, synthesis of cI is switched off; therefore, the presence of tryptophan in the growth medium of GI698, GI723, or GI724 will block expression of λ repressor and thus will turn on pL. Because the three strains carry ribosome-binding sequences of different strengths at the 5′-end of

PCU IASRI CENTRAL UNIVERSITY LIBRARY

Table 6.7.1 *E. coli* Strains for Production of Thioredoxin Fusion Proteins at Varying Temperatures

Strain	Desired production temperature (°C)	Pre-induction growth temperature (°C)	Induction period (hr)
GI698	15	25	20
GI698	20	25	18
GI698	25	25	10
GI724	30	30	6
GI724	37	30	4
GI723	37	37	5

their respective cI genes, they maintain intracellular concentrations of λ repressor that increase in the order GI698 < GI724 < GI723. The choice of which strain to use for a particular application is dependent on the desired culture conditions as described below.

Although some thioredoxin fusion proteins produced at 37°C are insoluble, expression at lower temperatures can often result in the fusion protein being produced in a soluble form. Each of the three pL host strains GI698, GI723, and GI724 is suitable for the production of thioredoxin fusion proteins over a particular temperature range. Table 6.7.1 indicates the correct strain for expression of thioredoxin fusion proteins at any temperature between 15°C and 37°C. The induction protocol at any of these temperatures is the same as that described for induction of GI724 at 37°C (see Basic Protocol), except the preinduction growth temperature and the length of the induction period vary according to the strain used and the temperature chosen. Cultures should be grown at the indicated preinduction growth temperature until they reach a density of 0.4 to 0.6 OD_{550}/ml. They should then be moved to the desired induction temperature and induced by the addition of 100 μg/ml tryptophan.

Low-temperature inductions are best performed in strain GI698. However, this strain makes only enough cI repressor protein to maintain the vectors in an uninduced state at temperatures below 25°C. GI698 should therefore never be grown above 25°C when it carries a pL plasmid. A nonrefrigerated water bath can be maintained below room temperature by placing it in a 4°C room and setting the thermostat to the desired temperature.

It is often a good idea to collect time points during the course of a long induction period and to fractionate cells from these time points (see Support Protocol 1, steps 9 to 13). Although a particular fusion protein may be soluble during the early part of an induction, during the later phases of induction it may become unstable or its concentration inside the cell may exceed a critical threshold above which it will precipitate and appear in the insoluble fraction.

BCU IAS CENTRAL UNIVERSITY LIBRARY

CONSTRUCTION AND EXPRESSION OF A THIOREDOXIN FUSION PROTEIN

This protocol describes construction and subsequent expression of a gene fusion between *trxA* (encoding thioredoxin) and a gene encoding a particular protein or peptide. After a clone carrying the correct fusion sequence is constructed, analyzed, and isolated, cultures are grown and expression is induced. The protocol is described in terms of the *E. coli* host strain GI724 with expression at 30°C; it may also be applied to strains GI698 and GI723 (also available from Genetics Institute) for expression at other temperatures by using the parameters specified in Table 6.7.1 (see Strategic Planning).

Materials

DNA fragment encoding desired sequence
Thioredoxin expression vectors (Fig. 6.7.1): pTRXFUS or pALtrxA-781 (Genetics Institute or Invitrogen) or hpTRXFUS (Genetics Institute)
E. coli strain GI724 (Genetics Institute or Invitrogen), grown in LB medium and made competent
LB medium (*UNIT 5.2*)
IMC plates (see recipe) containing 100 µg/ml ampicillin
CAA/glycerol/ampicillin 100 medium (see recipe)
IMC medium (see recipe) containing 100 µg/ml ampicillin
10 mg/ml tryptophan (see recipe)
SDS-PAGE sample buffer (see recipe)

30°C convection incubator
18 × 50–mm culture tubes
Roller drum (New Brunswick Scientific)
250-ml culture flask
70°C water bath
Microcentrifuge, 4°C

Additional reagents and equipment for SDS-PAGE (*UNIT 10.1*), and Coomassie brilliant blue staining (*UNIT 10.5*)

Construct the trxA gene fusion

1. Use DNA fragment encoding the desired sequence to construct either an in-frame fusion to the 3′-end of the *trxA* gene in pTRXFUS or hpTRXFUS, or a short peptide insertion into the unique *Rsr*II site of pALtrxA-781.

   A precise fusion of the desired gene to the enterokinase linker sequence in pTRXFUS or hpTRXFUS can be made by using the unique KpnI site trimmed to a blunt end with the Klenow fragment of E. coli DNA polymerase. The desired gene can usually be adapted to this blunt-end construct by using a synthetic oligonucleotide duplex ligated between it and any convenient downstream restriction site close to the 5′ end of the gene. When designing the fusion junction, note that enterokinase is able to cleave —DDDDK↓X—, where X is any amino acid residue except proline. Synthetic oligonucleotides encoding short peptides for insertion into the thioredoxin active-site loop at the RsrII site will insert only in the desired orientation, because the RsrII sticky end consists of three bases.

2. Transform the ligation mixture containing the new thioredoxin fusion plasmid into competent GI724 cells. Plate transformed cells onto IMC plates containing 100 µg/ml ampicillin to select transformants. Incubate plates in a 30°C convection incubator until colonies appear.

   Strains GI698, GI723, and GI724 are all healthy prototrophs that can grow under a wide variety of growth conditions, including rich and minimal media and a broad range of growth temperatures (see Table 6.7.1). These strains can be prepared for transformation with pL-containing vectors by growing them in LB medium at 37°C. LB medium may also

PCU IASI / CENTRAL UNIVERSITY LIBRARY

be used for these strains during the short period of outgrowth immediately following transformation. This growth period of 30 min to 1 hr is often used to express drug-resistance phenotypes before plating out plasmid transformations onto solid medium. Subsequently, however, these strains should be grown only on minimal or tryptophan-free rich media, such as IMC medium containing 100 µg/ml ampicillin (for expression of the fusion protein) or CAA/glycerol/ampicillin 100 medium (for plasmid DNA preparations). Except during transformation, LB medium should never be used with these three strains when they carry pL plasmids because LB contains tryptophan. The pL promoter is extremely strong and should be maintained in an uninduced state until needed so that expression of the protein will not lead to selection of mutant or variant cells with lower expression due to undesirable genetic selections or rearrangements in the expression strain.

3. Grow candidate colonies in 5 ml CAA/glycerol/ampicillin 100 medium overnight at 30°C. Prepare minipreps of plasmid DNA and check for correct gene insertion into pTRXFUS by restriction mapping.

4. Sequence plasmid DNA of candidate clones to verify the junction region between thioredoxin and the gene or sequence of interest.

Induce expression

5. Streak out frozen stock culture of GI724 containing thioredoxin expression plasmid to single colonies on IMC plates containing 100 µg/ml ampicillin. Grow 20 hr at 30°C.

   Occasionally there is induction of pL plasmids grown in GI698 and GI724 at 37°C, even in medium containing no tryptophan. Such induction appears to be a temperature-dependent phenomenon. If growth at 37°C prior to pL induction is essential, then GI723 should be used as the host strain because GI723 produces higher levels of cI repressor than both GI698 and to GI724. Otherwise, plasmid-containing GI698 should be grown at 25°C and plasmid-containing GI724 should be grown at 30°C prior to induction (see Table 6.7.1).

6. Pick a single fresh, well-isolated, colony from the plate and use it to inoculate 5 ml IMC medium containing 100 mg/ml ampicillin in an 18 × 150–mm culture tube. Incubate overnight at 30°C on a roller drum.

7. Add 0.5 ml overnight culture to 50 ml fresh IMC medium containing 100 µg/ml ampicillin in a 250-ml culture flask (1:100 dilution). Grow at 30°C with vigorous aeration until absorbance at 550 nm reaches 0.4 to 0.6 OD/ml (~3.5 hr).

8. Remove a 1-ml aliquot of the culture (uninduced cells). Measure the optical density at 550 nm and harvest the cells by microcentrifuging 1 min at maximum speed, room temperature. Carefully remove all the spent medium with a pipet and store the cell pellet at –80°C.

9. Induce pL by adding 0.5 ml of 10 mg/ml tryptophan (100 µg/ml final) to remaining cells immediately.

10. Incubate 4 hr at 37°C. At hourly intervals during this incubation, remove 1-ml aliquots of the culture and harvest cells as in step 8.

11. Harvest the remaining cells from the culture 4 hr post-induction by centrifuging 10 min at 3000 rpm (e.g., in a Beckman J6 rotor), 4°C. Store the cell pellet at –80°C.

    Procedures for further analysis of these cells are outlined in the support protocols.

Verify induction

12. Resuspend the pellets from the induction intervals (steps 8 and 10) in 200 µl of SDS-PAGE sample buffer/OD_{550} cells. Heat 5 min at 70°C to completely lyse the cells and denature the proteins. Run the equivalent of 0.15 OD_{550} cells per lane (30 µl) on an SDS-polyacrylamide gel (*UNIT 10.1*).

BU IAST/ CENTRAL UNIVERSITY LIBRARY

13. Stain the gel 1 hr with Coomassie brilliant blue (*UNIT 10.5*). Destain the gel and check for expression.

Most thioredoxin fusion proteins are produced at levels that vary from 5% to 20% of the total cell protein. The desired fusion protein should exhibit the following characteristics: it should run on the gel at the mobility expected for its molecular weight; it should be absent prior to induction; and it should gradually accumulate during induction, with maximum accumulation usually occurring 3 hr post-induction at 37°C.

SUPPORT PROTOCOL 1

E. COLI LYSIS USING A FRENCH PRESSURE CELL

A small, 3.5-ml French pressure cell can be used as a convenient way to lyse *E. coli* cells. The whole-cell lysate can be fractionated into soluble and insoluble fractions by microcentrifugation. Other lysis procedures may be used—for example, sonication (*UNIT 6.6*) or treatment with lysozyme-EDTA (*UNIT 6.5*). For use of the larger 40-ml French pressure cell, see *UNIT 6.2*.

Materials

Cell pellet from 4-hr post-induction culture (see Basic Protocol)
20 mM Tris·Cl, pH 8.0 (*APPENDIX 2E*), 4°C
Lysis buffer: 20 mM Tris·Cl (pH 8.0) with protease inhibitors (optional)—0.5 mM phenylmethylsulfonyl fluoride (PMSF), 1 mM *p*-aminobenzamidine (PABA), and 5 mM EDTA
SDS-PAGE sample buffer (see recipe)
French press and 3.5-ml mini-cell (SLM Instruments), 4°C

Additional reagents and equipment for SDS-PAGE (*UNIT 10.1*)

Lyse the cells

1. Resuspend cell pellet from 4-hr post-induction culture in 20 mM Tris·Cl, pH 8.0, to a concentration of 5 OD_{550}/ml.

Protease inhibitors can be included in the resuspension if desired. Cells can also be resuspended at densities of 100 OD_{550}/ml or greater; however, at high densities cell lysis may be less efficient.

2. Place 1.5 ml resuspended cell pellet in the 3.5-ml French pressure cell. Hold the cell upside down with the base removed, the piston fully extended downwards, and the outlet valve handle that holds the nylon ball seal in the open position (loose).

Before filling the pressure cell, check that the nylon ball, which seals the outlet port and sits on the end of the outlet valve handle, is not deformed. If it is, replace it with a new one. Both the condition of the nylon ball and its seat in the pressure-cell body are critical for the success of the procedure.

3. Bring the liquid in the pressure cell to the level of the outlet port by raising the piston slowly to expel excess air from the cell. With the outlet valve open and at the same time maintaining the piston in position, install the pressure-cell base. Gently close the outlet valve.

CAUTION: *Do not over-tighten the valve as this will deform the nylon ball and may irreparably damage its seat on the pressure-cell body.*

4. Turn the sealed cell right-side-up and place it in the hydraulic press.

5. Turn the pressure regulator on the press fully counter-clockwise to reset it to zero pressure. Set the ratio selector to medium. Turn on the press.

CAUTION: *The larger (50-ml) pressure cell is usually used with the selector set on high. The small (3.5-ml) cell is only used on medium ratio.*

ECU IASI CENTRAL UNIVERSITY LIBRARY

6. Slowly turn the pressure regulator clockwise until the press just begins to move. Allow the press to compress the piston.

   The press will stop moving after a few seconds.

7. Position a collection tube under the pressure-cell outlet. Slowly increase the pressure in the cell by turning the pressure regulator clockwise. Monitor the reading on the gauge and increase the pressure to 1000 on the dial, corresponding to an internal cell pressure of 20,000 lb/in^2.

8. While continuously monitoring the gauge, very slowly open the outlet valve until lysate begins to trickle from the outlet.

   The lysate should flow slowly and smoothly, and the cell pressure should not drop more than 100 divisions on the dial.

   At 20,000 lb/in^2 and 5 OD_{550}/ml, cell lysis will be complete after one passage through the press. Lower pressures and/or higher cell densities may require a second passage.

Fractionate the lysate

9. Remove a 100-µl aliquot of the lysate and freeze at –80°C (whole-cell lysate).

10. Fractionate the remainder of the lysate by microcentrifuging 10 min at maximum speed, 4°C.

11. Remove a 100-µl aliquot of the supernatant and freeze at –80°C (soluble fraction). Discard the remainder of the supernatant.

    Because this is a pilot experiment, it would not produce enough material to warrant saving any remaining supernatant.

12. Resuspend the pellet in an equivalent volume of lysis buffer. Remove a 100-µl aliquot and freeze at –80°C (insoluble fraction).

13. Lyophilize the 100-µl aliquots to dryness in a Speedvac evaporator. Solubilize in 100 µl SDS-PAGE sample buffer. Analyze 30-µl samples by SDS-PAGE (*UNIT 10.1*).

    This crude fractionation provides a fairly reliable indication of whether a protein has folded correctly. Usually proteins in the soluble fraction have adopted a correct conformation and proteins in the insoluble fraction have not. However, occasionally proteins found in the soluble fraction are not truly soluble; instead they form aggregates that do not pellet in the microcentrifuge. Conversely, sometimes a protein found in the insoluble fraction may be there because it has an affinity for cell-wall components and cell membranes, and it may not be intrinsically insoluble. Occasionally proteins can be recovered from these insoluble fractions by extracting with agents such as mild detergents.

OSMOTIC RELEASE OF THIOREDOXIN FUSION PROTEINS

SUPPORT PROTOCOL 2

Thioredoxin and some thioredoxin fusion proteins can be released with good yield from the *E. coli* cytoplasm by a simple osmotic shock procedure.

Materials

Cell pellet from 4-hr post-induction cultures (see Basic Protocol)
20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA/20% (w/v) sucrose, ice-cold
20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA, ice-cold

Additional reagents and equipment for SDS-PAGE (*UNIT 10.1*)

1. Resuspend cell pellet from 4-hr post-induction cultures at a concentration of 5 OD_{550}/ml in ice-cold 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA/20% sucrose. Incubate 10 min on ice.

2. Microcentrifuge 30 sec at maximum speed, 4°C, to pellet the cells.

BUNGE/CENTRAL UNIVERSITY LIBRARY

3. Discard the supernatant and gently resuspend the cells in an equivalent volume of ice-cold 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA. Incubate 10 min on ice and mix occasionally by inverting the tube.

   Osmotic release from the cytoplasm occurs at this stage.

4. Microcentrifuge 30 sec at maximum speed, 4°C. Save the supernatant (osmotic shockate). Resuspend the cell pellet in an equivalent volume 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA (retentate).

5. Lyophilize 100-µl aliquots of osmotic shockate and retentate to dryness in a Speedvac evaporator.

6. Solubilize each in 100 µl SDS-PAGE sample buffer. Analyze 30-µl aliquots by SDS-PAGE (*UNIT 10.1*).

   The osmotic-shock procedure provides a substantial purification step for some thioredoxin fusion proteins. This procedure will remove most of the contaminating cytoplasmic proteins as well as almost all of the nucleic acids. However the shockate will contain as contaminants about half of the cellular elongation factor-Tu (EF-Tu) and most of the E. coli periplasmic proteins.

SUPPORT PROTOCOL 3

PURIFICATION OF THIOREDOXIN FUSION PROTEINS BY HEAT TREATMENT

Wild-type thioredoxin is resistant to prolonged incubations at 80°C. A subset of thioredoxin fusion proteins also exhibit corresponding thermal stability, and heat treatment at 80°C can sometimes be used as an initial purification step. Under these conditions the majority of contaminating *E. coli* proteins are denatured and precipitated.

Materials

Cell pellet from 4-hr post-induction cultures (See Basic Protocol)
20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA
SDS-PAGE sample buffer (see recipe)

80°C water bath
10-ml glass-walled tube

Additional reagents and equipment for lysis using a French pressure cell (Support Protocol 1) and SDS-PAGE (*UNIT 10.1*)

1. Resuspend cell pellet from 4-hr post-induction cultures at a concentration of 100 OD_{550}/ml in 20 mM Tris·Cl (pH 8.0)/2.5 mM EDTA.

   It is important to start off with a high protein concentration in the lysate to ensure efficient precipitation of denatured proteins.

2. Lyse the cells at 20,000 lb/in^2 in a French pressure cell (see Support Protocol 1, steps 2 to 8). Collect whole-cell lysate in a 10-ml glass-walled tube.

3. Incubate whole-cell lysate 10 min at 80°C. Remove 100-µl aliquots after 30 sec, 1 min, 2 min and 5 min and plunge immediately into ice. At 10 min, plunge the remaining heated lysate into ice.

   A glass-walled tube (not plastic) provides good thermal conductivity to provide a rapid rise in temperature to 80°C and then a rapid drop in temperature to 4°C. A suitable volume to use in a 10-ml glass tube is 1.5 ml lysate. For large-scale work, a glass-walled vessel should be used and the lysate should be mixed well during both heat treatment and cooling.

4. Microcentrifuge the aliquots 10 min at maximum speed, 4°C to pellet heat-denatured, precipitated proteins.

ECU IASI / CENTRAL UNIVERSITY LIBRARY

5. Remove 2-µl aliquots of the supernatants and add 28 µl SDS-PAGE sample buffer. Analyze the samples by SDS-PAGE (*UNIT 10.1*) to determine the heat stability of the fusion protein and the minimum time of heat treatment required to obtain a good purification.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Casamino Acids (CAA), 2% (w/v)

20 g Casamino Acids (Difco-certified)
H_2O to 1 liter
Autoclave or filter sterilize through a 0.45-µm filter
Store ≤2 months at room temperature

Do not use technical-grade Casamino Acids because it has a higher NaCl content.

CAA/glycerol/ampicillin 100 medium

800 ml 2% (w/v) Casamino Acids (see recipe; 1.6% final)
100 ml 10× M9 salts (see recipe; 1× final)
100 ml 10% (v/v) glycerol (sterile; 1% final)
1 ml 1 M $MgCl_2$ (sterile; 1 mM final)
0.1 ml 1 M $CaCl_2$ (sterile; 0.1 mM final)
1 ml 2% (w/v) vitamin B1 (sterile; 0.002% final)
10 ml 10 mg/ml ampicillin (sterile; 100 µg/ml final)
Prepare fresh

IMC medium

200 ml 2% (w/v) Casamino Acids (see recipe; 0.4% final)
100 ml 10× M9 salts (see recipe; 1× final)
40 ml 20% (w/v) glucose (sterile; 0.5% final)
1 ml 1 M $MgCl_2$ (sterile; 1 mM final)
0.1 ml 1 M $CaCl_2$ (sterile; 0.1 mM final)
1 ml 2% (w/v) vitamin B1 (sterile; 0.002% final)
658 ml glass-distilled H_2O (sterile)
10 ml 10 mg/ml ampicillin (sterile; optional; 100 µg/ml final)
Use fresh

IMC plates

15 g agar [Difco; 1.5% (w/v)]
4 g Casamino Acids [Difco-certified; 0.4% (w/v)]
858 ml glass-distilled H_2O (sterile)
Autoclave 30 min
Cool in a 50°C water bath
100 ml 10× M9 salts (see recipe; 1× final)
40 ml 20% (w/v) glucose (sterile; 0.5% final)
1 ml 1 M $MgCl_2$ (sterile; 1 mM final)
0.1 ml 1 M $CaCl_2$ (sterile; 0.1 mM final)
1 ml 2% (w/v) vitamin B1 (sterile; 0.002% final)
10 ml 10 mg/ml ampicillin (sterile; optional; 100 µg/ml final)
Mix well and pour into petri plates
Store ≤1 month at 4°C

B. C. U. „M. EMINESCU" IAȘI
CHIMIE

BCU IAȘI / CENTRAL UNIVERSITY LIBRARY

M9 salts, 10×

60 g Na_2HPO_4 (0.42 M)
30 g KH_2PO_4 (0.24 M)
5 g NaCl (0.09 M)
10 g NH_4Cl (0.19 M)
H_2O to 1 liter
Adjust pH to 7.4 with NaOH
Autoclave or filter sterilize through a 0.45-µm filter
Store ≤6 months at room temperature

SDS-PAGE sample buffer

15% (v/v) glycerol
0.125 M Tris·Cl, pH 6.8 (*APPENDIX 2E*)
5 mM Na_2EDTA
2% (w/v) SDS
0.1% (w/v) bromphenol blue
1% (v/v) 2-mercaptoethanol (2-ME; add immediately before use)
Store indefinitely at room temperature

Tryptophan, 10 mg/ml

Heat 500 ml glass-distilled H_2O to 80°C. Stir in 5 g L-tryptophan until dissolved. Filter sterilize the solution through a 0.45 µm filter and store ≤6 months in the dark at 4°C.

COMMENTARY

Background Information

Two significant problems plague researchers who hope to express heterologous proteins in *Escherichia coli*: inefficient initiation of translation of many eukaryotic mRNA sequences on bacterial ribosomes (Stormo et al., 1982), and proteins that often form insoluble aggregates, called inclusion bodies, that are composed of misfolded or denatured proteins (Mitraki and King, 1989). Although successful protocols for refolding eukaryotic proteins from inclusion bodies can be developed, the process is always uncertain and usually time-consuming; in most instances it is preferable to prevent inclusion-body formation in the first place. The use of *trxA* fusions provides a solution to both problems.

Inefficient initiation of translation of eukaryotic messages in *E. coli* can often be improved by modifying sequences at the 5′ end of the gene. A more reliable technique that avoids the problem entirely is to use a gene-fusion strategy in which the gene of interest is linked in-frame to the 3′ end of a highly translated partner gene. In this case protein synthesis always initiates on the same efficiently translated fusion-partner mRNA, thus ensuring high-level expression. Some earlier gene-fusion expression systems, for example the *trpE* and *lacZ* systems, offer very reliable ways of producing large quantities of any desired eukaryotic protein. However, these gene-fusion systems still suffer from the pervasive inclusion-body problem. They are thus mainly useful for the production of antigens, rather than correctly folded, biologically active proteins. More recently the maltose binding protein (MBP; Riggs, 1994; *UNIT 5.1*) and glutathione-*S*-transferase (GST) gene fusion expression systems (see *UNIT 6.6*) have proven more successful in producing soluble fusion proteins; these systems retain the translation advantage of the earlier fusion systems. Apart from the obvious advantages in making a correctly folded product, the synthesis of soluble fusion proteins also allows for the development of generic purification schemes based on some unique property of the fusion partner.

Why would any particular eukaryotic protein produced in the *E. coli* cytoplasm be more soluble when it is linked to a fusion partner than it would be by itself? It is likely that physical properties of the fusion-partner protein are important, with efficient self-folding and high solubility being useful in this role. It is possible that some good fusion partners (proteins that fold efficiently and are highly soluble), by virtue of their desirable physical qualities, are able to keep folding intermediates of linked heterologous proteins in solution long enough for

PCU IASRI CENTRAL UNIVERSITY LIBRARY

them to adopt their correct final conformations. In this respect the fusion partner may serve as a covalently joined chaperone protein, in many ways fulfilling the role of authentic chaperone proteins (McCoy, 1992), analogous to the covalent chaperone role proposed for the N-terminal pro regions of a number of protein precursors (Silen et al., 1989; Shinde et al., 1993).

Many of the known properties of *E. coli* thioredoxin (Holmgren, 1985) suggested that it would make a particularly effective fusion partner in an expression system. First, thioredoxin, when overproduced from plasmid vectors, can accumulate to 40% of the total cellular protein, yet even at these expression levels all of the protein remains soluble. Second, the molecule is small (11,675 M_r) and would contribute a relatively modest amount to the total mass of any fusion protein, in contrast to other systems such as the *lacZ* system. Third, the tertiary structure of thioredoxin (Katti et al., 1990) reveals that both the N- and C-termini of the molecule are accessible on the surface and in good position to link to other proteins. The structure also shows that the molecule has a very tight fold, with >90% of its primary sequence involved in strong elements of secondary structure. This provides an explanation for thioredoxin's observed high thermal stability (T_m = 85°C), and suggests that the molecule might possess the robust folding characteristics that could make it a good fusion-partner protein. In support of this view, complete thioredoxin domains are found in a number of naturally occurring multidomain proteins, including *E. coli* DsbA (Bardwell et al., 1991), the mammalian endoplasmic reticulum proteins ERp72 (Mazzarella et al., 1990), and protein disulfide isomerase (PDI; Edman et al., 1985). These proteins can all be considered as natural precedents for thioredoxin fusion proteins.

The synthesis of small peptides in *E. coli* is often difficult, with the products frequently being extensively degraded or insoluble. The thioredoxin tertiary structure revealed that the characteristic active site, —CGPC—, protrudes from the body of the protein as a surface loop, with few interactions with the rest of the molecule. The loop does not seem to contribute to the overall stability of thioredoxin, so the production of peptides as insertions at this site was an attractive possibility. In this location they would be protected from host-cell amino- and carboxypeptidases, and thioredoxin's high solubility should help keep them in solution. In addition, the conformation of peptides inserted at this position would be constrained, which could be an advantage for applications in which it is desirable for the peptide to adopt a particular form.

Thioredoxin has indeed proven to be an excellent partner for the production of soluble fusion proteins in the *E. coli* cytoplasm (LaValllie et al., 1993b). Figure 6.7.2 demonstrates the production of soluble fusion proteins between thioredoxin and eleven human and murine cytokines and growth factors using the *trxA* vectors. All of these mammalian proteins had been previously produced in *E. coli* only as insoluble inclusion bodies. As thioredoxin fusions, the growth factors are not only made in a soluble form, but in most cases they are also biologically active in in vitro assays.

Experience gained while working with these and a number of other *trxA* fusion proteins shows that two further characteristics of thioredoxin can be exploited as purification tools. The first is the inherent thermal stability of the molecule, a property that is retained by some thioredoxin fusion proteins. This enables heat treatment to be used as an effective purification step. The second additional property relates to thioredoxin's cellular location. Although *E. coli* thioredoxin is a cytoplasmic protein, it has been shown to occupy a special position within the cell—it is primarily located on the cytoplasmic face of the adhesion zones that exist between the inner and outer membranes of the *E. coli* cell envelope (Lunn and Pigiet, 1982). From this location thioredoxin is quantitatively released to the exterior of the cell by simple osmotic shock or freeze/thaw treatments, a remarkable property that is retained by some thioredoxin fusion proteins, thus providing a simple purification step.

A more generic method for purification of any soluble thioredoxin fusion employs a modified form of thioredoxin (called "His-patch Trx"), which has been designed to bind to metal chelate resins (Lu et al., 1996; *UNIT 9.4*).

If the fusion protein is soluble after lysis or osmotic release (see Support Protocols 1 and 2), then any of the conventional purification methods described in Chapter 8 can be used. Alternatively, an affinity-based purification method can be used where an immobilized arsenical compound forms an adduct with the redox-sensitive vicinal dithiols present at the active site of thioredoxin. This affinity matrix was originally prepared by covalently linking 4-aminophenylarsenine oxide to cyanogen bromide–activated Sepharose 4B (Hannestad et al., 1982). Hoffman and Lane (1992) coupled the same ligand to Affi-Gel 10 (Bio-Rad); the

BOSTON UNIVERSITY LIBRARY

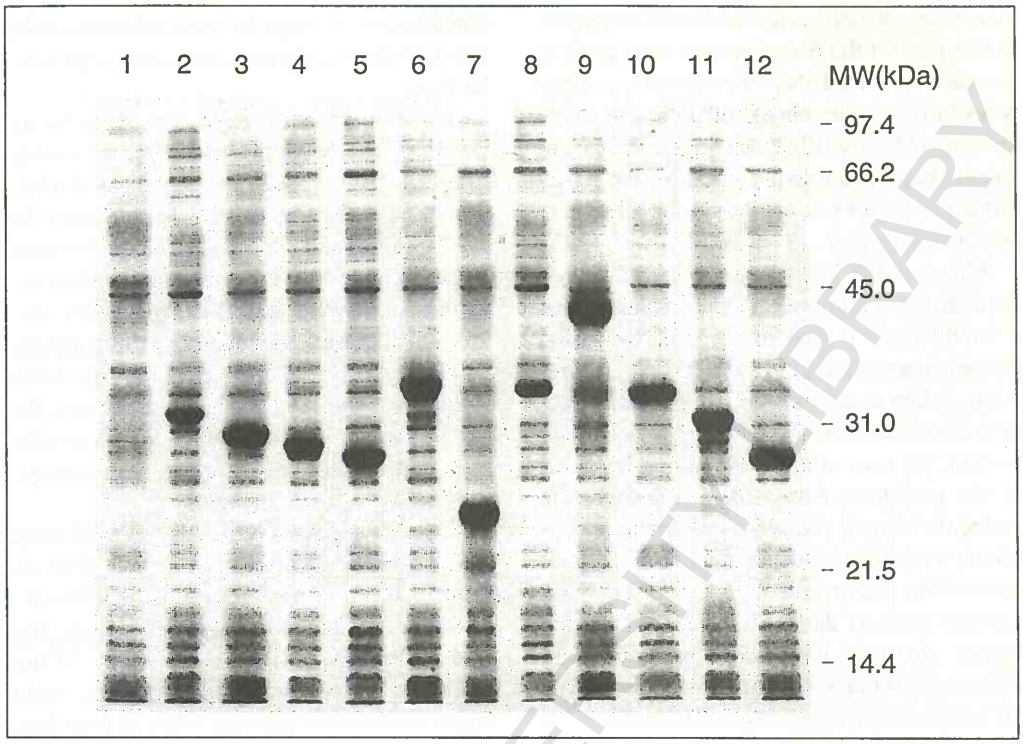

Figure 6.7.2 Expression of thioredoxin gene fusions. The gel shows proteins found in the soluble fractions derived from *E. coli* cells expressing eleven different thioredoxin gene fusions. Lane 1, host *E. coli* strain GI724 (negative control, 37°C); lane 2, murine interleukin-2 (IL-2; 15°C); lane 3, human IL-3 (15°C); lane 4, murine IL-4 (15°C); lane 5, murine IL-5 (15°C); lane 6, human IL-6 (25°C); lane 7, human MIP-1a (37°C); lane 8, human IL-11 (37°C); lane 9, human macrophage colony-stimulating factor (M-CSF; 37°C); lane 10, murine leukemia inhibitory factor (LIF; 25°C); lane 11, murine steel factor (SF; 37°C); and lane 12, human bone morphogenetic protein-2 (BMP-2; 25°C). Temperatures in parentheses are the production temperature chosen for expressing each fusion. This is a 10% SDS-polyacrylamide gel, stained with Coomassie brilliant blue.

resultant affinity matrix has a 10-atom spacer which makes it more useful for affinity chromatography. The resin is commercially available from Invitrogen (ThioBond) and Sigma. Protocols detailing the affinity-based purification approach can be obtained on-line from the Invitrogen web site (*http://www.invitrogen.com/manuals.html*), and a recent example from the literature is the expression of human glutamate decarboxylase (Papouchado et al., 1997). Other specific purification approaches include immunoaffinity chromatography using antibodies against either the target protein or against the thioredoxin moiety (monoclonal antibodies against thioredoxin are commercially available). Thioredoxin fusions with additional histidine tags or thioredoxin fusions based on mutant thioredoxins with metal-chelating affinity (Lu et al., 1996) can be purified using metal-chelate chromatography (see *UNIT 9.4*). Finally, if the fusion protein is insoluble, then attempts to solubilize and fold the fusion protein can be made prior to purification, in a technique analogous to that used with insoluble GST fusion proteins (see *UNIT 6.6*). Thioredoxin from *E. coli* is a very soluble protein that can be readily denatured and refolded (Kelley et al., 1987).

Critical Parameters

Lack of protein solubility leading to inclusion-body formation in *E. coli* is a complex phenomenon with many contributing factors: simple insolubility as a result of high-level expression, insolubility of protein-folding intermediates, lack of appropriate bacterial chaperone proteins, and lack of glycosylation mechanisms in the bacterial cytoplasm. Fusion of heterologous proteins to thioredoxin or to other fusion partners can help address most of these solubility issues. However, another important factor contributing to inclusion body formation is the inability to form essential disulfide bonds in the reducing environment of the bacterial cytoplasm, which leads to incorrect folding. Thermal lability of even correctly

ECU IAS CENTRAL UNIVERSITY LIBRARY

folded heterologous proteins in the absence of these stabilizing disulfide cross-links is a significant problem, so the expression of fusion genes should be attempted over a wide range of temperatures, even as low as 15°C (the limit for *E. coli* growth is ~8°C). Thermal denaturation is a time-dependent process, so it is also prudent to monitor the solubility of the expressed fusion protein over the time course of induction.

A great many proteins contain distinct structural domains. For example, hormone receptor proteins usually have an extracellular ligand-binding domain, a transmembrane region, and an intracellular effector domain. Sometimes, expressing these domains individually as fusion proteins can yield better results than expressing the entire protein. The exact positions chosen for boundaries of the domains to be expressed in the fusion protein are important and can be determined from a knowledge of the tertiary structure of the protein of interest, by homology comparisons with similar proteins, by limited proteolysis or other domain-mapping experiments, or empirically by generating multiple fusions that test different boundary positions.

It is important to be consistent in treating samples for loading on gels. For example, using different heating conditions from one experiment to the next can result in a mobility shift for the protein of interest.

Anticipated Results

Thioredoxin fusion protein yields are usually in the range of 5% to 20% of total cell protein. At these expression levels, a 1-liter induction culture in a shaker flask will yield ~3 g (wet weight) of cells, 300 mg total protein, and 15 to 60 mg of thioredoxin fusion protein. The final recovered yield will depend on factors such as solubility of the fusion protein and the efficiency of downstream purification procedures.

Time Considerations

From a single colony on a plate, the basic induction protocol requires an overnight growth to prepare a liquid inoculum and a 3.5-hr preinduction growth at 30°C the next day, followed by a 4-hr 37°C induction period. These times are significantly longer if lower induction temperatures are required (see Table 6.7.1). Lysis of a sample in the French pressure cell should require ≤ 5 min, and both the heat-treatment and osmotic-shock procedures require <1 hr each. SDS-PAGE takes 2.5 hr.

CHAPTER 7
Characterization of Recombinant Proteins

INTRODUCTION

Once a protein has been purified, it is necessary to characterize the protein preparation. The initial and most fundamental analyses performed are checks of purity and of biological or enzymatic activity. Indeed, to purify a protein in the first place a specific assay for the protein must be available, and limited purity determinations are usually made en route to the finished product by SDS-PAGE monitoring of the sample at different purification stages. The first unit of this chapter (*UNIT 7.1*) provides an overview of the approaches and methods used for more detailed characterization of recombinant proteins. It should be noted that none of the techniques or methods mentioned are used uniquely for recombinant proteins, and protocols dealing with some of the methods are included elsewhere in this book. However, the emphasis of the discussion in *UNIT 7.1* (and of the protocols which will appear in future updates) is on addressing the detection and determination of the most pertinent sources of contamination and heterogeneity commonly associated with proteins isolated from recombinant sources.

The first section of the overview describes common sources of contamination, both proteinaceous and nonproteinaceous. Because these contaminants are derived from the host cell, their specific characteristics will depend on the particular expression system used (also see Chapter 5). Once the purity of the protein has been established, the primary structure (amino acid sequence) is checked by standard protein-chemical methodologies. Throughout the overview, the use of HPLC and mass spectrometry is emphasized; these are important tools for checking the primary structure and especially for detecting both nonspecific and specific post-translational modifications.

Because many proteins expressed in *E. coli* form insoluble aggregates known as inclusion bodies, before purification they must be extracted under conditions that unfold the protein (see *UNITS 6.1, 6.3 & 6.5*). After folding and purification of the protein, there is always the possibility that varying amounts of misfolded conformers may be present. Misfolded protein can be considered as a contaminant. A number of spectroscopic and other methods used to study protein conformation and structure are tabulated in the overview. Protocols describing the most commonly used of these methods are included in this chapter (see *UNITS 7.2, 7.4, 7.6, 7.7 & 7.9*).

Proteins expressed in *E. coli* can retain N-terminal methionine derived from the initiating *N*-formylmethionine. The retention or nonretention of N-terminal methionine is a potential source of heterogeneity, and is discussed in the last section of the overview (also see *UNIT 6.1*).

In *UNIT 7.2* the analysis of proteins using ultraviolet (UV) absorption spectroscopy is described. The first part deals with direct (or batch-mode) spectroscopic measurement, in which the purified protein is simply placed in a quartz cuvette and analyzed. Data collection and interpretation protocols allow assessment of the identity and, to a lesser degree, the purity of the protein. The second part of *UNIT 7.2* describes the analysis of proteins simultaneously separated by HPLC chromatography. This can be considered to be a two-dimensional method in which the first dimension is chromatography; the peaks thus separated are spectroscopically analyzed using diode array detection in the second

BOSTON CENTRAL UNIVERSITY LIBRARY

dimension. Both batch-mode and column-based spectroscopic analysis complement purity analysis using SDS-PAGE (Chapter 10) in that the former methods can detect the presence of nonproteinaceous contaminants, especially nucleic acid.

The primary sequence of a recombinant protein is known from the cDNA coding sequence. However, the sequence of an isolated recombinant-derived protein may differ from the predicted sequence due to, for example, post-translational modifications; it is therefore important to confirm its primary sequence. The amount of analysis required to do this will depend on the intended use of the protein. For many investigators the analysis may consist of limited N-terminal and C-terminal sequencing, peptide mapping, and either amino acid analysis (*UNIT 3.2*) or molecular weight determination using mass spectrometry (Chapter 16). On the other hand, a full structural determination is usually required for proteins intended for pharmaceutical use.

UNIT 7.3 describes some techniques that give information on the primary structure. The method most commonly used to review the primary sequence of a protein is peptide mapping. Peptides derived from protein chemically or enzymatically fragmented are separated by HPLC or electrophoresis. The interpretation of the resultant chromatograms, or band patterns, is based on the specificity of the cleavage method (usually very selective) and the expected sequence of the protein. Often comparisons are made with well-characterized standards. The most common post-translation modification is the oxidation of paired sulfhydryl residues to form a disulfide bond. The technique of peptide mapping is usually used to determine which sulfhydryl residues are paired (the linkage pattern). Specific details of HPLC methodology (Chapter 11) and gel electrophoresis (Chapter 10) are detailed elsewhere and peptide analysis using mass spectrometry will be described in Chapter 16. The electrophoretic technique of two-dimensional titration curve analysis is also included in *UNIT 7.3*, as it can give information on the charged residue composition of the protein in addition to guiding the selection of ion-exchange resins used for protein purification.

The topic of protein conformation is addressed in *UNIT 7.4*, in which the electrophoretic method known as transverse urea-gradient gel electrophoresis (UGGE) is described. The unfolding of a protein exposed to a linear gradient of urea (usually 0 to 8 M) is monitored simply by observation of the electrophoretic mobility. Gel patterns can be analyzed to estimate conformational stability and help identify covalent or conformational heterogeneity. Spectroscopic methods such as circular dichroism (*UNIT 7.6*) and fluorescence (*UNIT 7.7*), and to a lesser degree, UV-spectroscopy (*UNIT 7.2*), are among the standard methods used to analyze protein conformation, and descriptions of these methods are planned for this chapter. However, for investigators not wishing or not able to invest in expensive and dedicated equipment, the gel electrophoretic approach described herein may be a useful alternative, although not as flexible or rigorous (potentially) as spectroscopic and calorimeter-based methods.

For a purified protein, determination of the molecular weight and physical homogeneity in solution are of fundamental importance. With recombinant proteins the molecular weight can be predicted from the cDNA coding sequence and rapidly confirmed by mass spectroscopy (Chapter 16). Determination of the molecular weight of the native protein in solution is not so straightforward, but is still fairly routine using the modern analytical ultracentrifuge. *UNIT 7.5* is an overview of analytical ultracentrifugation that includes a discussion of methods for determining both the molecular weight and hydrodynamic properties of proteins.

Light-scattering methods can also provide information about the native molecular weight, oligomeric composition, and overall conformation. Techniques using size-exclusion

BCU IAS / CENTRAL UNIVERSITY LIBRARY

chromatography with on-line light scattering detectors are especially useful for characterizing proteins and glycoproteins (for review see Wen et al., 1996). *UNIT 7.8* provides an overview of the various light-scattering methods used to characterize proteins and macromolecular complexes. It should be noted that this method, like analytical centrifugation, provides direct molecular weight information without the use of calibration standards or models.

Circular dichroism and fluorescence spectroscopy are popular methods for determining protein conformation. Basic protocols for determining the circular dichroic spectra of proteins are described in *UNIT 7.6* and for determining the fluorescence spectra in *UNIT 7.7*. Circular dichroism and fluorescence spectroscopy are similar to most other spectroscopic methods in that careful interpretation of the data is required together with an understanding of the limitations and pitfalls of the method. These points are emphasized throughout these units.

Differential scanning calorimetry (DSC), described in *UNIT 7.9*, is an instrumental method used to measure heat energy uptake (heat capacity) in proteins undergoing thermal denaturation. This is accomplished by varying the temperature of a dissolved protein sample and measuring the difference in heat generated by the protein compared to a reference cell that contains solvent alone. This heat difference is related to the conformational energy of the protein molecule. In practice, when proteins undergo thermal denaturation, typically at 40° to 80°C, there is usually heat generated (i.e., it is an exothermic process); this heat can be very accurately measured by modern DSC instruments. The unit discusses the theoretical background of the method and details methods for actually performing DSC. For background on basic thermodynamic principles consult, for example, Tinco et al. (1995), and for overview of DSC applications in biotechnology see Chowdhry and Cole (1989). The Internet sites of the various instrument manufacturers are also useful sources of information.

CONFORMATIONAL ANALYSIS OF RECOMBINANT-PRODUCED PROTEINS

The assays for many protein functions, for example in the case of cytokines, can be time consuming and of relatively low precision. As proteins depend for their function on the correct 3D fold of the polypeptide chain, demonstration that the conformation of the recombinant protein is the same as that of the authentic protein should provide a more convenient means of characterizing the product. The methods described in *UNITS 7.4, 7.6 & 7.7*, although providing average structural information only, as compared with X-ray crystallography or NMR, are sensitive indicators of conformation and conformational change and, as such, can provide a highly specific "fingerprint" of a protein. Such conformational analysis will follow assurance of chemical authenticity and homogeneity, as described in *UNITS 7.1-7.3* (and elsewhere in the book). Urea gradient gel electrophoresis (*UNIT 7.4*) is a hydrodynamic technique that monitors the degree of compactness of the protein. It allows unfolding and refolding to be studied, leading to characterization of the protein in terms of its stability and kinetics. Near-UV circular dichroism (CD) results in spectra that are characteristic of the polar asymmetry of the environments of the aromatic residues, mainly tryptophan and tyrosine. Far-UV CD monitors the polypeptide backbone conformation, and hence, the secondary structure. Fluorescence spectra are determined chiefly by the polarity of the environment of the tryptophan and tyrosine residues and their interactions.The four techniques thus provide different, but complementary, fingerprints of the protein conformation that provide a high degree of assurance of nativeness within a few hours. For quality assurance of the native conformation and for general

BOJANA CENTRAL UNIVERSITY LIBRARY

characterization, it is important to employ as broad a range of the available techniques as possible.

Besides confirming the nativeness of the folded conformation of a sample of a protein that has already been characterized, either as the previously produced recombinant protein or as the authentic protein, the techniques described here offer a rapid means of obtaining structural and dynamic information, together with estimates of the stability of the protein.

Overview of the Characterization of Recombinant Proteins

With the advent of recombinant DNA technology and the availability of numerous expression systems, scientists are now able to prepare large amounts of proteins in relatively short periods of time. Many of the proteins produced by this technology are new and previously uncharacterized. Current developments in protein purification techniques, especially the use of affinity matrices, can eliminate a number of less-specific purification steps, accelerating this process. It is still challenging, however, to purify a protein to complete homogeneity, removing all proteinaceous and nonproteinaceous contaminants.

How clean a protein product needs to be largely depends on its final use. Some applications require exhaustive testing to ensure that no foreign material accompanies the protein. This is extremely important, for example, when the protein is to be used therapeutically, because even a minor contaminant can lead to side reactions that may be fatal. For such applications, it is therefore critical to evaluate the recombinant protein not only for its physical impurities, but also for its potential to cause immunogenic or allergic responses (Bristow, 1989). Strict guidelines for validating the purity of proteins for therapeutic use are in place at the U.S. Food and Drug Administration (Geisow, 1991; Garnick et al., 1991).

Such careful characterization may not be required for proteins used in research, where a slight impurity may not affect the activity of a protein. It is known, however, that failure of crystallization is often due to microheterogeneity of the protein. The most troublesome impurities result from deamidation of Asn and Gln, Cys oxidation, proteolysis, sequence polymorphisms, and variability in post-translational modifications (Wood, 1989).

A number of different expression systems are available for producing recombinant proteins, including bacteria (most commonly *E. coli*), yeast, insect cells, and mammalian cells infected with retroviruses (Chapter 5). Bacterial expression systems are generally the easiest to handle, and the first systems tried. Some proteins, however, require specific post-translational modifications (e.g., phosphorylation, glycosylation, and/or fatty acid acylation) for optimal activity, thus forcing the use of the other (eukaryotic) expression systems. Each expression system has its own set of advantages and disadvantages (Chapter 5), and each has its own set of likely contaminants. A comprehensive set of analytical techniques is available to ascertain the purity of the protein products.

COMMON SOURCES OF CONTAMINATION

Contaminating Proteins

It is critical to check that the sample is free of other contaminating proteins. The hardest to detect and eliminate are those of similar molecular weight, pI, and hydrophobicity. The best way to analyze for such impurities is by HPLC, using at least two complementary chromatographic separations (e.g., reversed-phase chromatography on a C4 column and ion-exchange chromatography, or the use of two types of ion-pairing agents in reversed phase) with the aid of a diode-array detector. Another powerful method is the use of high-resolution peptide mapping by HPLC, alone or in combination with electrospray mass spectrometry (Scoble and Martin, 1990; Carr et al., 1991) or matrix-assisted laser-desorption ionization time-of-flight (MALDI TOF) mass spectrometry (see *UNIT 11.6*).

If authentic pure protein is available for comparison, proteolytic digestion of both the authentic and the recombinant protein under the same conditions can be used to assess purity of the recombinant protein. Both proteins should generate the same fragmentation pattern; differences may be interpreted as being due to contaminants or as indicating chemical heterogeneity. Electrospray and MALDI TOF mass spectrometry eliminate the requirement for pure authentic protein, because the mass assignments for each proteolytic fragment of the recombinant protein are accurate enough on their own to indicate if the fragments are all derived from the parent protein. Any fragments that do not fit may belong to a contaminant or indicate incorrect primary sequence.

Proteolytically Clipped Proteins

Many proteins become proteolytically cleaved during the purification process, even in the presence of protease inhibitor cocktails, due to the ubiquitous distribution of proteolytic agents in cell lysates. In some circumstances it may be difficult to separate the fragments from the product of interest, especially when the protein is nibbled from one end or the other by

BOKU-UNIVERSITÄT LIBRARY

exoproteases, as these products will be almost the same size and have nearly identical physical properties. This task becomes especially difficult when the level of contamination is below normal detection levels. For proteins used therapeutically, this problem may have major ramifications, because it is well known that degraded proteins, or those that are not folded correctly, may be more antigenic than their intact counterparts, causing the patient to produce antibodies to the protein itself (Walsh and Headon, 1994). Determination of the N- and C-terminal sequences may be required to ensure purity from this type of contamination.

Nucleic Acid

Host DNA may accompany the purified protein. The main concern with this contaminant is the possibility that an oncogene from the host may be present in the sample. DNA is generally efficiently removed from samples by chromatography through anion exchangers such as DEAE. Spectroscopic measurements at 260 nm will indicate the presence of nucleic acids.

Pyrogens

Bacterial endotoxins and lipopolysaccharides can often accompany a protein through its purification (Bristow, 1989). These agents, if present even in small amounts, can produce fever in patients. Thus, for proteins used therapeutically, it is important to prove that such contaminants are not present in the sample. Apart from chromatography by HPLC, sensitive immunological methods also exist to test for the most common of these contaminants. For example, bacterial proteins can be detected by using antibodies against total *E. coli* cell lysates in immunoblots of the recombinant protein of interest. If the presence of lipopolysaccharides is suspected, they usually can be removed by gel filtration or by using membranes of the appropriate molecular weight cutoff, as these contaminants are very hydrophobic and tend to aggregate.

For further details on the detection and analysis of nonproteinaceous contaminants, see Walsh and Headon (1994).

CHEMICAL IDENTITY

Checking Primary Structure of Recombinant Proteins

Once the purity of the recombinant protein has been ascertained, it is imperative to prove that the isolated protein indeed has the correct amino acid sequence. There are a number of analytical techniques that can be used to characterize the protein, each providing different but overlapping answers. Some of the techniques are more exacting than others. They all, however, generally require expensive instrumentation, such as HPLC machines or mass spectrometers, that may not be available in all laboratories. Other techniques are less precise in their measurements, but provide reasonable data if authentic protein is available as a control.

The first test is to determine the mass of the recombinant protein, especially as it compares to the authentic protein. This can be accomplished in most laboratories by SDS-PAGE. Although the mass determined in this manner is not very accurate, it can be compared to the control to determine whether the protein is close to the right size. A more precise measure of the mass can be obtained by mass spectrometry, either electrospray or MALDI TOF. These measurements are generally within 0.01% to 0.05% of the correct mass.

Next, it is useful to determine the isoelectric point (pI) of the recombinant protein. This can be accomplished by isoelectric focusing (IEF) gel electrophoresis (*UNIT 10.2*) using flat-bed agarose or acrylamide gels or slab gels. The pI is determined from a standard curve constructed using IEF standards (proteins of known pI). It is good practice to include the native protein, if available, in an adjacent lane. Differences in pI from the expected value are diagnostic for differences in charged amino acids.

A small sample of the protein (1 to 5 μg) should be analyzed for its amino acid composition. This can usually be done in a protein chemistry core facility, available at most universities, for a small fee. This analysis should provide confirmation that all the expected amino acids are present in the protein. A second sample (25 to 50 pmol) should be submitted for N-terminal amino acid sequencing. This sample can be provided on a PVDF membrane (electroblotted from an SDS gel), or in solution (provided the sample is free of salts). This analysis should verify that the protein starts with the expected sequence, an important consideration if the N-terminal Met is cleaved after translation. A blocked N-terminus, such as occurs when the terminal amino acid is post-translationally modified, requires special procedures to be identified (LeGendre et al., 1993).

High-resolution peptide maps (fingerprinting) provide information on internal sequences

by comparing digests of the recombinant and the authentic protein, both treated under the same conditions. The best diagnostic fingerprints are analyzed by HPLC, where the retention times of over a hundred different fragments can often be compared. A difference in amino acid sequence between the recombinant protein and the authentic protein is highly likely to result in a change in the mobility of at least one fragment. If an HPLC unit is not available, one can get relatively good information from analysis of digested proteins by high-resolution SDS-PAGE. In that case one should use multiple partial digests to compare fragments that are ≥2 kDa in size. The Tris-tricine gel system (*UNIT 10.1*) is recommended for this type of analysis.

New, powerful methods are being developed that combine peptide mapping with mass spectrometry (Pappin et al., 1993). In these procedures, the mass of each fragment is obtained with high accuracy, allowing direct comparison with the predicted sequence from the cDNA. Thus, it is not necessary to include the authentic protein in the analysis, unless post-translational modifications are expected.

Characterizing Post-Translational Modifications

It is important to determine the nature and location of all post-translational modifications of recombinant proteins. Among the most problematic are unwanted, nonspecific modifications, including oxidation of Met residues and chance deamidation of Asn or Gln. These modifications can easily be detected as retention time shifts when HPLC profiles of peptide maps of the recombinant protein are compared to those of the authentic protein. The presence of reducing agents, such as 2-mercaptoethanol or dithiothreitol, in the isolation buffer often prevents oxidation of Met.

There are situations in which one wants to determine if the correct post-translational modification has been made in the recombinant protein, especially if the modification is important for the activity of the protein. Usually, the expression system has been carefully selected to provide the appropriate modification. Among the most frequent post-translational modifications are phosphorylation, N-methylation, acetylation, glycosylation, farnesylation, and sialic acid capping of oligosaccharides.

Pinpointing these modifications can be time-consuming, requiring specific methods for each modification if traditional approaches are to be used (see Chapters 12 and 13 for protocols for determining sites of glycosylation and phosphorylation). The usual method is to digest the recombinant protein, separate the fragments by HPLC, then pick fragments suspected of being modified for further analysis by N-terminal sequencing using Edman chemistry. A major disadvantage to this approach is that some of the modifications are not stable when exposed to the chemicals used in sequencing, and will therefore be missed. For example, phosphorylated Ser and Thr residues are not easily detected because they undergo β-elimination of the phosphoryl group (Mercier et al., 1971). Instead, a system using radioactive tracers has been developed in which the assignment of the phosphorylation sites is based on the release of [^{32}P]Pi during Edman degradation (Wettenhall and Cohen, 1982).

Newer approaches are being developed that rely on mass spectrometry to pinpoint the location of the modifications (Wang et al., 1994). These approaches offer direct procedures for identifying the modified residues and should cut the time required for analysis.

PHYSICAL AND CONFORMATIONAL CHARACTERIZATION

Once the chemical identity of a protein has been established, its physical and conformational properties are probed using a variety of biophysical techniques. Unlike chemical analysis, most of these techniques require that the protein be pure, as otherwise the interpretation of the data can be difficult or impossible. Some of the basic questions that are addressed are: (1) Is the protein monodisperse? (2) What is the quaternary (subunit) structure? (3) Is the protein folded? (4) What are the secondary and tertiary structures of the protein?

The commonly used methods for studying protein conformation and structure are listed in Table 7.1.1 (nonspectroscopic) and Table 7.1.2 (spectroscopic). References have been included that emphasize the practical aspects of the various techniques. Because of the complexity of the subject matter, several outstanding textbooks that cover most of the theoretical background have also been cited (see Key References).

Physical Appearance and Absorbance

It is always useful to visually inspect purified protein placed in a glass or quartz cuvette; it may be obvious on holding the cuvette up to the light that the protein is colored, cloudy, or perhaps slightly opalescent. For recombinant

BOUNTIFUL ETRAL UNIVERSITY LIBRARY

Table 7.1.1 Nonspectroscopic Methods for Studying Protein Structure and Conformation

Method	Information obtained	Notes	Reference(s)
Urea gradient electrophoresis	Size, shape, and unfolding transitions	Amount of material required depends on size of gel and detection system. If antibodies are used, crude samples can be analyzed.	Goldenberg (1989)
Gel filtration	Size, shape, and molecular interactions	Most commonly used method for determining molecular radii. M_r can be determined if sedimentation coefficient is known. Conformation changes can be followed.	Ackers (1970); Ptitsyn et al. (1990)
Ultracentrifugation		Various sedimentation velocity measurements used to gain information on shape/conformation.	
Sedimentation velocity	Shape	Useful check of homogeneity. Determination of sedimentation coefficient (S). S is sensitive to protein conformation. Small differences in S between samples may be difficult to detect.	Van Holde (1975); Harding (1994); Ralston (1993)
Difference sedimentation	Shape	The measurement of very small differences in sedimentation coefficient (~0.01 S). Sensitive to very small conformation differences between samples.	Van Holde (1975)
Sedimentation equilibrium	Molecular weight, quaternary structure, and molecular interactions	The method of choice for direct determination of the molecular weight (precision ±3%). Also widely used for studying reversible self-association of proteins and ligand binding.	Van Holde (1975); Harding (1994); Ralston (1993); McRorie and Voelker (1993)
Accessibility assays			
Protease sensitivity	Conformation	Protease action on folded proteins depends on both the cleavage-site specificity and its accessibility. In unfolded proteins only the former is important.	Price and Johnson (1989)
Chemical reactivity	Conformation	Similar in principal to above except using chemical reagents specific for various amino acid side chains (e.g., sulfhydryl reagents).	Ballery et al. (1993)
^2H and ^3H-exchange	Conformation/dynamics	HPLC and NMR used to measure exchange reactions.	Englander and Kallenbach (1984)
Calorimetry			
Differential scanning	Conformation; thermal stability	Measurement of heat uptake (heat capacity) during change in temperature. Used for study of thermal unfolding of proteins and nucleic acids. In modern instruments sample requirements are modest: 1-2 ml at 0.5-2.0 mg/ml per scan. Proteins often irreversibly denature at neutral pH; this is sometimes circumvented by analysis at acid pH or by addition of low concentrations of chaotropes.	Sturtevant (1987); Cooper and Johnson (1994)
Isothermal titration	Molecular interactions	Direct measurement of the energetics of bimolecular interactions (including binding constants). Larger samples needed than for differential scanning.	Cooper and Johnson (1994)

Bimolecular interaction analysis	Molecular interactions	Bimolecular interaction analysis using the Pharmacia BIAcore instrument. Uses surface plasmon resonance to detect bimolecular interactions. Examples: protein ligand binding to receptor, protein binding to nucleic acid, and antibody-antigen interactions. Wet chemistry required to immobilize one of the reaction partners on a matrix.	Chaiken et al (1993); Cunningham and Wells (1993)
Immunological assays	Conformation	Affinity of an antibody for its antigen depends on the structural complementarity between the molecules. Changes in the antigen conformation result in changes in the binding affinity for appropriate antibodies. Monoclonal antibodies are usually used.	Figuet et al. (1989)

proteins isolated from *E. coli*, all of these observations are usually bad news. Running an absorption spectrum from 240 nm (in the near-UV) to 600 nm (in the visible region) will enable one to decide if the protein is partially aggregated or is contaminated with colored chromophores. The absorbance of a ~1 mg/ml protein solution (using a 1-cm path length cell) in the region of 400 and 320 nm should be <0.05; this is a spectral region where pure protein does not absorb, and high absorbance (>0.1) is usually due to light scattering from aggregated protein. It should be noted that light scattering from macroscopic particles increases with decreasing wavelength; hence, the detection of scattering artifacts is aided by measuring an absorption spectrum rather than single wavelengths. Filtration with a 0.2-μm-pore-size filter, or low-speed centrifugation, often removes the material responsible for light scattering. A clearer picture of what proportion of the sample is aggregated requires further analysis by gel-filtration (see discussion of Molecular Size and Subunit Structure) or analytical ultracentrifugation. The main absorption peak should be at ~280 nm and the A_{280}/A_{260} ratio should be ~1.5 to 2.0. If there is high absorbance at 260 nm, it may be due to nucleic acid or other chemical contaminants.

Molecular Size and Subunit Structure

The next step is to apply the sample to a gel-filtration column to see if the protein elutes in a single symmetrical peak as expected for a monodisperse protein (*UNIT 8.3*). The appearance of material eluting at the void volume of the column indicates highly aggregated protein. If the column is calibrated with molecular size markers, an approximate idea of the size can be obtained. It should be remembered that to get an accurate molecular weight, it is necessary to combine the gel-filtration data with a knowledge of the sedimentation coefficient, which must be obtained either by analytical ultracentrifugation or density gradient analysis (*UNIT 4.2*).

If the molecular weight of the native protein is known, the subunit composition can be determined, as the monomeric mass is known from the amino acid sequence translated from the DNA coding sequence. The only commonly used methods capable of directly determining molecular weight are sedimentation equilibrium and light scattering (osmotic pressure measurement also gives this information but is rarely used nowadays).

Determination of the molecular weight of recombinant glycoproteins by gel filtration is especially unreliable. If the amount of carbohydrate associated with the protein has been determined (e.g., by mass spectrometry), the molecular weight can be directly determined by sedimentation equilibrium. With ultracentrifugation, the association state of a glycoprotein (e.g., whether it is a monomer or dimer) can be determined even when the carbohydrate composition is unknown (Pennica et al., 1992; Shire, 1992).

Apart from some of the methods referred to above, a more modest approach, equipment-wise, to molecular weight determination is the use of native gel electrophoresis (*UNIT 10.3*).

Conformation and Structure

It is important to assess if the purified recombinant protein has been folded correctly,

EDINBURGH CENTRAL UNIVERSITY LIBRARY

Table 7.1.2 Spectroscopic Methods for Studying Protein Structure and Conformation

Method	Information obtained	Notes	Reference(s)
Ultraviolet absorption			
Standard spectroscopy	Secondary and tertiary structure	Method available to most laboratories. Modern instruments have diode array detectors and are computer controlled.	Wetlaufer (1962)
Difference spectroscopy	Conformational change	Spectral differences between perturbed (e.g., using pH, temperature, and denaturants) and nonperturbed samples give information on relative conformation.	Donovan (1969, 1973)
Fluorescence		Very sensitive; small samples needed compared to other spectroscopic methods.	
Steady-state	Secondary and tertiary structure	Intrinsic fluorescence mainly due to tryptophan. Proteins can be labeled with fluorophores (extrinsic fluorescence). Steady-state quenching studies give information on exposure of chromophores.	Chen et al. (1969); Haugland (1994)
Time-resolved	Conformational change	Trp fluorescence lifetimes (decay time) lie in the nanosecond region. Molecular dynamics can be studied by time-resolved quenching and depolarization.	Eftink and Ghiron (1981); Varley (1994)
Circular dichroism	Conformational change	One of the most commonly used techniques to compare overall (or gross) conformational properties of proteins.	
Far-UV	Secondary structure	Measurements in the range 240-180 nm. α-helix most accurately determined. Computer-aided analysis of spectra by various methods to estimate secondary structure contents.	Yang et al. (1986); Johnson (1990)
Near-UV	Tertiary structure	Measurements in the range 340-240 nm. Depends on environment of aromatic residues. Conformational fingerprint. Interpretation not easy, but useful for comparative purposes.	Strickland (1974)
Raman scattering	Secondary structure	Raman scattering (and infrared absorption) known as vibrational spectroscopy. Useful for large macromolecular assemblies, precipitates, and crystals. Secondary structure estimates using Raman Amide I and III spectra.	Bussian and Sander (1989); Williams (1986)
Infrared absorption	Secondary structure	Modern computerized Fourier transform (FT-IR) instrumentation used; allow measurements in H_2O (particulate samples can also be measured). Secondary structure from Amide I spectra. Better than circular dichroism for β-structure estimation.	Haris and Chapman (1992, 1994); Surewicz et al. (1993)
Light scattering		Direct M_r determination (cf. sedimentation equilibrium). Especially useful for large macromolecular assemblies.

Table 7.1.2 Spectroscopic Methods for Studying Protein Structure and Conformation, continued

Static light scattering	Molecular weight and shape	Classical light scattering. Modern instruments use lasers. Samples must be dust-free. Determination of M_r requires that the refractive index increment (dn/dc) be known. M_r distributions and conformational information can be obtained by combining gel filtration with an in-line multi-angle light scattering detector.	Harding (1994)
Dynamic quasi-elastic	Shape and molecular weight	Also known as photon correlation spectroscopy. The translation diffusion coefficient (D) is measured. Knowledge of the sedimentation coefficient (S) is required to determine M_r.	Harding (1994); Phillies (1990)
Nuclear magnetic resonance			
^1H	Secondary structure; 3-D structure of small proteins and polypeptides (<10 kDa)	Large sample requirements. Proteins must be very pure and stable.	Clore and Gronenborn (1992)
Multidimensional	Secondary structure; 3-D structure of proteins 10-30 kDa	Proteins uniformly labeled with combinations of ^{15}N, ^{13}C, and ^2H by expression in *E. coli* using minimal medium (see *UNIT 5.3*). 2-D ^1H-^{15}N correlation spectra are very useful as protein conformational fingerprints.	Clore and Gronenborn (1994)
X-Ray diffraction	3-D structure at atomic resolution	Proteins must be crystallized. Commercially available Crystal screen kit widely used.	McRee (1993); Ducruix and Giege (1992); Hampton Research
Scanning transmission electron microscopy	Molecular weight	Scanning transmission electron microscopy; mass determination of individual molecules. Useful for large particles beyond the mass range of sedimentation equilibrium.	Thomas et al. (1994)

especially if it was prepared from inclusion bodies (insoluble aggregates of the over-expressed protein), which are often found in bacterial expression systems (*UNITS 6.3-6.5*). Spectroscopic methods and calorimetry are the usual techniques used to monitor or measure protein conformation. Urea-gradient electrophoresis is also used and has the advantage that pure protein is not required. It is advantageous—as in mapping the chemical identity of the protein—to have some type of standard available for comparative purposes. The power of the spectroscopic methods, especially circular dichroism (CD) and fluorescence, lies in their ability to detect differences rather than to make absolute determinations. The standard may be the natural or authentic protein or may be the same recombinant protein separately prepared and analyzed by independent methodologies.

Apart from the use of protein standards, model compounds are often used as conformation standards (especially for fluorescence and UV spectroscopy). These may be the free amino acids tryptophan and tyrosine: the model protein is constructed using the appropriate molar ratio of tryptophan and tyrosine and represents a fully denatured protein in which the aromatic residues are fully exposed to the solvent. Alternatively, the recombinant protein can be denatured with 4 to 8 M guanidine·HCl (see *APPENDIX 3A*). Comparison of either simulated or denatured protein with the test protein will give some indication of whether the protein is folded.

The most commonly used spectroscopic methods are CD and fluorescence. Nuclear magnetic resonance (NMR) spectroscopy measurements are especially useful when the recombinant protein is uniformly labeled with

UCSF MISSION BAY CONTRA COSTA UNIVERSITY LIBRARY

^{15}N; for example, ^{1}H-^{15}N correlation spectra are excellent protein conformational fingerprints. (A conformational fingerprint is related to the overall tertiary structure as a classical two-dimensional peptide map is related to the primary sequence.) CD spectra in the far-UV region (240 to 180 nm) can be used to estimate secondary structure, and spectra in the near-UV region (350 to 240 nm) give information on the tertiary structure. When interpreting CD spectra, it should be borne in mind that a protein can have an apparently normal far-UV CD spectrum, yet have a near-UV spectrum characteristic of an unfolded protein. This is characteristic of partially folded protein or so-called molten globules (*UNIT 6.4*).

Apart from the analysis of recombinant proteins that contain the native sequence, mutant proteins are produced for various structure-function studies. It is almost mandatory for some conformational analyses to be made on these proteins so that functional differences can be related to specific chemical differences (i.e., different amino acid side chains) rather than merely being explained as due to conformational perturbation. For an example of a spectral-based analysis of site-directed mutants, see Mulkerrin and Cunningham (1993).

The folding question is also important for proteins prepared by other expression systems (e.g., yeast and baculovirus). Although these systems offer the advantage of providing proteins with the correct post-translational modifications and thus by supposition the correct structure, it is critical to demonstrate that the recombinant product has the same secondary and tertiary structures as the authentic protein. Incorrect disulfide bonding is sometimes encountered in these systems and will introduce conformational heterogeneity.

When analyzing protein conformation, it is a mistake to depend on any one physicochemical technique, especially the spectroscopic methods. The more corroborative data that is accumulated using different techniques and approaches, the more reliance can be placed on any conclusions.

For spectroscopic analysis, the ideal sample is protein freshly purified by all titration. The peak fractions of a symmetrically shaped elution peak are tested using the column elution buffer as reference material. If rapid buffer exchange is required, for example to remove excess salt prior to far-UV CD measurements, the sample (0.1 to 1.0 ml) can be applied to a prepacked column (1.5-cm diameter × 5 cm) of Sephadex G-25 (PD-10 columns from Pharmacia Biotech) and eluted in <5 min.

High-Resolution Structure

The ultimate test of a protein's structural integrity and conformational homogeneity is determination of its three-dimensional structure. For X-ray structure determination, crystals must be obtained that diffract to high resolution (<3 Å). The fact that the protein can be crystallized is in itself a fairly good indication that the preparation is both physically and chemically homogeneous. For reviews of the methodologies involved in protein crystallization and X-ray diffraction, see McRee (1993) and Ducruix and Giege (1992).

Structural determination of proteins in solution can be achieved by NMR spectroscopy. For small proteins (<10 kDa), conventional homonuclear two-dimensional methods have been used. For larger proteins, three- and four-dimensional heteronuclear methods are required to resolve the spectral complexity due to the larger numbers of protons. For this purpose, proteins expressed in *E. coli* are uniformly labeled with ^{15}N and/or ^{13}C as mentioned in *UNIT 5.3*. Structures of medium-sized proteins (~15 to 20 kDa) can be determined at high resolution using the current methodologies. For further details see references listed in Table 7.1.1 and Table 7.1.2.

Biological Activity and Immunogenicity

The biological activity of the isolated protein should be carefully studied. When possible, the activity should be compared to that of the authentic protein. For an apparently pure protein, a lower activity is often a clue that the protein has not folded correctly, is partially aggregated, or has been improperly post-translationally modified. A low specific activity may also indicate the presence of other proteinaceous contaminants that have been undetected by the analytical methods used. It is of course essential to accurately determine protein concentrations (Chapter 3) in order to make realistic comparisons between samples.

The main problem with all types of activity measurement is to know what proportion of the preparation is active. For an enzyme, active-site titration can give this information (Fersht, 1985). However, a small proportion (<5%) of any preparation may be inactive due to denaturation upon storage and standing, and this would not be detected by most of the spectroscopic methods referred to above. The presence

ECU IASHG CENTRAL UNIVERSITY LIBRARY

of small amounts of misfolded protein may normally be of no consequence, the main requirement being that the protein have similar biological activity to the standard. (The standard, especially if it is an authentic protein, will probably be even less well characterized than the recombinant protein).

If, on the other hand, the protein is to be used for in vivo studies, misfolded protein may be immunogenic and, thus, must be considered as a contaminant even though it may be chemically indistinguishable from the correctly folded protein. This is of special concern for therapeutic proteins, especially those repeatedly administered (for review, see Walsh and Headon, 1994).

The ability of antibodies to detect subtle conformational change has long been known (Goldberg, 1991). Conformational changes in local regions of the protein can be measured by determining changes in affinity. Furthermore, conformational differences between samples can be detected where spectroscopic and, more importantly, activity measurements, do not show a difference (Hattori et al., 1993).

BASIC PLAN OF ACTION

The task tree presented in Figure 7.1.1 is a suggested path for fully characterizing recombinant proteins. Some of the analytical techniques overlap in the type of information they provide. In order to avoid running multiple tests, we recommend using the high-technology methods, such as HPLC, mass spectrometry, circular dichroism, NMR, and fluorescence spectroscopy. However, if these are not available, good information can still be extracted from the more traditional approaches, keeping in mind that they are less resolving and therefore require complementary analytical strategies.

ANALYSIS OF N-TERMINAL HETEROGENEITY OF RECOMBINANT PROTEINS PRODUCED IN *E. COLI*

When a purified recombinant protein presents as a single band on an SDS-PAGE gel, gives a satisfactory amino acid analysis, gives the expected N-terminal amino acid sequence upon Edman degradation, shows the correct

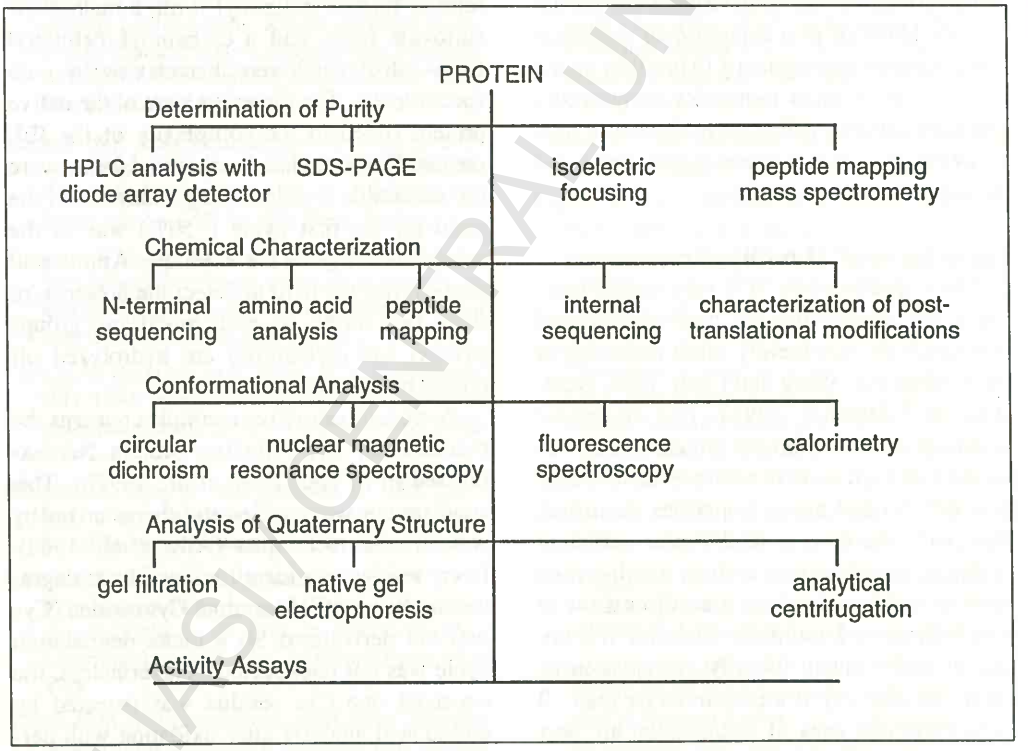

Figure 7.1.1 Task tree graphically representing the five steps (branches) required to fully characterize a recombinant protein. The first step is to determine the purity of the protein, which can be done by a variety of methods; the choice will depend on the availability of instrumentation and the degree of purity desired. This is followed by chemical characterization of the protein. Specific methods for the third and fourth steps, determination of protein conformation (folding) and structure, are listed in in Table 7.1.1 and Table 7.1.2. The last step, determining the activity of the protein, will require unique assays developed specifically for the protein of interest.

CHIMIE

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

disulfide bond linkages, and is biologically active, most people are quite satisfied. However, insufficient resolution on SDS-PAGE, imprecise amino acid analysis (4% at best) and bioassays, and nonquantitative yield (particularly on the first cycle) during Edman degradation may all combine to mask protein heterogeneity.

High-resolution, charge-sensitive techniques, such as two-dimensional gel analysis involving isoelectric focusing (*UNIT 10.4*) and capillary electrophoresis, may reveal quite extensive heterogeneity in proteins that seem pure by the criteria described above. This heterogeneity may be due to deamidation of Asn or Gln residues—some of which, because of their position in the polypeptide chain, may be particularly susceptible to hydrolysis of their side chain amide—but other explanations are possible. For example, the carboxy terminus may be "ragged" (i.e., longer or shorter polypeptide chains may be present, with not all molecules terminating at the same residue). A ragged N-terminus is normally detected by Edman degradation, but other forms of post-translational modification at the N-terminus can go unnoticed because the amino group is blocked and so not accessible to the Edman chemistry. Various kinds of post-translational modification can create heterogeneity (when they do not affect all the protein molecules in question), and some can affect all of the molecules in such a way that the product is homogenous but is not the expected protein product.

Importance of Mass Spectrometry

Mass spectrometry is a very useful technique for identifying all post-translational modifications, not merely those occurring at the N-terminus (Wang and Chait, 1994; Bradshaw and Stewart, 1994). The molecular weight of the recombinant protein can be obtained with high accuracy and precision (better than 0.01%) and minor impurities identified. This performance is normally quite sufficient to detect modifications such as missing residues or additional groups (see discussion of Two Instructive Examples). However, it is not usually sufficient to identify deamidation (1 mass unit change) of a protein larger than 10 kDa. Particular sites of deamidation are best located by peptide mapping, and *Staphylococcus aureus* V8 endoprotease Glu-C and *Pseudomonas fragi* endoprotease Asp-N are useful in this regard because they can cleave at the sites of Glu and Asp residues, respectively (*UNIT 11.1*). If deamidation has occurred to a small extent at many sites, the problem of locating such sites becomes much more difficult.

Ideally, a protein should be purified to a single species prior to characterization, but this is not always possible. Once it is known that a portion of the sample has different charge (by IEF) or mass (by mass spectrometry), attempts should made to identify the site and nature of the modification by peptide mapping (*UNIT 11.6*). As is evident from the two examples that follow, and from *UNIT 11.6*, mass spectrometry has an essential role to play in the characterization of recombinant proteins.

Two Instructive Examples

A simple but instructive example is that provided by interleukin 5 (IL-5). Recombinant human IL-5 expressed in *E. coli* is a single band on SDS-PAGE but shows several bands on IEF (Rose et al., 1992a). Electrospray ionization mass spectrometry showed a major component with the expected molecular weight (observed, 13282.5 ± 2; calculated, 13280.4), but also showed evidence of the presence of species of slightly greater molecular weight. Peptide mapping led to isolation of four forms of the N-terminal peptide—the expected (methionyl) form, a formyl-methionyl form, a methionyl-sulfoxide form, and a carbamoyl-methionyl form—all of which were characterized by mass spectrometry. The dimeric nature of the native protein added to the complexity of the IEF results. The formyl and carbamoyl forms were not accessible to Edman degradation, and the yield on the first cycle (~50%) was in the acceptable range for the technique. Amino acid analysis did not help to detect the presence of these two forms, as both modifying groups (formyl and carbamoyl) are hydrolyzed off during hydrolysis.

A second instructive example concerns the recombinant DNA-binding protein Ner expressed in *E. coli* (Rose et al., 1992b). This small protein was purified and characterized by conventional techniques (Allet et al., 1988). Every residue was identified by Edman degradation except the N-terminal Cys residue (Cys was not derivatized, so a blank degradation cycle was not unexpected). Nevertheless, the expected one Cys residue was detected by amino acid analysis after oxidation with performic acid. It was only when mass spectrometry showed that the protein was too heavy by 70 mass units that a problem was recognized. After much effort, involving peptide mapping, mass spectrometry, microchemistry, and two-dimensional NMR spectroscopy, it turned out

CUA CITY OF HOPE NATIONAL MEDICAL CENTER LIBRARY

that the N-terminal residue was modified with pyruvate, but in a way not involving the carboxyl group of pyruvate (Rose et al., 1992b). This modification was unstable in mild acid and in mild base (although stable at physiological pH), which explained why it had been missed when the protein was analyzed by Edman degradation and amino acid analysis. Thus, although the protein was blocked (N-terminally modified), the modifying group became detached during the first coupling step of the Edman chemistry and so was invisible to the technique.

Determining the Identity and Purity of Recombinant Proteins by UV Absorption Spectroscopy

Ultraviolet absorption spectrophotometry can be used to confirm the identity and, to a lesser extent, assess the purity of recombinant proteins and their peptide fragments. The near-UV (250 to 350 nm) absorbance spectrum of a protein is almost entirely a function of its aromatic amino acids—tryptophan, tyrosine, and phenylalanine (Fig. 7.2.1). Because each protein (gene product) has a unique amino acid sequence, the particular aromatic amino acid content of each protein results in a unique spectrum in the near-UV region. The highly specific microenvironment experienced by each aromatic residue in the three-dimensional protein matrix results in fine shifts in a protein's spectrum, which can be detected (Basic Protocol 1) and analyzed (Support Protocol). Thus, quality UV spectra serve as indicators of the structural integrity of proteins. In contrast to electrophoretic analyses (Chapter 10), UV spectroscopy allows the detection of nucleic acids, certain prosthetic groups, and metal ions which are frequently associated with proteins.

The unique UV spectral properties of proteins can in turn be used to assess their purity. This application is inherent in the use of a diode array detector to monitor the effluent

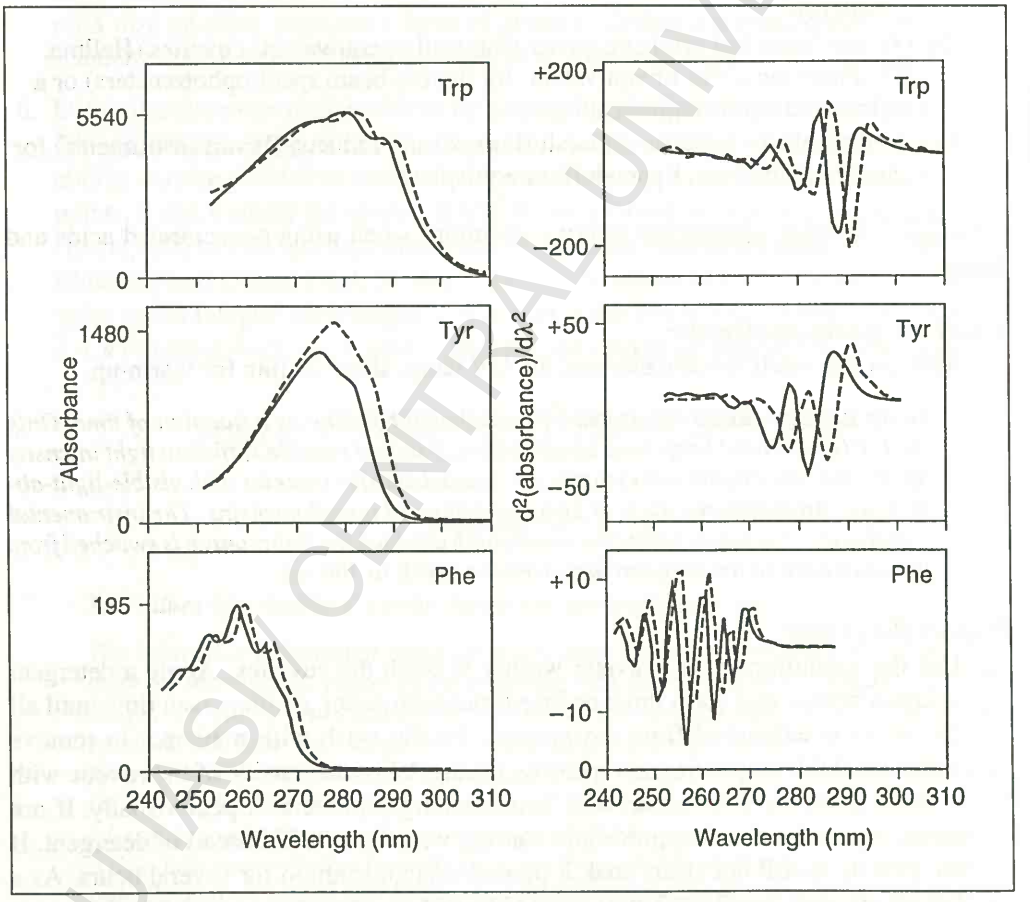

Figure 7.2.1 Normal (zero-order) and second-derivative spectra of aromatic model compounds: *N*-acetyl-L-tryptophanamide, *N*-acetyl-L-tyrosineamide, and *N*-acetylphenyl ethyl ester (solid lines) and "average" aromatic amino acid residues as determined using a set of globular, water-soluble proteins (dotted lines). Absorbance and second-derivative values correspond to 1 M solutions, 1-cm path length. The band positions in denatured proteins usually have intermediate positions.

from a high-performance liquid chromatography (HPLC) column. A protocol using this technique to assess the purity of recombinant proteins is presented in Basic Protocol 2.

BASIC PROTOCOL 1

ANALYSIS OF PROTEINS USING NEAR-UV SPECTROPHOTOMETRY

This procedure identifies proteins using near-UV spectrophotometry. Protein solution is placed in a UV-transparent quartz cuvette, absorption of light is measured as a function of wavelength, and the resulting spectrum is transferred either to a displaying device (e.g., CRT or printer) for inspection or to a computer that can employ a spreadsheet or other program for derivative calculations and/or quantitative analyses (see Support Protocol).

Materials

Detergent solution
Methanol
0.1 N hydrochloric acid
Acid/ethanol cleaning solution (see recipe)
10 N NaOH
4% holmium oxide (aqueous solution in 10% perchloric acid; see recipe)
Buffer identical to that containing the protein (reference standard)
Sample for analysis in solution at an appropriate concentration (e.g., 0.05 to 1 mg/ml; see below)

Vacuum-powered cuvette washer (NSG Precision Cells, Kontes Glass, or equivalent)
Two factory-matched synthetic quartz (Suprasil or equivalent) cuvettes (Hellma, NSG Precision Cells, or equivalent; for double-beam spectrophotometers) or a single cuvette (for single-beam use)
Gel-loading plastic pipet tips (Marsh Biomedical Products; Rainin Instruments) for a pipettor (Pipetman, Eppendorf, or equivalent)

CAUTION: Employ appropriate safety precautions when using concentrated acids and bases.

Ready the spectrophotometer

1. Turn on the spectrophotometer and the UV lamp; allow 20 min for warm-up.

   Lamp stability can be monitored by recording a baseline as a function of time. Only the UV (deuterium) lamp need be turned on; it should provide sufficient light intensity up to ~400 nm. Higher wavelengths are needed only for proteins with visible-light-absorbing chromophores, such as heme proteins and metalloproteins. The instrumental wavelength cross-over point (the wavelength at which the light source is switched from the deuterium to the tungsten lamp) must be set ≥ to 360 nm.

Prepare the cuvette

2. Use the vacuum-powered cuvette washer to wash the cuvettes. Apply a detergent solution briefly and wash three or four times with water, waiting each time until all the water is exhausted from the cuvette. Finally wash with methanol to remove water-insoluble impurities and speed up drying. Wipe the outside of the cuvette with a tissue (Kimwipe) or, better, with lens cleaning paper and inspect visually. If not clean, repeat the cleaning procedure starting with 0.1 N HCl instead of detergent. If the cuvette is still not clean, soak it in acid/ethanol solution for several hours. As a last resort, soak briefly (20 min) in 10 N NaOH.

   Cuvettes should always be cleaned immediately after use. Denatured proteins may often be removed by soaking overnight in a mild pepsin solution. Prolonged contact with the NaOH may partially dissolve quartz faces of the cuvette.

CSU IASI CENTRAL UNIVERSITY LIBRARY

Set up appropriate instrument parameters

3. Identify the cross-sectional area of the light beam (from the instrument's instruction manual) and determine the correct height to which the cuvettes should be fitted.

   The light beam may be as large as 1 × 2 cm. The sample volume must be large enough so that the meniscus is completely above the beam. The light must not impinge on the air-solution interface. If the beam is wider than the portion of the cuvette containing the solution, the remaining portions of the cuvette walls should be masked by a light-absorbing coat; special blackened cuvettes are available for this purpose. In some instruments the height of the beam can also be reduced; do so if sample availability is a problem. The cuvettes must be positioned vertically; any deviations may alter the effective path length and reduce the precision of measurements.

4. Adjust the wavelength (scanning) range to 240- to 360-nm. For diode-array spectrophotometers, use 10-sec measurement times. For conventional scanning spectrophotometers use bandwidths of 1 or 2 nm, time constants (response times) of 2 sec (medium) or less, and scanning speeds of 60 nm/min or less. Set the data point interval to 1 nm (scanning instruments only).

   Use the same settings if spectra are to be compared to previously collected ones.

Measure the spectrum of a reference standard

5. Measure the baseline (background) spectrum with no cuvettes in the sample holders. Insert a sealed cuvette containing 4% holmium oxide (aqueous solution in perchloric acid; Weidner et al., 1985) into the sample holder. Measure the spectrum and save it on a disc or other permanent form of storage. Collect a second spectrum using a scanning speed approximately one-half of that initially used.

6. Determine the exact peak positions by calculating the first-derivative spectrum in the 280- to 290-nm range. If the spectrophotometer has a built-in derivative calculation ability, choose derivative order 1, polynomial degree 2, and a window of five data points. If not, transfer the spectra in ASCII (text) format (or type it) into a spreadsheet (Excel, LOTUS-123, or equivalent) and perform the calculation using Equation 7.2.1 (Savitzky and Golay, 1964; Steiner et al., 1972), where FD(λ) is the first-derivative value at the integral wavelength λ, $A(\lambda \pm n)$ is the absorbance values at wavelength $\lambda + n$ (where $n = -2, -1, 1$, and 2), and k is the data point interval (in nanometers).

$$FD(\lambda) = \frac{-2[A(\lambda-2)] - A(\lambda-1) + A(\lambda+1) + 2[A(\lambda+2)]}{10 \times k}$$

Equation 7.2.1

   The values of n double if a 2-nm data point spacing is employed.

   The derivative calculation using an Excel spreadsheet is performed as follows: (1) copy the absorbance values of the spectrum into the first column (typically A1:A100 range); (2) fill second column (B1:B100) with the corresponding wavelength values, entering the first wavelength and using Edit/Fill/Series commands; (3) enter the formula in the cell of the third column, which corresponds to A(λ) absorbance value (B3)—e.g., for Equation 7.2.1 and k=1, cell C3 contains =(−2×A1−A2+A4+2×A5)/10 (derivative values cannot be calculated for first two and last two data points because a five-data point window is used); (4) copy the content of that cell (the formula) down onto the entire column (B3:B98) using Edit/Copy and Edit/Paste commands; and (5) use the Chart Wizard option to plot the resulting spectrum.

7. Note where the spectra cross the zero line (change sign from positive to negative) and calculate the exact positions of these intercepts using Equation 7.2.2, where λ is

BOULDER / CENTRAL UNIVERSITY LIBRARY

the wavelength prior to the intersection point, k is the data point interval (in nanometers), and |FD(λ)| and |FD(λ + 1)| are the absolute values of the first derivative at the integral wavelengths λ (before the intersection point) and λ + 1 (after the intersection point).

$$\text{peak position (nm)} = \lambda + k\frac{|FD(\lambda)|}{|FD(\lambda)| + |FD(\lambda+1)|}$$

Equation 7.2.2

This equation arises from simple geometric interpolation, illustrated for the second-derivative spectra in the inset of Figure 7.2.2B.

Note that the resulting intersection point is the position of the peak near 287 nm and serves as a reference point for further determination of exact peak positions of the protein spectra.

8. Calculate the intersection point for the second spectrum collected using a slower scanning speed (scanning instruments only); if the position is different, decrease the time constant (response time) or use a slower scanning speed until the positions of the intersections become independent of these parameters.

Test for the proper response time only with the first spectra acquired. Once established, the settings can then be used with confidence. The 287-nm holmium oxide peak is found at 287.18 nm (for 1-nm bandwidths) and at 287.47 nm (for 2- and 3-nm bandwidth) on an instrument extensively verified by measurements of mercury and deuterium emission lines (Weidner et al., 1985). Commercial instruments will deviate somewhat from this value. Correct the wavelength results for proteins for the difference observed. Diode-array instruments (see Basic Protocol 2) will typically require such calibration once a year; scanning instruments should be calibrated frequently depending on use. If a holmium oxide standard is not readily available, Trp (monomeric amino acid) or a related compound can be used for reference purposes.

Measure the protein spectrum

9. Identify the number of light beams by looking at the number of sample holders and their positions in the sample compartment. In a double-beam spectrophotometer, use two matched cuvettes and perform an initial background (baseline) measurement with just buffer (identical to that in which the protein sample is dissolved) in both cuvettes. Then substitute protein solution for the buffer in the sample position cuvette, leaving the reference buffer in the other cuvette. Acquire the sample spectrum and subtract the previously measured background spectrum if necessary. In a single beam spectrophotometer, use a single cuvette. Measure the background with buffer in the cuvette. Then remove the buffer, measure the spectrum of the unfiltered protein solution using the same cuvette in the same orientation, and subtract the background spectrum (baseline).

Sample can be removed from the cuvette using a pipettor with gel-loading plastic pipet tips. Do not scratch the inner optical surface of the cuvette. Many proteins, especially when partially unfolded, strongly adhere to quartz and are not removed by brief detergent or organic solvent washes. If UV absorption peaks at 270- to 280-nm are detected in the baseline, clean the cuvette again (step 2).

10. Note the absorbance at the protein peak centered between 275 and 282 nm. If the absorbance value is >1.0 at the maximum, check the range of linearity of the instrument in use (from the instruction manual). If the absorbance value observed is above this range, dilute the sample or decrease the path length. If a fluorescence-type 2-5 × 10–mm cell is used, turn the cuvette sideways to reduce the path length. A new baseline should be obtained. If the absorbance falls below 0.2, carefully observe the

VJU IASI CENTRAL UNIVERSITY LIBRARY

noise levels and use longer acquisition times (both for the baseline and the actual spectrum).

11. Save the spectrum in a proper format for the particular instrument employed or transfer the spectrum in an ASCII (text) format to a disc for retrieval by a spreadsheet for further analysis. If this is not feasible, print or manually record absorbance values as a function of wavelength.

Most protein solutions containing 1 mg/ml protein have an absorbance near 1.1 ± 0.5 in the 280-nm region. If an estimate of the concentration of the solution is available, the sample can be diluted or concentrated to obtain an absorbance in the 0.2 to 1.0 range. Alternately, make a preliminary measurement at a single wavelength (e.g., 280 nm) to obtain this information. Note that with modern spectrophotometers very low values of absorbance (<0.01) can be accurately measured; however, care must be taken to avoid adsorption artifacts, as a substantial portion of the protein may now reside on the interior surface of the cuvette. This can be checked by obtaining a spectrum of the empty cuvette after carefully removing the protein solution.

INTERPRETING PROTEIN NEAR-UV SPECTRA

SUPPORT PROTOCOL

Normal (zero-order) spectra are spectra of absorbance versus wavelength as measured by a spectrophotometer without derivative calculation. Different regions of the spectrum contain information about various aspects of the structure of the protein. The 320- to 350-nm region may contain information about aggregation state (due to light scattering) or the presence of UV-absorbing prosthetic groups; the 250- to 300-nm region provides information about the aromatic amino acids and their environment (Fig. 7.2.1 and Table 7.2.1). Numerical calculation of the second derivative of the spectrum minimizes the effect of broad spectral components (such as light scattering or anion absorption), exaggerating fine structure originating from absorption by aromatic rings. This method is particularly useful for precise determination of tertiary structure–dependent band positions as well as for quantitative analysis.

Correct for light scattering

1. Examine the spectral region between 320 and 350 nm (Fig. 7.2.2 contains an example for a typical protein).

Significant "apparent absorbance" of gradually, almost linearly decreasing intensity with increasing wavelength indicates that a portion of the light beam did not reach the detector because it was scattered. Absorbance that falls to zero at 350 nm or does not gradually decline (Fig. 7.2.2) is probably true absorbance arising from prosthetic groups or contaminants.

2. Use Equation 7.2.3 to calculate optical density (OD) due to light scattering, where a and b are constants.

$$\log OD = a \log \lambda + b$$

Equation 7.2.3

If the instrument's software cannot make such a correction, use a spreadsheet (Microsoft Excel, LOTUS-123, or equivalent; see Basic Protocol 1, step 6 annotation, for an example) to generate the light-scattering curve using optical density values at 320 nm and 350 nm. Calculate the light-scattering correction from Equation 7.2.4, where $m = 64.32 - 25.67 \log \lambda$.

$$A_c = 10^{[(m+1) \times \log OD_{320} - m \times \log OD_{350}]}$$

Equation 7.2.4

BCU RSI / CENTRAL UNIVERSITY LIBRARY

If this is not feasible, calculate the light-scattering OD at 260 nm (m = 2.31) and 280 nm (m = 1.50) with a calculator. If significant light scattering is detected, remeasure the sample after filtration through a 0.1 to 0.45-micron diameter cut-off filter. The difference of protein concentration before and after filtration will indicate the fraction of aggregated protein. Compare the second-derivative spectra to determine whether the initial sample was homogenous.

Note that optical density (OD) refers to the total extinction of light produced by all processes (including light scattering) whereas absorbance (A) refers only to the actual absorption process. The coefficient a varies from –4 (the ideal case of scattering from a small particle, not larger than one-tenth the wavelength of the light; this situation is known as Rayleigh scattering) to +2.2 for submicron-sized aggregates (Mie theory, in which the scattering intensity becomes a complex function of molecular size; Timasheff, 1966). Because the light-scattering contribution to the optical density is almost linear in the 300- to 350-nm region, a simple linear fit using a spreadsheet or even a crude graphic estimate can serve as a rudimentary measure of the correction necessary to obtain the correct absorbance in the 250- to 300-nm range.

Visually recognize the presence of the individual types of aromatic residues

3. Inspect the spectrum in the 250- to 300-nm range.

A small inflection point on the declining shoulder of the main peak around 290 nm (Fig. 7.2.2) originates from Trp residues; the sharper the inflection point, the more homogeneous and apolar the average microenvironment of these side chains. The distinctive spectral features of Tyr residues are usually masked and less pronounced as a consequence of the less-sharp fine structure of these residues, their broadening by the medium, and their greater heterogeneity from their usually greater frequency in proteins. The presence of the Tyr residues can be deduced, however, from the deviation of the overall spectral shape from that expected for pure Trp. The presence of Phe residues is usually manifested as a series of weak but distinctive bumps superimposed on the rising 250- to 270-nm region, which is dominated by more strongly absorbing Trp and Tyr side chains.

Table 7.2.1 Spectroscopic Properties of UV-Absorbing Amino Acids, Natural Ligands (Prosthetic Groups), and Nucleic Acids

Chromophore	λ (nm)[a]	ε (M^{-1} cm^{-1})[b]
Tryptophan (in native proteins)	280	5540
Tyrosine (in native proteins)	280	1480
Disulfide bond (glutathione)	280	134
N-Acetyl-L-tryptophanamide	280	5390
N-Acetyl-L-tyrosinamide	275	1390
N-Acetyl-L-tyrosinamide	280	1185
N-Acetyl-L-phenylalanine ethyl ester	257	195
Cu^{2+} (azurin)	781	320
FAD (pyruvic dehydrogenase)	460	1270
Fe^{3+}-heme (cytochrome *c*, reduced)	550	2770
FMN (amino acid oxidase)	455	1270
Retinal-Lys (rhodopsin)	498	4200
DNA (native, per base)	258	6600
RNA (per base)	258	7400

[a]Wavelengths listed indicate the peak maxima, except for tyrosine, *N*-Acetyl-L-tyrosinamide, and L-cystine at 280 nm.

[b]Molar absorptivity values of tryptophan and tyrosine in native proteins as well as oxidized glutathione (disulfide bond) at 280 nm are used for the calculation of molar extinction coefficients of proteins.

EDU IASI / CENTRAL UNIVERSITY LIBRARY

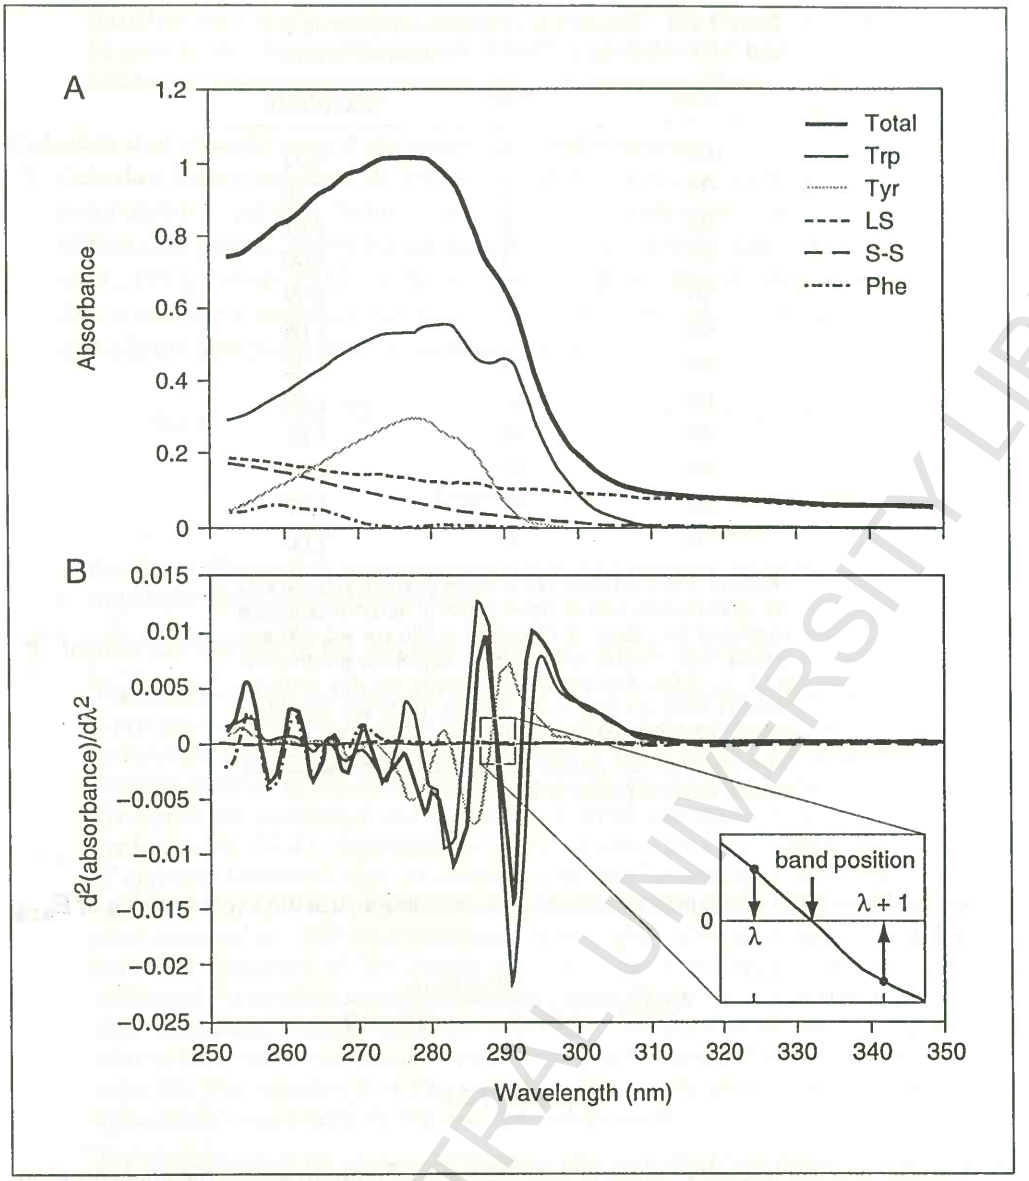

Figure 7.2.2 (**A**) Normal (zero-order) spectrum of a 100 µM solution of a hypothetical protein containing 1 Trp, 2 Tyr, 3 Phe, and 4 Cys (S-S) residues. The constituent spectral components and a typical light scattering (LS) contribution are also shown. (**B**) Calculated second-derivative spectra of **A**. The second-derivative spectra of cystine and light-scattering components are essentially zero. Inset: Enlargement of the marked segment illustrating the interpolation between adjacent second-derivative points that yields the precise position of the intersect with the wavelength axis.

Estimate the nucleic acid content

4. Calculate the ratio R of absorbances at 260 nm and 280 nm, $A_{260,c}$ to $A_{280,c}$ after correction for light scattering (Equation 7.2.4). Use Table 7.2.2 to estimate % weight of DNA (%N) in the sample (Glasel, 1995).

Estimate protein concentration in the sample

5. If a significant amount of DNA was detected (R>0.70), calculate the protein absorbance $A_{280,c,p}$ using % weight of protein and DNA found in Table 7.2.2, where $E_{0.1\%}$ is the extinction coefficient of the protein (per 1 mg/ml). If the amino acid composition is known, calculate $E_{0.1\%}$ using Equation 7.2.7 and divide the result (ε) by the

BOSTON UNIVERSITY / CENTRAL UNIVERSITY LIBRARY

Table 7.2.2 Theoretical R(260/280) Values vs %P and %N in Mixtures of Nucleic Acids and Proteins[a]

%P[b]	%N[b]	R(260/280)
100	0	0.57
99	1	0.70
98	2	0.81
97	3	0.90
96	4	0.99
95	5	1.06
90	10	1.32
80	20	1.59
60	40	1.81
40	60	1.91
20	80	1.97
0	100	2.00

[a]Amount of DNA as small as 1% can be detected. This is due to the approximately tenfold higher values of the DNA extinction coefficient (i.e., $E_{0.1\%}$ of 10 and 20 at 280 nm and 260 nm, respectively). Average value of R for 12 globular proteins was 0.57 +/– 0.06. The empirical equation for this table is: %N=(11.16×R–6.32)/(2.16–R) (Glasel, 1995; see also Manchester, 1995, for further comments).

[b]Abbreviations: %N, percent weight of DNA in the sample; %P, percent weight of protein in the sample.

molecular weight of the protein. For a crude estimation, use the average value of $E_{0.1\%} = 1.1$.

$$A_{280,c,p} = \frac{\%P \times E_{0.1\%}}{\%P \times E_{0.1\%} + \%N \times 10}$$

Equation 7.2.5

6. Use the spectral intensity values at 280, 320, and 350 nm to assess the concentration of protein based on the known amino acid composition of the protein using Equation 7.2.6 and Equation 7.2.7 (Mach et al., 1992b), where C is the protein concentration (molar), ε is the molar extinction coefficient (M^{-1} cm^{-1}) that would be obtained from a solution of 1 M concentration and a 1-cm path length (L), and N_{Trp}, N_{Tyr}, and $N_{S\text{-}S}$ are the numbers of Trp, Tyr, and disulfide bonds (cystine residues) in the protein. $A_{280,c}$ is the optical density at 280 nm (OD_{280}) corrected for light scattering (see Equation 7.2.4). When sufficient amount of protein is available, the extinction coefficient ε is usually determined by quantitative amino acid analysis (*UNIT 3.2*).

$$C = \frac{A_{280,c}}{\varepsilon L}$$

Equation 7.2.6

$$\varepsilon = 5540N_{Trp} + 1480N_{Tyr} + 134N_{S\text{-}S}$$

Equation 7.2.7

CU IASH CENTRAL UNIVERSITY LIBRARY

Based on studies of a series of proteins (Equation 7.2.7), the above relationships can be used to determine the extinction coefficients of proteins and, consequently, their aqueous concentration to an accuracy generally within 2%.

Calculate and visually inspect the second-derivative spectra

7. Calculate the second-derivative spectrum. If the instrument's software has derivative computation capability, choose derivative order 2, polynomial order 2, and a window of five data points. Otherwise use Equation 7.2.8 (Savitzky and Golay, 1964; Steiner et al., 1972), where SD(λ) is the second-derivative value at integral wavelength λ, $A(\lambda \pm n)$ is the absorbance value at $\lambda + n$ wavelength (where n = –2,–1, 0, 1 and 2), and k is the data point interval (in nanometers).

$$SD(\lambda) = \frac{2[A(\lambda-2)] - A(\lambda-1) - 2[A(\lambda) - A(\lambda+1) + 2[A(\lambda+2)]}{7 \times k}$$

Equation 7.2.8

See Basic Protocol 1, step 6 annotation, for an example. Note that the values of n double for 2-nm spectral bandwidth.

8. Inspect the features of the resultant second-derivative spectrum.

The negative peak centered near 290 nm (Fig. 7.2.2) originates from the Trp inflection point observed in the zero-order spectrum. Although its position is partially influenced by the overlapping Tyr spectrum, the position of the negative 290-nm peak reflects the average polarity of Trp microenvironments: the more hydrophobic the environment, the higher the wavelength (i.e., an apolar environment produces a "red shift" in this peak; see Fig. 7.2.1). The magnitude of this negative peak is diminished by a Tyr band of opposite (positive) sign. In contrast, Trp and Tyr bands of the same sign (both negative) amplify the composite second-derivative peak near 280 nm. The positive peak centered at ~285 nm is composed mostly of the Trp component, as the second-derivative spectrum of Tyr crosses the zero axis in this region. In some proteins individual Tyr residues have microenvironments different enough to produce 2- to 3-nm shifts and band overlap sufficient to obviate individual peaks in this region. The alternating positive and negative peaks between 250 and 270 nm are the result of the wave-like fine structure from Phe side chains seen in the zero-order spectrum and are affected only marginally by Trp and Tyr counterparts.

The magnitudes of the second-derivative peaks are proportional to the concentration of aromatic amino acids, revealing both the relative content of each type of aromatic residue and the protein concentration. The relative heights of the second-derivative peaks constitute a characteristic "fingerprint" by which purity and structural integrity of a protein can be recognized. Some instruments (e.g., Hewlett-Packard 8452) have software capable of comparing two spectra using linear regression and providing a quantitative "match factor." Unlike that for holmium oxide, the first derivative cannot be used for protein solutions because of residual nonzero values originating from light scattering, cystine, and other amino acid absorbance below 270 nm.

9. Calculate the positions of the intersections of the second derivative spectrum with the wavelength axis in the 285- to 295-nm region. Use Equation 7.2.9, where λ is the wavelength prior to the intersection point, k is the data point interval (in nanometers), and |SD(λ)| and |SD(λ + 1)| are the absolute values of the second derivative at the integral wavelengths λ (before the intersection point) and λ + 1 (after the intersection point).

$$\text{peak position (nm)} = \lambda + k\frac{|SD(\lambda)|}{|SD(\lambda)| + |SD(\lambda+1)|}$$

Equation 7.2.9

B. C. U. „M. Eminescu" IAŞI
CHIMIE

BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

These values can be used as probes of protein structural integrity. In future manipulations or purification of the same protein, identical values of these parameters will indicate that the structure of the protein did not significantly change. The values of intersection points are typically reproducible within a 0.05-nm error margin using diode-array spectrophotometers. Scanning spectrophotometers require frequent wavelength calibration using standardized spectra to obtain this precision. The intersections of the second-derivative spectra of the holmium oxide standard determined using Equation 7.2.9 provide suitable reference points with which to compare results obtained at different times or using different instruments.

BASIC PROTOCOL 2

ANALYSIS OF PROTEINS USING AN HPLC WITH A DIODE-ARRAY DETECTOR

Purifying recombinant proteins relies on large-scale chromatographic procedures that generally lack the resolution of the analytical methods on which they are based. A common problem in the large-scale process is that a second protein (or some other compound, e.g., a detergent) may coelute with the protein of interest, contaminating the sample. High-performance liquid chromatography (HPLC) with a diode-array detector is a good method to determine the purity of a sample. By exquisitely regulating the pumps, this chromatography system minimizes flow problems that can otherwise interfere with peak detection, yielding highly reproducible gradients. Thus, HPLC provides the best chromatographic resolution of a protein.

A diode-array detector can be coupled to virtually any type of chromatographic separation, including reversed-phase, ion exchange (*UNIT 8.2*), and gel filtration (*UNIT 8.3*). The method assesses the purity of proteins or peptides equally well. In this protocol, the purity of a protein is determined using a C_4 reversed-phase column. The same protocol can be adapted to peptides by substituting a C_{18} reversed-phase column.

Materials

Buffer A: 0.1% (v/v) trifluoroacetic acid (TFA; reagent grade) in water (Milli-Q or equivalent purity)

Buffer B: 0.09% (v/v) TFA in 80% acetonitrile (HPLC grade)

C_4 reversed phase column and guard: (e.g., Vydac C_4, 250 × 4.6-mm-i.d. column, 5-μm particle size, 300-Å pore size for samples in the 0.5 to 5 nmol range or a 250 × 2.1-mm-i.d. column for samples in the 100 to 500 pmol range)

HPLC with a diode-array detector (e.g., Hewlett-Packard, Waters, Beckman)

1. Set scan limits on the diode array detector to cover the 200- to 300-nm region.

   Peptide bonds have strong absorption in the 200- to 230-nm region (wavelength maximum = 188 nm) and aromatic amino acids have specific maxima in the 240- to 300-nm region.

2. Set the primary sample wavelength at 215 nm, with secondary tracings being made at 254 nm and 280 nm. Set bandwidth at 4 nm.

   The sample wavelength is the wavelength at which absorbance is measured as a function of time for the whole run. The bandwidth can be set from 4- to 20-nm for a sample. A bandwidth of 4 nm for the primary wavelength of 215 nm means that the absorbance measurement will extend between 213 and 217 nm.

   It is important to set the primary wavelength to measure peptide bonds. The peak absorbance (188 nm) cannot be used, however, because many of the HPLC reagents also absorb strongly in this region and obscure the signal from the protein. At 215 nm, the solvents do not interfere with the protein.

   The secondary tracings cover the absorption of aromatic amino acids. Although having

the whole chromatogram at these secondary wavelengths is not essential for this method, it can be useful (see Anticipated Results).

3. Set reference wavelength at 550 nm with a bandwidth of 100 nm.

   The reference wavelength is generally set outside the range of protein absorption. Because proteins do not absorb at this wavelength, a wide bandwidth is recommended to avoid spurious readings. The absorbance of the reference wavelength is subtracted from the absorbance of the sample wavelength to give the absorbance of the signal for the protein.

4. Determine the points at which diode-array spectra will be taken and saved. Set acquisition and storage of spectrum to "peak controlled."

   This means that diode-array spectra will be taken at a point on the upslope, at the apex, and at a point on the downslope of a peak. The information obtained will be used to assess peak purity. If a peak has shoulders or is asymmetrical, spectra will automatically be obtained at additional points using the peak purity program.

5. Set threshold to define height of signal expected for the smallest peak from 0.1 to 999 milliabsorbance units (mAU).

   A threshold of 5 mAU is suggested for a sample of 50 pmol protein.

   This parameter is relevant to the size of the record that will be made and saved during the run. Diode-array spectra will be saved only for peaks that are higher than the threshold height defined, not for peaks that are lower.

6. Set peakwidth to equal the half-height width expected for the narrowest peak, with limits from 0.007 to 10 min.

   A suggested starting value for this parameter is 0.15 min. Together with the threshold, the peakwidth determines the size of the record made for the run. Diode-array spectra will be saved only for peaks displaying a wider half-height width than the value chosen, not for peaks narrower than this width. This eliminates saving spectra for peaks that are due to noise.

7. Set stop time for acquisition of spectra.

   This value controls the diode-array detector only; it can be set to stop independently from the run, earlier than the run, or automatically with the run.

8. Set a gradient rate of 1% buffer B/min and a flow rate of 1 ml/min for the 4.6-mm-i.d. column, 200 µl/min for the 2.1-mm-i.d. column. Set the amount of buffer A plus the amount of buffer B to equal 100%.

   HPLC pumps are controlled by the B pump, which can vary from 0% to 100%. The amount of buffer A plus the amount of buffer B must equal 100%. Thus 0% buffer B means that the B pump is off and only the A pump is working (e.g., 100% A), and 100% buffer B means that the A pump is off and only the B pump is working. To achieve the same chromatographic separation on a 2.1-mm-i.d. column as obtained with a 4.6-mm-i.d. column, adjust the flow rate according to the ratio of the cross-sectional areas of the two columns. A 4.6-mm-i.d. column is roughly five times the cross-sectional area (πr^2) of a 2.1-mm-i.d. column.

   Gradient rate defines the change in the gradient over time. The gradient should not be started until the sample has had time to flow onto the column. For a sample 100 µl in volume and a flow rate of 1 ml/min, it will take 0.1 min to load the sample onto the column. The following table illustrates typical gradient conditions for a 100-µl sample and a flow rate of 1 ml/min. This information would be entered into a liquid chromatography (LC) time table. The time required for the run should be determined and

BCU LIBRARY CENTRAL UNIVERSITY LIBRARY

entered at the appropriate place in the program. This time limit should be long enough to allow for all of the events specified in the LC time table.

Time (min)	% B
0	10
1	10
51	60
56	80
66	10

After a trial run, if peaks of interest are too close to each other, the gradient rate can be made shallower (e.g., 0.5% buffer B/min) to spread out the gradient or steeper (e.g., 1.5% buffer B/min) to sharpen well-resolved peaks.

9. Equilibrate the column with 10% buffer B by running a volume equivalent to at least 3 column volumes.

10. Prepare experimental and control samples in 10% buffer B, keeping the volume to a minimum and making all samples the same volume.

A good control sample will contain everything present in the experimental sample except the protein. The following table illustrates a sample preparation:

	Control	Experimental
Protein sample	—	90 µl
Sample buffer	90 µl	—
HPLC buffer B	10 µl	10 µl

Quantities of protein in the sample can range from 0.5 to 5 nmol for a 4.6-mm-i.d. column and from 100 to 500 pmol for a 2.1-mm-i.d. column. For reversed phase chromatography, sample volumes of 20 to 100 µl will work.

11. Filter samples through a low-protein-absorption 0.21-µm pore size filter or microcentrifuge 5 min at maximum speed to remove particulates.

12. Choose an appropriate label for the control run. Inject the control sample into the HPLC apparatus.

The control sample is used to control for spectral impurities in buffers. The control should be run before the experimental sample to permit careful inspection of the entire gradient. The HPLC starts acquiring data on injection. If a rheodyne injector is used, leave the sample loop on line long enough to allow the whole sample to be applied to the column.

13. Choose an appropriate label for the experimental run. Inject the experimental sample into the HPLC.

As above, the injection of the sample starts the acquisition of data. The data is stored in a computer file under the given label.

Data analysis

14. Subtract the UV spectrum of the control from that for the protein to take into account impurities found in the sample buffer.

15. Run the peak purity program, which compares spectra for points at the apex and on the upslope and downslope of each peak.

16. Compare normalized overlaid spectra.

PGIMER-IASLC CENTRAL UNIVERSITY LIBRARY

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Acid/ethanol cleaning solution (3 N HCl/50% ethanol)

Add 50 ml of 12 N HCl to 50 ml deionized water. Add the resulting solution to 100 ml ethanol. Store several months at room temperature.

CAUTION: *Never pour water or ethanol into the concentrated acid. Always pour the acid into water or ethanol. Wear appropriate personal protection.*

Holmium oxide reference solution

4% holmium oxide in aqueous solution of 10% (v/v) perchloric acid sealed in a nonfluorescent fused silica cuvette of optical quality (National Institute of Standards and Technology, Standard Reference Materials catalog; see *SUPPLIERS APPENDIX*).

Store at room temperature for several months.

COMMENTARY

Background Information

Ultraviolet absorption spectroscopy played a key role in early investigations of protein structural transitions (Wetlaufer, 1962). The explosive growth of molecular biology and expanded use of more powerful spectroscopic techniques such as nuclear magnetic resonance (NMR), X-ray crystallography, circular dichroism, and fluorescence relegated this technique to use in simple assays and concentration determinations. During this period, however, electronic and optical systems improved considerably, allowing extraction of much more detailed information from simple near-UV spectra. It was soon shown that the magnitude of the near-UV second derivative peaks can be used for quantitative determination of the content of aromatic amino acids in proteins (Ichikawa and Terada, 1977; Servillo et al., 1982, Levine and Federici, 1982; Nozaki, 1990). These methods employ either peak-to-peak distances or least-squares multicomponent analysis and are capable of resolving all three components simultaneously. In fact, the spectrum of a mixture of three proteins can be easily resolved by this method if the spectra of the individual proteins are known (Mach et al., 1989). The composition of simple protein mixtures and complexes can then be monitored without actual chromatographic separation.

Generally, the spectra of the individual aromatic amino acids become red-shifted (move to higher wavelengths) upon incorporation into protein structures (see Fig. 7.2.1). These shifts can be as large as 5 nm for Tyr, 4 nm for Trp, and 2 nm for Phe residues (Mach and Middaugh, 1994). Of course, many side chains naturally exist in quite polar microenvironments in native structures, so these shifts are not always so large. Unfolding of a protein usually results in some increased solvent exposure of aromatic side chains and, consequently, in blue shifts (toward lower wavelengths). If the spectral signal near 295 nm (Fig. 7.2.2) shifts left even a fraction of a nanometer, the absorbance value at any given wavelength in this vicinity may change significantly because of the steepness of the slope. This phenomenon can be effectively utilized to follow the unfolding of a protein by measuring the spectral intensity at this wavelength as a function of a structure-perturbing variable (e.g., temperature, pH, protein concentration, or urea concentration) or by measuring the difference spectra between two proteins of identical concentration, one of which is subject to structural perturbation. The resulting values, however, are relative. Use of the intersection of a portion of the second-derivative spectrum with the wavelength axis is therefore recommended.

Application of more complex fitting routines and use of systematically shifted standard spectra allow the individual spectra of Trp, Tyr, and Phe to be resolved from the composite protein spectrum (Mach and Middaugh, 1994). This allows the fractional exposure of aromatic residues to be assessed using additions of apolar compounds as perturbants. The observed shifts are compared to the shifts in model, solvent-exposed compounds (e.g., acetylated and amidated aromatic amino acid derivatives), and the solvent exposure is estimated from a comparison of these values. In addition to proteins, DNA and RNA possess strongly absorbing chromophores (purine and pyrimidine bases) in the near-UV (Table 7.2.1), result-

BRANDEIS UNIVERSITY LIBRARY

ing in the well-known featureless spectrum of nucleic acids with a peak near 260 nm. The molar absorptivity (extinction coefficient) of polynucleotides is strongly structure dependent and this is often utilized in monitoring thermal structural transitions (i.e., in melting experiments). In addition, DNA and RNA have well-defined, albeit weak, second-derivative spectra that can be employed to determine the amount of protein in the presence of DNA (Mach et al., 1992a).

Very strong absorbance is also produced by all proteins in the far-UV range (180 to 250 nm). This is primarily the result of the intense absorption by the peptide bond in the far-UV. Because of amide absorption near 188 to 190 nm, a peak is actually present, but the intense absorption by oxygen as well as most solutes in this region makes it difficult to resolve experimentally. In some spectrophotometers, this peak can be resolved by flushing the instrument with N_2 and by the use of UV-transparent anions (e.g., phosphate or perchlorate), but this is rarely done today. Although the structure and position of this peak contain secondary-structure information as well as side-chain contributions, the peak is rarely used experimentally because of the superiority of circular dichroism measurements in the same region. It is occasionally employed, however, for concentration measurements or simple protein detection during chromatography by monitoring wavelengths on the slope of the peak (e.g., 210 and 215 nm). If the protein or peptide studied lacks aromatic amino acids, or the concentration of the sample does not produce sufficient signal, its concentration can be calculated by employing a set of average extinction coefficient values in the far-UV range that were obtained based on the analysis of twelve proteins (Scopes, 1974):

(1) E(1 mg/ml, 1 cm) at 205 nm = 31 with stated error of 5%

(2) E(1 mg/ml, 1 cm) at 205 nm = 27.0 + 120 A_{280}/A_{205} with stated error of 2%.

Extreme care should be taken when correcting for the many buffer components absorbing in this region.

In principle, methods such as SDS-polyacrylamide gel electrophoresis (SDS-PAGE; *UNITS 10.1 & 10.3*) are more effective than UV spectroscopy in assessing the purity of a protein sample, based on detection of the presence and absence of additional bands. Such methods, however, may fail to ascertain contaminating proteins of similar molecular weight, unless isoelectric focusing (IEF) gels are used (*UNITS 10.2 & 10.8*). In contrast to electrophoretic (Chapter 10) or chemical (Chapter 11) analyses, the UV absorption technique is both nondestructive and rapid. Moreover, only a modest amount of sample is required.

This unit describes recombinant protein analyses using the two general types of UV spectrophotometers (Fig. 7.2.3): conventional scanning instruments, in which light absorption is measured by mechanically moving a monochromator allowing data to be accumulated temporally as a function of wavelength (Basic Protocol 1 and Support Protocol) and diode-array spectrophotometers (Basic Protocol 2), in which a light beam containing all frequencies is simultaneously split onto an array of detectors (diodes) after passing through the sample. Diode-array spectrophotometers (Hewlett-Packard 8450 to 8453 series or Beckman DU 7000) are simpler and consequently have excellent wavelength reproducibility. A single spectrum is typically acquired in 0.1 sec; longer acquisition times provide an average of a number of measurements. Spectral bandwidth is fixed at 1 or 2 nm. The small cross-sectional area of the light beam (~1×5 mm for the Hewlett-Packard diode-array instrument) allows small sample volumes and free choice of cuvette format. Such instruments can be easily used on-line to collect and analyze spectra of protein fractions leaving a chromatographic column—e.g., from gel filtration (*UNIT 8.3*), ion-exchange (*UNIT 8.2*), and reversed-phase media. In contrast, conventional scanning spectrophotometers require longer acquisition times, since at any given time only one wavelength is read.

Critical Parameters

The spectrophotometers contain moving internal parts that require frequent wavelength calibration. Of great importance when using scanning spectrophotometers is the setting of proper detector response time relative to scanning speed. A decrease in absorbance values, broadening of bands, and shifts are often observed in such cases.

Although the intrinsic absorbance of the aromatic amino acids varies little with temperature, it is advisable in many cases to control the temperature of the sample. Many processes destructive to proteins (e.g., oxidation, deamidation, unfolding, and aggregation) are accelerated at elevated temperature (Volkin and Middaugh, 1992). Under most conditions of humidity, however, a temperature of 15°C should be regarded as minimal. Decreasing the

BOU IAS CENTRE UNIVERSITY LIBRARY

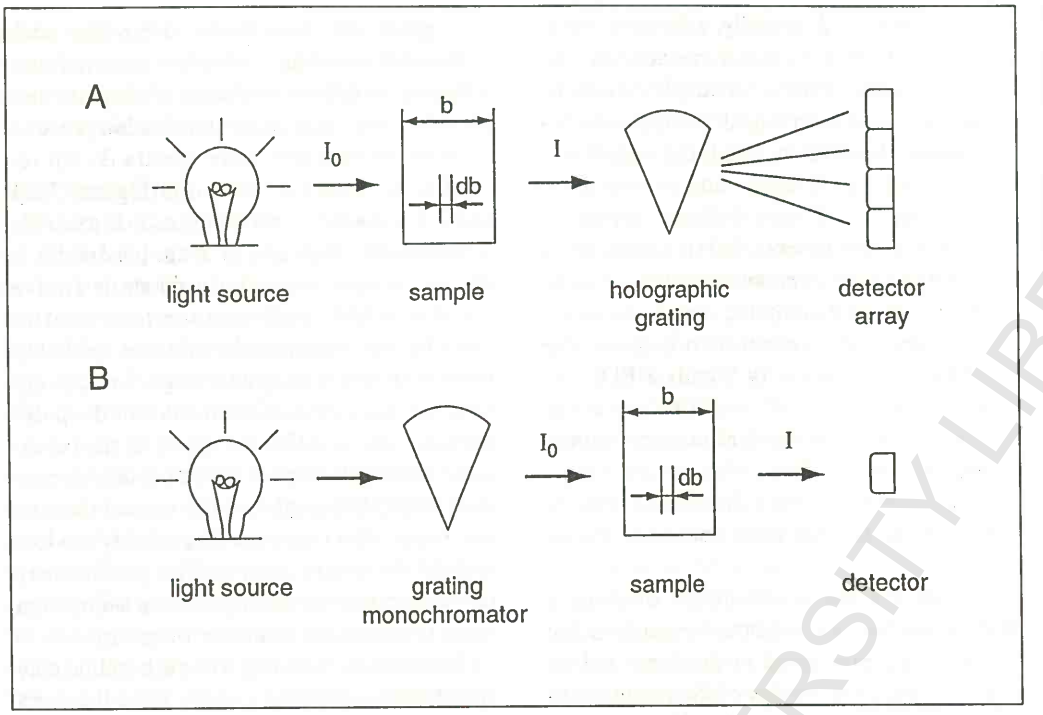

Figure 7.2.3 Basic scheme for spectrophotometric measurements: lamp, sample and detector; b (path) and db are shown in the sample and *I* and I_0 are denoted (see below). **(A)** Diode-array and **(B)** conventional scanning spectrophotometers. The relative decrease of the intensity of the light beam after passing through the sample is proportional to the distance (db) and the concentration of the absorbing component: $-db/b = kc \times db$, where k is an absorption coefficient. Upon integration, the result is $\ln(I/I_0) = -kcl$. The fraction of light transmitted through the sample is known as the transmittance $T = I/I_0$. Absorbance is defined as $A = \log I_0/I = \varepsilon cb$, where ε is a molar absorptivity (extinction coefficient), c is the molar concentration, and b is the path length (in centimeters). Alternatively, weight extinction coefficients $E_{1\ cm,\ 0.1\%}$ expressed per 1 mg/ml (0.1%) concentration are used.

temperature below this level may result in water condensing on the optical surface of the cuvette. The power of deuterium lamps used in UV spectrophotometers is usually not sufficient to cause photooxidation of aromatic residues. However, if the fluorescence spectra were acquired using the same sample, some of the tryptophan residues may have been oxidized to *N*-formylkynurenine and kynurenine by light from more powerful xenon lamps. This condition can be recognized by the appearance of a broad spectral band extending over 350 nm (similar to light scattering) and can be identified by comparing spectra as a function of irradiation time in a fluorometer or by direct observation of photoproduct fluorescence bands at ~400 nm (with excitation at 320 nm). Solvent-accessible tryptophan side chains are particularly prone to photooxidation, with half-lives as short as several minutes (Mach et al., 1995).

An aqueous buffer in which the protein of interest is stable should always be used. For example, phosphate-buffered saline, pH 7.4 (PBS; *APPENDIX 2E*), or an equivalent buffer containing 10 mM sodium phosphate and 120 to 150 mM sodium chloride, pH 7.0 to 7.4, is often employed. Choice of pH is important, because the spectral contribution of absorbing residues may be directly or indirectly (effect on protein conformation) pH dependent. Whereas tyrosine ionization (pK=10) results in an entirely different spectrum (λmax = 294 nm), ionization of nonabsorbing or weakly absorbing side chains (e.g., lysine, pK~10; aspartic and glutamic acids, pK~4.5; histidine, pK~6.5; or cysteine, pK~8.5) may produce subtle shifts if the microenvironments of UV-absorbing chromophores or the overall conformation are altered. The pH should be sufficiently different from the isoelectric point to ensure good solubility. Note that many agents used to improve protein solubility (e.g., surfactants, denaturing agents, and sugars; Middaugh and Volkin, 1992) may affect spectral band positions.

For HPLC analysis, it is important that HPLC-grade solvents, free of UV-absorbing contaminants, be used. Similarly, the sample

PRINCETON UNIVERSITY LIBRARY

should be prepared carefully, with the highest-grade components, to avoid inadvertently introducing contaminants. All samples should be either filtered or centrifuged to remove particulate matter. In addition, HPLC tracings should be examined for shoulders and unusual peak broadening, which may indicate impurities (Zavitsanos and Goetz, 1991). Diode-array spectra will be obtained automatically at additional points if the computer detects an asymmetrical peak. This information is invaluable in determining peak purity. Finally, HPLC column performance should be routinely assessed by injecting a set of standard proteins or peptides (Mant and Hodges, 1991), as poor resolution may broaden peaks. Resolution deteriorates on columns that have been used excessively.

One of the major advantages of using a diode-array detector to determine purity is that it is relatively unaffected by gradients and requires no prior knowledge of the sample. Absence of a strong absorption band between 200 and 230 nm indicates that the analyzed peak is not a protein but rather a nonproteinaceous contaminant, such as a detergent or a chromophore, picked up during the purification procedure.

Troubleshooting

A few recurring problems are encountered in the analysis of proteins by UV spectrophotometry. A major, often unrecognized difficulty is the phenomenon known as absorption flattening. Imagine a large number of protein molecules aggregating so that some incident light is able to pass "in between" them without encountering an absorbing entity. However, because of the high concentration of chromophores in the aggregated particle, photons that happen to encounter the aggregate are unlikely to emerge on the other side. As a result, the intensity of such spectra are significantly reduced and often distorted. If this problem is suspected, the length of the effective light path should be changed. If absolute values of protein concentration are found to be pathway dependent, this phenomenon may be present.

The presence of anomalies such as significant curvature, negative values, or "bumps" in the 300- to 350-nm spectral region indicates either technical problems or the presence of unknown absorbing components, perhaps due to contaminating solutes. The spectra of any suspected absorbing impurities can be measured and compared to the experimental spectra to help determine if impurities are present. Detergents are often found to produce such extraneous absorbance, and their potential contribution should be evaluated if they are employed at any stage in the purification process.

If the second-derivative spectra do not resemble the examples shown in Figures 7.2.1 and 7.2.2, the most probable reason is too wide a bandwidth. Typically, a 2-nm bandwidth is the largest value permitting accurate derivative calculation. If the derivative spectrum is calculated by the instrument's software, probably more than five data points (e.g., 7 to 21) are used for calculation of each value or the polynomial order is different from 2. If the calculated second-derivative spectra resemble random noise, the signal-to-noise ratio of the normal (zero-order) spectrum is probably too low to allow this type of analysis. This problem may be overcome by increasing spectral acquisition times or averaging a number of spectra.

Problems in obtaining a stable baseline may arise from a number of factors. If the incorrect lamp was turned on—the tungsten-halogen (or "visible") instead of the deuterium (or "UV") lamp—spectra will not be obtainable. Failure of the UV lamp will usually manifest itself in an inability to obtain zero absorbance values during a "blank" measurement after collecting the baseline with both cuvettes containing the buffer. Many instruments contain an indicator of this condition. Care should be taken not to directly inspect the deuterium lamp for ignition, as UV irradiation can seriously damage the retina of the eye. The cuvette itself should also be reexamined. Only synthetic quartz provides sufficient transparency over the UV region. The inadvertent use of a glass cuvette will block passage of light through the system. If spectra cannot be obtained, the cuvette may have been positioned incorrectly, with opaque or black walls perpendicular to the light beam.

Instability of the absorbance signal can occur for a number of other reasons, such as liquid smears, water vapor condensation or fingerprints on the optical surfaces, or air bubbles or other suspended or sedimenting particles in the test solution. As indicated previously, the meniscus should be above the upper edge of the beam and no light should be able to bypass the sample. In some cases, the problem of insufficient volume of sample available can be solved by inserting some space-filling material beneath the cuvette.

In diode-array detection schemes, it is important to run a control sample consisting of the solution in which the protein is dissolved, to detect possible contaminants. Threshold and

BIBLIOTECA UNIVERSITARIA

peak width values should be set correctly to ensure that all peaks of interest are seen by the diode-array detector. Otherwise, small contaminating peaks may be skipped.

Anticipated Results

Figure 7.2.2A illustrates a typical example of a near-UV protein spectrum. Despite differences in aromatic amino acid compositions in proteins, spectra are usually qualitatively similar, with a maximum falling between 276 and 282 nm and only marginal absorbance above 300 nm. Small soluble monomeric proteins do not usually produce any light scattering. The second-derivative pattern should have the distinct features shown in Figure 7.2.2B characteristic of tryptophan, tyrosine, and phenylalanine residues, if these are present in the sequence. The position of the intersect with the wavelength axis of the declining second-derivative region near 290 nm is usually found at 289.41 ±0.61 nm using 1-nm data point spacing (based on the average from 14 tryptophan-containing proteins). This value should be ~0.5 nm lower when the 2-nm data point interval is used. The reproducibility should be within 0.05 nm for pure and structurally intact proteins.

The diode-array detector obtains spectra of very high quality and precision, enabling the operator to check the purity of a protein by comparing normalized spectra from different points of the eluted peak. It uses information within the protein (i.e., its amino acid composition) to check purity. Proteins of differing composition will have different spectral absorptions, particularly if they vary widely in aromatic amino acid content. Thus, if the retention times of two proteins are close enough, the proteins appear to be in the same peak. Based on their absorption characteristics the diode-array detector can distinguish them by comparing normalized spectra at the front end of the peak on the upward slope, at the back end of the peak on the downward slope, and at the apex. If the protein is pure, the spectra collected from these three points will superimpose exactly. If the protein is impure, the spectra collected from the three points will deviate, aside from the rare case in which the impurity and the sample exactly coelute from the column. The general rule is that small-to-moderate levels of impurity can be detected in a contaminated sample, provided the spectral properties of the contaminant vary from the recombinant protein.

The examples in Figures 7.2.4 and 7.2.5 illustrate pure and impure samples. Figures 7.2.4A and 7.2.5A show the main chromatography tracings at 215 nm. The first visible peak in each chromatogram is the injection peak and the second is the protein of interest. Figures 7.2.4B and 7.2.5B show the stored diode-array spectra for points collected on the upswing, the apex, and the downswing of the protein peak of interest. A pure protein is characterized by identical spectra at these points, whereas an impure protein will have different spectra at each point. In Figure 7.2.4B, the spectra are close to identical, indicating that the protein is fairly pure. In Figure 7.2.5B, on the other hand, the spectra vary widely. Diode-array spectra for points 1 and 2 were collected early in the peak. These spectra have little absorbance in the region from 200 to 220 nm, indicating that a nonproteinaceous component is eluting at the front end of the BSA peak. Peaks 3, 4, and 5 correspond to the upswing, the apex, and the downswing, respectively, of the main peak. The diode-array spectra of these points are different enough to indicate contamination. Figures 7.2.4C and 7.2.5C show the superposition of tracings measured at the primary, secondary, and tertiary wavelengths. Note that these closely superimpose for the pure sample (Fig. 7.2.4C) but not for the impure sample (Fig. 7.2.5C).

Time Considerations

The entire procedure for measurement and analysis of protein UV spectra can usually be completed within 30 min, of which 20 min is needed for lamp warm-up and sample preparation. This time should be shorter if the instrument is already turned on. Diode-array spectrophotometers interfaced to computers equipped with data processing programs are especially time efficient when a larger number of samples is analyzed. Characteristically, even the most complex analysis routines, when implemented within the existing software, usually require only seconds for completion. In the case of conventional scanning instruments, calibration (measurements of standards) combined with slower scanning rates may require some additional time.

An HPLC run takes ~2 hr, including the column equilibration with buffer A. Examination of the diode-array detector information should take at most 1 additional hour for the novice and 30 min for the experienced operator.

Determining the Identity and Structure of Recombinant Proteins

After isolating a recombinant-derived protein and establishing that it is pure, it is necessary to confirm that it has the same primary sequence as predicted from the cDNA coding sequence. There are several reasons why this may not be the case: (1) errors in sequencing the gene (e.g., single-base errors resulting in single amino acid substitutions) and typographical errors in translating the sequence; (2) translation errors leading to the misincorporation of various amino acids (e.g., Harris et al., 1993; Randhawa et al., 1994); (3) unexpected translation start and finish points (see *UNIT 6.1* for sample references); (4) retention or nonretention of N-terminal methionine when expressing proteins in *E. coli* (*UNIT 6.1* and *UNIT 7.1*); (5) proteolytic processing by host cell proteases or, if the expressed protein is a protease, autolysis; and (6) chemical modification of specific amino acids: e.g., deamidation of amides (Asn and Gln), oxidation of cysteine and methionine, and, if urea was used for protein purification or folding, carbamylation of lysine residues (*UNIT 6.1*). Although this list is not exhaustive, it is enough to indicate that there are sufficient reasons to warrant a careful analysis of the primary sequence of the isolated protein to confirm that it corresponds to that expected from the cDNA sequence.

The standard methods for confirming the primary sequence of a recombinant protein are combinations of (1) accurate amino acid analysis (*UNIT 3.2*) and mass spectrometry (Stults, 1995); (2) N- and C-terminal amino acid sequence determination by Edman degradation; and (3) peptide mapping in conjunction with the first two methodologies.

In this unit peptide mapping protocols with separation of the constituent peptides by high-performance liquid chromatography (HPLC) analysis (Basic Protocol 1) and by high-resolution SDS-polyacrylamide gel electrophoresis (Alternate Protocol) are presented. The latter approach is included for the benefit of laboratories that do not have access to the more expensive HPLC equipment. Other peptide mapping techniques are described in *UNIT 11.6*.

When peptide mapping a recombinant protein, the peptide bonds are first cleaved using specific proteases or chemical reagents to produce a mixture of peptides. The composition of the mixture is a function of both the primary sequence and the specificity of the protease or chemical reagent. In the protocols described, proteases with strict specificity are used, and as the translated protein sequence is known, it is possible to predict the number and size of the peptides. The composition of the peptides can be determined by mass spectrometry and/or amino acid analysis (*UNIT 3.2*). Peptide mapping is ideally suited for comparative purposes—for example, combined analysis of the recombinant protein and its natural counterpart (or some other well-characterized standard). The method also has the advantage of reviewing the whole sequence.

The most common post-translational modification, regardless of whether the protein is derived from a prokaryotic or eukaryotic host, is the oxidation of paired cysteine residues to form disulfide bonds. Proteins can contain one or more intramolecular disulfide bonds (for a general review, see Thornton, 1981). For dimeric proteins, intermolecular disulfide bonds can occur between the subunits, as in interleukin-5 (Proudfoot et al., 1991) and macrophage colony-stimulating factor (Glocker, et al., 1993). Some dimeric proteins contain both intra- and intermolecular disulfide bonds; the best known example is insulin (Sanger, 1959).

In this unit the general strategy used to determine the linkage pattern of a monomeric recombinant protein containing two intramolecular disulfide bonds is described (Basic

Copyright © 1996 by John Wiley & Sons, Inc.

POLYTECHNIC UNIVERSITY LIBRARY

Protocol 2). The approach used is an extension of peptide mapping, where the aim is to isolate and characterize peptides containing only a single disulfide bond.

In addition to the standard protein chemical approaches, isoelectric focusing in polyacrylamide gels can indicate charge heterogeneity arising from specific and nonspecific post-translational modifications. The usefulness of isoelectric focusing is increased when it is combined with electrophoresis. The resultant two-dimensional electrophoretic method, in which the protein isoelectric point is displayed as a function of pH, is described as electrophoretic titration curve analysis (Basic Protocol 3). This method is especially useful for checking for deamidation (e.g., of Asn to Asp) in which additional negative charge is introduced into the modified protein (Wingfield et al., 1987). Other modifications that can introduce charge heterogeneity include oxidation of cysteine residues, carbamylation of lysine side chains resulting from use of urea, and internal proteolytic clipping in which additional N- and C-termini are introduced (i.e., within a disulfide loop; Niekamp et al., 1969). Proteins expressed in eukaryotic systems can be subject to specific post-translational modification such as glycosylation and phosphorylation (Chapters 12 and 13, respectively), which can also introduce charge heterogeneity. Proteins produced in *E. coli* can also be subject to certain post-translational modifications such as acetylation of the N terminus and of the ε-side chain of lysine. These modifications will also result in charge heterogeneity (Violand et al., 1994).

Electrophoretic titration curve analysis is also extremely useful for predicting suitable conditions for ion-exchange chromatography (see *UNIT 6.1* for further details).

BASIC PROTOCOL 1

PEPTIDE MAPPING BY HPLC

The most important way to characterize a recombinant protein is to show that its primary amino acid sequence matches the predicted translation of the DNA coding sequence. In theory, one can simply digest the protein with an enzyme or chemical agent that is highly specific and compare the resulting fragments with those expected. There are computer programs that predict fragmentation patterns for proteins with all of the commonly used enzymes or chemical agents. In practice, however, the comparison can be a little tricky, because often digestions do not go to completion or peptide fragments behave differently than predicted due to slight variations in technique.

This section covers protocols for two different strategies for peptide mapping. The first, based on high-performance liquid chromatography (HPLC), provides the best resolution of the digested protein and can be used in tandem with other analytical techniques to identify each fragment if this is necessary. The second method is based on high-resolution SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Though less powerful than HPLC, in the sense of providing lower resolution of fragments, SDS-PAGE offers the advantage of allowing comparison to minute amounts of native protein, by using either very sensitive stains or radiolabeled protein. SDS-PAGE is also more feasible than HPLC in some laboratories.

Peptide mapping by HPLC is the method of choice if native material is not available for comparison. In this event, HPLC fractions must be collected for further analyses, including amino acid compositional analysis and N-terminal sequencing. New methods, recently developed, that couple peptide mapping by HPLC with mass spectrometry, are accurate enough to determine to within 0.01% the masses of the components of a digest of a recombinant protein. Tandem MS methods can even provide extensive sequence information. However, mass spectrometers may not be easily accessible and are not absolutely required for this analysis.

BAU IASI CENTRAL UNIVERSITY LIBRARY

Of course, the quickest way to determine the primary structure of a recombinant protein is to compare it to the native material. In this case, both the native material and the recombinant protein are digested under similar conditions and the resulting chromatograms (or SDS gels) are simply compared. Often identical chromatograms (or patterns in a gel) suffice to identify the recombinant protein in a preliminary way. However, native material is not always available, and when it is, it may be available only in minute quantities.

For all of these procedures, a recombinant protein is first denatured and alkylated and is then digested with a specific protease or chemical agent (in these protocols endoproteinase Lys-C, which specifically cleaves at Lys residues, is used as an example). The resulting fragments are analyzed by HPLC (Basic Protocol 1) or by high-resolution SDS-PAGE (Alternate Protocol). Another option presented that may be convenient in some cases is to perform the protein digestion or chemical cleavage in an SDS-polyacrylamide gel slice (see Support Protocol). Of course, both methods can be readily adapted to a number of other specific proteases or chemical cleaving agents. These are discussed in the Commentary section; specific protocols are given in *UNITS 11.1 & 11.4*.

Materials

Samples of recombinant and, if possible, native protein
Acetone/1 M HCl, –20°C (acidified acetone; optional)
8 M urea/50 mM Tris·Cl, pH 7.5
45 mM dithiothreitol (DTT)
100 mM iodoacetamide, prepared fresh and kept wrapped in foil
Sequencing-grade protease (*UNIT 11.1*) or chemical cleavage agent (*UNIT 11.4*):
e.g., endoproteinase Lys-C (Wako Chemicals)
Digestion buffer (see recipe)
HPLC solvents A and B for peptide mapping (see recipes)

50°C water bath or heating block
15- to 25-cm, 2.5-mm-i.d. C18 HPLC column (e.g., Vydac C18, 300 Å, 5-µm bead)
Analytical high-performance liquid chromatography system

Additional reagents and equipment for proteolytic digestion (*UNIT 11.1*) and/or chemical cleavage (*UNIT 11.4*) of proteins in solution and for digestion in SDS-polyacrylamide gel (optional; see Support Protocol)

Prepare samples and controls

1. Prepare a 50- to 300-pmol protein sample and, if available, an equal amount of the native protein (as control) by lyophilizing or by precipitating from solution with 9 vol of –20°C acidified acetone.

   In experiments in which both the recombinant protein and the native protein are used, the amounts of both should be similar; refer to UNITS 11.1 & 11.4 for appropriate protocols. Proteolytic digests can also be done directly in a gel slice for proteins purified by gel electrophoresis; in this case steps 1 to 6 of this protocol should be replaced by gel purification and digestion in the gel slice (see Support Protocol and UNIT 11.3).

   In the event that the protein cannot be precipitated or lyophilized, the conditions can be adjusted by adding solid urea directly to the protein sample, then adding DTT to the appropriate concentration and incubating (see step 3), before continuing with alkylation (step 4). In this case, expect that solid urea added to 8 M concentration will double the volume of the sample.

2. Label three microcentrifuge tubes: one for the recombinant protein, one for a control consisting of enzyme (or chemical cleavage agent) alone, and one for the native protein, if available.

BOSTON UNIVERSITY MEDICAL LIBRARY

Denature and alkylate protein

3. Place each sample in the appropriately labeled microcentrifuge tube, add 50 µl of 8 M urea/50 mM Tris·Cl, pH 7.5, and dissolve. Add 5 µl of 45 mM dithiothreitol. Incubate 15 min at 50°C.

   In the presence of 8 M urea and dithiothreitol, the protein sample becomes completely denatured and all disulfide bonds are reduced.

4. Add 5 µl of 100 mM iodoacetamide to alkylate cysteine residues. Incubate 15 min at room temperature in the dark.

   Iodoacetamide solution should be made fresh and kept protected from light. Wrapping the tube in foil works well. If a larger volume is used in step 3, the volume of iodoacetamide should be adjusted proportionately. The iodoacetamide concentration should always be at least twice the concentration of sulfhydryls, including those present in the protein and in the reducing agent, DTT, added to reduce disulfides.

Digest or chemically cleave the sample

5a. *For enzymatic digestion:* Add an appropriate quantity of the selected protease in digestion buffer: e.g., 140 µl digestion buffer containing 0.003 U endoproteinase Lys-C per µg protein, or ~1:25 (w/w) enzyme/protein. Cap tube, wrap a strip of Parafilm tightly around the cap to prevent evaporation, and allow to digest overnight (~16 hr) at 37°C.

   Refer to UNIT 11.1 for protocols for different proteolytic enzymes, including appropriate digestion buffers.

   It is important to reduce the urea concentration to ≤2 M for this step. Proteolytic enzymes are not active in higher urea concentrations because they become denatured. Most proteolytic agents will tolerate up to 10% acetonitrile as well; several published procedures include 10% acetonitrile in the digestion buffer (Fernandez et al., 1992).

5b. *For chemical cleavage*: Precipitate the reduced and alkylated protein with 9 vol ice-cold (–20°C) acidified acetone for 2 hr in a dry ice/ethanol bath and microcentrifuge 15 min at maximum speed, 4°C, to collect the precipitate. Solubilize the sample in the solvent appropriate for the cleavage.

   Specific conditions for use of CNBr, which cleaves at Met groups; BNPS-skatole, which cleaves at Trp groups; or hydroxylamine, which cleaves at Asn-Gly bonds, can be found in UNIT 11.4.

6. Microcentrifuge 15 min at maximum speed, room temperature, to pellet any particulate material that might have formed during the digestion or cleavage.

   The sample is now suitable for direct injection onto the HPLC column.

Perform HPLC analysis

7. Equilibrate a C18 column with HPLC solvent A, setting flow rate at 150 µl/min for a 2.1-mm-i.d. column.

   If a column with a wider i.d. is used (e.g., 4.6 mm), the flow rate should be adjusted in proportion to the increase in the cross-sectional area of the column. A 4.6-mm-i.d. column has roughly five times the cross-sectional area (πr^2) of a 2.1-mm-i.d. column.

8. Set gradient conditions on the chromatograph. A recommended gradient protocol for peptide mapping is as follows:

0-5 min	10% B
5-65 min	10%-60% B
65-70 min	60%-90% B
70-80 min	90% B.

BCU IASI CENTRAL UNIVERSITY LIBRARY

Gradient rate defines the change in the gradient over time. HPLC gradients are controlled by the pump dispensing buffer A, which can vary from 0% to 100% of the total flow. The amount of buffer A plus the amount of buffer B must equal 100%. Thus 0% B means that the B pump is off and only the A pump is dispensing buffer, i.e., 100% A; and 100% B means that only the B pump is running.

9. Set detector settings at 215 nm primary trace and 280 nm secondary trace.

   A single-channel HPLC apparatus is perfectly acceptable for this procedure; monitoring should be at 215 nm.

10. Begin the HPLC analysis. Perform a blank run with buffers alone, a second run with the enzyme-only (or chemical cleavage agent–only) control, and finally the run with the protein sample (with a separate run for the native-protein control, if available). Inject 100 µl of each sample to start run and do not start gradient until the sample has had time to flow onto the column. Equilibrate with HPLC buffer A between runs.

    A 100-µl sample will take 0.66 min to load at a flow rate of 150 µl/min.

    The injection of the sample initiates data acquisition.

11. Compare traces at all wavelengths.

    See Anticipated Results for a discussion of data analysis.

PEPTIDE MAPPING BY HIGH-RESOLUTION SDS-PAGE

ALTERNATE PROTOCOL

This method has less resolving power than HPLC, but allows a comparison of the recombinant product with very small amounts (in the 10 to 100 ng range) of purified native protein using sensitive stains (such as silver or gold staining) or radiolabeling as a detection method. In addition, gel electrophoresis equipment is more commonly available in laboratories.

Additional Materials (also see Basic Protocol 1)

2× SDS sample buffer (*UNIT 10.1*)
16 × 16–cm × 1-mm or 16 × 20–cm × 1-mm Tris-tricine slab gel (*UNIT 10.1*)
85°C water bath or heating block
XAR X-ray film or equivalent (optional; for detection of radiolabeled proteins, if used)
Additional reagents and equipment for radiolabeling of proteins (*UNITS 3.3*; optional), proteolytic digestion (*UNIT 11.1*) and/or chemical cleavage (*UNIT 11.4*) of proteins in solution, digestion in SDS-polyacrylamide gel (optional; see Support Protocol), one-dimensional SDS-PAGE (*UNIT 10.2*), and detection of proteins in gels (*UNIT 10.5*) or on membranes (*UNIT 10.8*)

Prepare protein sample

1. Prepare the sample as for peptide mapping by HPLC by digesting either in solution (see Basic Protocol 1, steps 1 to 5) or in SDS-polyacrylamide gel (see Support Protocol, steps 1 to 9).

   It is important to prepare the recombinant and native proteins in the same way. Always include an enzyme-only control.

   Start with 25 to 50 pmol protein if silver staining is to be used as the detection method. For Coomassie staining, start with 150 to 300 pmol protein. For more sensitive detection, proteins in the 1 to 5 pmol range can be visualized by gold staining (UNIT 10.8) or radiolabeled before digestion with ^{125}I by the iodogen method (Markwell and Fox, 1978; UNIT 3.3).

BOULAS/CENTRAL UNIVERSITY LIBRARY

2. Add 1 vol of 2× SDS sample buffer to each sample. Heat 5 min at 85°C and then load into wells formed in a high-resolution Tris-tricine slab gel.

For this method to work, it is important to use Tris-tricine gels, as regular Laemmli gels do not provide the required resolution of small fragments. If the sample was prepared by digestion in a gel slice (Support Protocol) and already contains some SDS, then simply calculate how much 2× SDS sample buffer needs to be added to provide a final concentration of 2% SDS. If the sample was precipitated with acetone, redissolve it in 10 µl of 2× SDS sample buffer and add 10 µl water.

3. Perform one-dimensional electrophoresis as indicated in *UNIT 10.1*.

Bromphenol blue accompanies fragments in the 3-kDa range. It is wise to stop the run when the bromophenol blue band is at least 1 cm from the bottom of the gel.

4. Prepare gel for staining as recommended in *UNIT 10.5* for the particular stain (silver or Coomassie blue) that is to be used.

With silver staining, best results are obtained if the gel is washed with at least four changes of 50% methanol over 2 hr or equilibrated with 50% methanol overnight. Small peptides do not stain as intensely as larger peptides and may leak out of the gel. Fixing with glutaraldehyde (UNIT 10.5) may prevent this from happening and will enhance the staining obtained with silver.

5a. Detect proteins by standard methods, such as silver or Coomassie blue staining (*UNIT 10.5*).

5b. If proteins have previously been radiolabeled, fix and dry the gel, then detect proteins directly using a phosphoimager *or* by autoradiography (for ^{32}P or ^{125}I) or fluorography (for ^{3}H, ^{14}C, or ^{35}S) with XAR X-ray film.

Methods for autoradiography and fluorography can be found in Laskey and Mills (1975).

SUPPORT PROTOCOL

DIGESTION OF PROTEIN IN AN SDS-POLYACRYLAMIDE GEL SLICE

On occasion, it is desirable to compare a recombinant protein with authentic material after purification by SDS-PAGE. For this protocol, ~50 pmol protein is required. The samples are subjected to SDS-PAGE in the normal manner (*UNITS 10.1 & 10.4*) and stained with Coomassie blue (*UNIT 10.5*). Bands of interest are simply cut from the gel and treated as described below; the digested fragments can then be analyzed by HPLC (Basic Protocol 1) or by high-resolution gel electrophoresis (Alternate Protocol).

***Additional Materials** (also see Basic Protocol 1)*

10 mM Tris·Cl (pH 7.5)/0.1% (w/v) SDS
1.5-ml Kontes microcentrifuge tube and pestle, or equivalent
1.5-ml low-protein-binding microfilterfuge tube (0.2-µm cellulose acetate; Rainin or Costar)
Dry ice/ethanol bath (optional)
Additional reagents and equipment for one- or two-dimensional SDS-PAGE (*UNITS 10.1 & 10.4*), staining with Coomassie blue (*UNIT 10.5*), and proteolytic digestion of proteins in gels (*UNIT 11.3*)

Gel purify the protein of interest

1. Load a sample containing ≥50 pmol protein onto an SDS-polyacrylamide gel and perform one- or two-dimensional SDS-PAGE (*UNITS 10.1 & 10.4*), then stain with Coomassie blue and destain in standard fashion (*UNIT 10.5*).

The following list of equivalences is helpful for determining the required amount of protein: for a 100-kDa protein, 100 µg = 1 nmol; for a 50-kDa protein, 50 µg = 1 nmol;

BRU IASI / CENTRAL UNIVERSITY LIBRARY

and for 25-kDa protein, 25 ug = 1 nmol. Because proteins are reduced and denatured in SDS sample buffer, it is not generally necessary to further treat the protein with reducing or alkylating agents. However, if there is concern about disulfides, the protein can be reduced and alkylated prior to electrophoresis.

2. Wash the gel slice in water, using four changes in 1 hr with constant shaking, to remove as much of the destaining solution as possible.

3. Dry the gel slice in air for 15 min.

Digest or chemically cleave the sample

4. Rehydrate the gel slice with digestion buffer containing an appropriate amount of the selected enzyme or chemical cleavage agent: e.g., 140 µl digestion buffer containing 0.003 U endoproteinase Lys-C per µg protein, or ~1:25 (w/w) enzyme to protein.

   Refer to UNITS 11.1 & 11.3 for protocols for different proteolytic enzymes, including appropriate digestion buffers. This methodology can also be used to cleave proteins using chemical agents such as CNBr, which cleaves at Met groups; BNPS-skatole, which cleaves at Trp groups; or hydroxylamine, which cleaves at Asn-Gly bonds. Procedures for using these agents can be found in UNIT 11.4.

5. Macerate the gel with a tight-fitting pestle (a Kontes microcentrifuge tube and pestle are ideal). Carefully rinse the pestle with an additional 50 µl digestion buffer.

6. Cap the tube, wrap a strip of Parafilm tightly around the cap to prevent evaporation, and allow to digest overnight (~16 hr) at 37°C.

7. After digestion, separate the protein fragments from the gel pieces by centrifuging 5 min at ~2000 to 4000 × *g* (see manufacturers' recommendations) through a 1.5-ml low-protein-binding microfilterfuge tube.

   An efficient way to transfer the gel mixture to a microfilterfuge tube is to simply cut the bottom off the microcentrifuge tube containing the digest with a microcentrifuge cutter (Fisher) and assemble onto a microfilterfuge tube. The whole unit (cut microcentrifuge tube and microfilterfuge tube) can be stabilized by assembling it inside a 10-ml round plastic disposable tube. The unit is then centrifuged 5 min at low to medium speed (e.g., ~2000 to 4000 × g; see manufacturers' recommendations) in a tabletop centrifuge to allow all gel pieces to flow into the top compartment of the microfilterfuge. The use of a micropipet to transfer the mashed gel pieces to the microfilterfuge is not recommended. The use of a micropipet is not recommended because gel pieces will adhere to the inside of the pipet tip, reducing fragment recovery.

   Extracting the protein fragments from the gel is critical for good resolution of fragments by high-resolution gel electrophoresis.

8. Reextract the gel pieces with 100 µl of 10 mM Tris·Cl (pH 7.5)/0.1% SDS for 20 min at room temperature and then recentrifuge through the microfilterfuge tube.

9. Combine the extracts (containing the peptide fragments).

   If samples are to be analyzed by high-resolution SDS-PAGE, these extracts can be applied directly to the gel and steps 10 to 12 of the present protocol should be omitted; instead, proceed directly to electrophoresis (see Alternate Protocol, step 2).

Acetone precipitate samples that are to be analyzed by HPLC

10. Add 9 vol of –20°C acidified acetone to sample. Allow to precipitate overnight at –20°C or 2 hr in a dry ice/ethanol bath.

11. Microcentrifuge sample 15 min at maximum speed, 4°C. Carefully decant supernatant from the pellet.

BOULDER / CENTRAL UNIVERSITY LIBRARY

12. Dry the pellet in a Speedvac to remove all traces of acetone. Resuspend pellet in HPLC buffer A and proceed to separation by HPLC (see Basic Protocol 1, step 7).

Acetone precipitation is necessary to remove excess SDS present when digestion is performed in a gel slice. SDS levels should be reduced below 0.05% before the sample is applied to the HPLC column.

BASIC PROTOCOL 2

DETERMINING THE DISULFIDE LINKAGE PATTERN OF A RECOMBINANT PROTEIN

Correct formation of the disulfide linkages of a recombinant protein is at least as important for protein function as correct amino acid sequence, but can sometimes be more difficult to establish. First, the sample is treated to alkylate any free thiol groups so as to block their ability to catalyze disulfide interchange ("scrambling"); this is done using denaturing but nonreducing conditions to expose any buried thiols. In the next, key step the protein is digested by chemical or enzymatic means in such a way as to cleave the polypeptide chain at least once between successive Cys residues (except where two consecutive Cys residues share a disulfide bond, when this is not necessary). Resulting fragments containing only a single disulfide bond are then isolated by reversed-phase high-performance liquid chromatography (RP-HPLC) and identified by a combination of mass spectrometry and Edman analysis; each bond will either be holding two small peptide chains together, or holding a single polypeptide chain in a loop. This apparently simple task is often frustrated by the presence of closely spaced Cys residues (because it is necessary to cleave between them) and by the difficulty in ensuring that disulfide scrambling does not occur.

Given the huge variety of possible protein properties, it is impossible to give a single recipe for determining disulfide linkage patterns that can be blindly followed in all cases. The protocol that follows takes protein idiosyncracies into account as much as possible in the annotations which follow (or sometimes precede) critical steps; the proteins granulocyte/macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF) are discussed as examples.

NOTE: All reagents used should be of analytical grade or better. Solutions should be made fresh except where otherwise stated (see Reagents and Solutions). Special precautions are necessary when working with iodoacetic acid, concentrated formic acid, cyanogen bromide, and trifluoroacetic acid (TFA): these precautions are described at the points where use of these chemicals is described.

Materials

Sample of recombinant protein
Alkylation buffer (see recipe)
Nitrogen or argon, oxygen-free
Guanidine hydrochloride
50 mM and 2 M ammonium bicarbonate
2 mg/ml cyanogen bromide in 70% formic acid (see recipe)
HPLC solvents A and B for disulfide linkage analysis (see recipe)
1% formic acid
Proteases: pepsin, *Staphylococcus aureus* V8 protease (endoproteinase Glu-C), and/or trypsin (porcine variety, Sigma)
Glacial acetic acid
1 M dithiothreitol (DTT)

Pretreated dialysis tubing with appropriate MWCO (see recipe)
Apparatus for reversed-phase high-pressure liquid chromatography (RP-HPLC), preferably with automatic sample injector

BGU IASI UCENTRALNY UNIVERSITY LIBRARY

Appropriate analytical HPLC column: e.g., 25 cm × 4 mm i.d. filled with Nucleosil 5 µm, 300 Å C8 particles (Macherey-Nagel)

Appropriate preparative HPLC column: e.g., 25 cm × 4 cm i.d. filled with Nucleosil 5 µm (as above) for purifying up to ~0.2 mg protein, or 25 cm × 10 mm i.d. with same packing for up to ~1.5 mg protein (see Critical Parameters for further guidance)

Vacuum centrifuge: e.g., Speedvac (Savant)

Equipment for mass spectrometry of peptides

Additional reagents and equipment for dialysis (*UNIT 4.4*; *APPENDIX 3B*)

Block free thiols

1. Dissolve the protein to ~0.1 mM in alkylation buffer and incubate 30 min at room temperature (~22°C) in the dark under nitrogen or argon.

   Use 0.2 to 2 mg protein (depending on availability) for steps 1 to 3 in the first instance, and repeat on a larger scale if necessary.

   This step serves to alkylate any easily accessible thiol groups. Radiolabeled alkylating reagent (e.g., [^{14}C]iodoacetic acid) may be used to facilitate the later location of modified peptide.

2. Add solid guanidine hydrochloride to a final concentration of 6 M and continue incubation for a further 60 min.

   At this stage any previously buried thiols should become alkylated. Do not add thiol at the end of the incubation to consume excess alkylating agent in the normal fashion, as disulfides would then be at risk.

   It may be necessary to add the guanidine earlier on in order to solubilize the protein, in which case the 30-min preincubation should be omitted.

3. Transfer the sample to a prepared dialysis bag. Dialyze the sample (*UNIT 4.4; APPENDIX 3B*) in the dark at 4°C against 50 mM ammonium bicarbonate, using a bath volume ≥2000 times greater than the sample volume and stirring the bath magnetically. Change the solution after 1 hr, 2 hr, and 4 hr, and continue dialysis overnight (~18 hr total). Recover the protein by lyophilization.

   IMPORTANT NOTE: *Take great care not to damage the dialysis bag. A plastic automatic pipet tip is preferred for the transfer, but if a glass Pasteur pipet is used, remove sharp edges by heating it in a flame prior to taking up sample; avoid damage due to sharp fingernails, especially when knotting the bag.*

   Proteins known not to precipitate on removal of chaotrope can be recovered more quickly by gel filtration than by dialysis. Furthermore, steps 1 to 3 are usually omitted when it is known from attempted reaction with thiol-specific reagents or radiolabeled reagents that there are no unpaired Cys residues. Whenever there is reason to suspect the presence of an unpaired Cys—e.g., an odd number of Cys residues in the sequence, reaction with thiol-specific reagents (Ellman, 1959; Thannhauser et al., 1984) or radiolabeled reagents —these blocking steps must precede the fragmentation procedures. For example, blocking was necessary for the protein G-CSF (Wingfield et al., 1988) but not for GM-CSF (Schrimsher et al., 1987).

Fragment the polypeptide chains

4. Depending on the known or expected amino acid sequence, select digestion conditions (cyanogen bromide, one or more proteolytic enzymes, or a combination of these in succession) that will cleave the polypeptide chain at least once between successive Cys residues (see Critical Parameters for guidance). Perform an appropriate combination of the treatments described in steps 5 to 8.

   If the protein is known to contain a few well-spaced Met residues, cyanogen bromide is often useful as a first fragmentation step.

B. C. U. „M. EMINESCU" IAŞI
CHIMIE

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

For cyanogen bromide treatment

5. Dissolve the recombinant protein at 1 mg/ml in 2 mg/ml cyanogen bromide/70% formic acid. Seal the tube and incubate 24 hr in the dark at room temperature.

   CAUTION: *Cyanogen bromide is toxic and volatile; concentrated formic acid is very corrosive (see recipes for detailed precautions).*

6a. If the complexity of the analysis is high (i.e., a large protein and/or many disulfide bridges are involved) and the expected sequence suggests the problem can be simplified by working individually with the cyanogen bromide fragments, dilute the cyanogen bromide digest at least three-fold with HPLC solvent A and separate by RP-HPLC (steps 9 and 10), then proceed to subdigest the large fragments enzymatically.

6b. Otherwise, simply remove solvent and reagent under high vacuum in a vacuum centrifuge (avoid exposing other samples in the vacuum centrifuge to reagent vapors), then proceed to enzymatic digestion.

   Here and throughout the protocol, use the vacuum centrifuge with the heater switched off to lessen the risk of such reactions as deamidation, oxidation, and N-terminal cyclization.

For protease treatment

7a. *Using pepsin:* Dissolve the protein or protein fragments at ~1 mg/ml in 1% (v/v) formic acid, add pepsin to obtain a 1/100 (w/w) enzyme/substrate ratio, and incubate 16 to 24 hr at room temperature.

   Pepsin was useful for G-CSF, although trypsin or V8 protease were more useful for GM-CSF (Schrimsher et al., 1987).

7b. *Using trypsin or V8 protease:* Dissolve the protein or protein fragment at ~1 mg/ml in 0.1 M phosphate buffer, pH 7.0. Add enzyme to obtain a 1/100 (w/w) enzyme/substrate ratio, and incubate 4 hr at 37°C.

   When using trypsin, the porcine variety (Sigma) is preferred over the bovine enzyme as it retains its activity at lower pH.

8. If trypsin or V8 protease is used for digestion at neutral or slightly alkaline pH, acidify the digest to pH 3 with acetic acid just prior to HPLC (step 9) to stop the digestion and prepare the sample to be placed in the automatic injector.

   A peptic digest is already acidic and is injected directly; if it sits in the automatic injector, the digestion will continue.

Analyze digest by RP-HPLC

9. Subject the cyanogen bromide or enzyme digest to analytical RP-HPLC—e.g., using the trifluoroacetic acid/acetonitrile RP-HPLC system (*UNIT 11.6*), which is very convenient because both solvents are completely volatile. Use a gradient of 2% HPLC solvent B/min up to 100% B. Monitor at low wavelength (e.g., 214 nm), as many fractions may not contain aromatic residues.

Perform preparative HPLC

10. Perform preparative HPLC separations on digests that showed a suitable number of well-separated fragments in step 9. For best results, use a much shallower gradient (e.g., 0.2% solvent B/min) over the percentages of interest deduced from the screening run.

    For further discussion of the design of the preparative gradient, see, for example, Rose et al. (1992).

BSU IASI CENTRAL UNIVERSITY LIBRARY

Particularly for preparative HPLC runs, it is preferable to acidify the digest (if not already acid) to pH 3 with acetic acid prior to injection (check by spotting onto pH paper), as otherwise the early part of the chromatogram may be compromised. Ideally, choose column dimensions and flow rate compatible with the quantity of digested protein (see Critical Parameters). If several milligram of protein are available, it makes life much easier to work at the 1.5-mg scale, but remember that it may sometimes be necessary to return to step 7 and continue the analysis with a different digest.

11. Recover peptides by drying the collected fractions in the vacuum centrifuge, then redissolve each in 200 µl HPLC solvent A. Divide each fraction, placing two analytical-sized aliquots (10 µl each if a major peak and >0.5 mg digest were used; 30 µl if a minor peak and <0.5 mg digest were used) directly into the automatic injector sample tubes, and retaining the remainder separately.

The original chromatogram obtained during collection of the corresponding preparative fraction should be used to select an appropriate sample volume and attenuation level for the analytical runs that will follow.

Locate fractions containing disulfide bonds

12. To one sample add 2 M ammonium bicarbonate to 50 mM final and 1 M DTT to 50 mM final. To the second sample (control) add ammonium bicarbonate but no DTT. Close tubes and incubate 2 hr at 37°C.

Steps 12 and 13 constitute the simplest of several possible ways of locating fragments containing a disulfide bond: attempted reduction of disulfide bonds in each HPLC fraction with DTT followed by reinjection on a shallow gradient.

To perform this assay on a dry sample, the peptide can simply be dissolved in 50 mM ammonium bicarbonate/50 mM DTT.

13. Acidify the samples with a few microliters of acetic acid (test a blank with pH paper), agitate to liberate the carbon dioxide bubbles, then analyze the samples in pairs (reduced and nonreduced) by RP-HPLC, using the analytical column but with the shallow gradient used for the preparative run (step 10).

As mentioned in step 11, the original chromatogram obtained during collection of the corresponding preparative fraction, and the proportion taken for analysis, permit an appropriate choice of attenuation to be made for these analytical runs.

14. Interpret the pairs of chromatograms (attempted reduction and control). When all has gone well, if no disulfide bond is present there should be essentially no difference between attempted reduction and control. If a disulfide bond is present, then either this bond is holding two small peptide chains together, or it is holding a single polypeptide chain in a loop. In the former case, two peaks should be visible on reduction; in the latter case all that will be observed is a small shift to later retention time (opening of the loop exposes more of the peptide chain to the stationary phase).

The reason for performing a control incubation in the absence of reductant is that some fractions may shift retention time or develop structure due to changes such as opening of a homoserine lactone, cyclization of an N-terminal Gln, or oxidation of methionine to its sulfoxide, and this change might otherwise be mistaken for reduction.

Other sources of difficulty in interpreting results include the following: One of the components liberated by reduction of a disulfide bond may elute early and be difficult to detect because of the presence of salt and DTT peaks. One component may be short and devoid of aromatic residues and so be much less visible on the chromatogram. Finally, because only one HPLC dimension was used for the initial collection, there may be a nonreducible component present in addition to a reducible one; this need not be a problem when both Edman and mass spectrometric techniques are used for characterization.

BOULDER / CENTRAL UNIVERSITY LIBRARY

Characterize Cys-containing peptides

15. For each fraction identified as containing a disulfide bond, repeat the reduction (step 12) with an appropriate portion of the remaining nonreduced fraction (set aside in step 11), repeat the HPLC separation, and collect the reduced components.

    For an example of where this repeated reduction and separation strategy was used, see Schrimsher et al. (1987). To determine sample size, the mass spectroscopist who will perform that analysis should be consulted regarding how much protein will be required.

16. Divide the fractions and submit these reduced components, together with some of the unreduced fraction, for examination both by mass spectrometry and by Edman degradation.

    The combination of mass spectrometry and Edman degradation provides the quickest and surest approach to characterizing the fractions containing disulfide bonds. Mass spectrometry provides the molecular weight of the peptide component (or components) present, while Edman analysis should give their N-terminal sequences.

    The expense and sophistication of mass spectrometric equipment is such that usually, where it exists, a competent person is present to give advice on its use. Electrospray ionization mass spectrometry (ESI-MS) is most suited to this application, although good results may also be obtained by fast-atom-bombardment (liquid secondary-ion) mass spectrometry if a high-performance machine is available. Matrix-assisted laser-desorption ionization time-of-flight (MALDI-TOF) mass spectrometry may also be used (see UNIT 11.6); mass precision is generally lower than with fast-atom-bombardment or ESI spectrometry, but can be adequate if the time-of-flight analyzer is operated in reflectron mode and carefully calibrated (using an internal standard), and is excellent if the MALDI source is connected to a Fourier-transform ion cyclotron resonance analyzer.

    Some peptide components may not be susceptible to Edman degradation. A peptide may be N-terminally blocked (e.g., by acetyl for the N-terminal peptide of the protein, or by a residue of pyroglutamic acid if a Gln residue liberated during proteolysis has cyclized). This problem is discussed in Critical Parameters and Troubleshooting.

17. Align the peptides identified in step 16 with the known sequence of the recombinant protein. Interpret the molecular weights determined quite precisely by mass spectrometry.

    Even if the Edman degradation did not provide sequence information up to the C terminus of a given peptide, the N-terminal starting point should be unambiguous: the C terminus can then be deduced from the mass of the peptide. Taken together, the Edman and mass spectrometry data generally allow the disulfide bonding pattern of the component peptides to be deduced, and hence the bonding pattern of the recombinant protein. Even where this is not the case, sufficient information is gained to greatly facilitate a second attempt.

    In some cases, the fragments identified indicate neither a single disulfide bond in a loop nor two short chains held together by one disulfide bond. In such cases (e.g., where two chains are both linked to a third by disulfide bonds; Rose et al., 1992), further cycles of fragmentation, isolation, and identification must be performed in order to cleave between the Cys residues.

    Scintillation counting of fractions permits rapid location of any Cys residues radioalkylated in Step 1. Characterization of any such fractions by Edman degradation and mass spectrometry completes linkage assignment by proving that the Cys residues so alkylated could not have been involved in disulfide bonds.

BRU IASI / BETRAUNIVERSITY LIBRARY

DETERMINING CHARGE HETEROGENEITY BY TWO-DIMENSIONAL TITRATION CURVE ANALYSIS

Unfolding of proteins can be monitored by running the sample across a urea gradient—the resulting denaturation curve, often sigmoidal in shape, represents the transition from the folded to the unfolded state. In general, pH/mobility curves of proteins are generated in a polyacrylamide IEF slab gel (see Fig. 7.3.1 for an outline of the procedure).

Materials

Acrylamide/bisacrylamide stock solution (see recipe)
Carrier ampholytes: e.g., Pharmalyte (Pharmacia Biotech), Bio-Lyte (Bio-Rad), or Servalyte (Serva)
10% (w/v) ammonium persulfate stock solution (see recipe)
N,N,N′,N′-tetramethylethylene diamine (TEMED)
Kerosene
Electrode solutions (see recipe)
Sample of recombinant protein in aqueous solution containing ≤10 mM Tris·acetate (or other salt or buffer consisting of weak acids and bases)
Coomassie blue staining solution: 0.1% (w/v) Coomassie brilliant blue R-250/25% (v/v) ethanol/8% (v/v) acetic acid
Destaining solution: 25% (v/v) ethanol/8% (v/v) acetic acid

Gel Bond PAG sheets
Electrophoresis unit for horizontal slab gel operation: e.g., Multiphor (Pharmacia Biotech)
Levelling table
IEF electrode filter paper strips (Pharmacia Biotech)

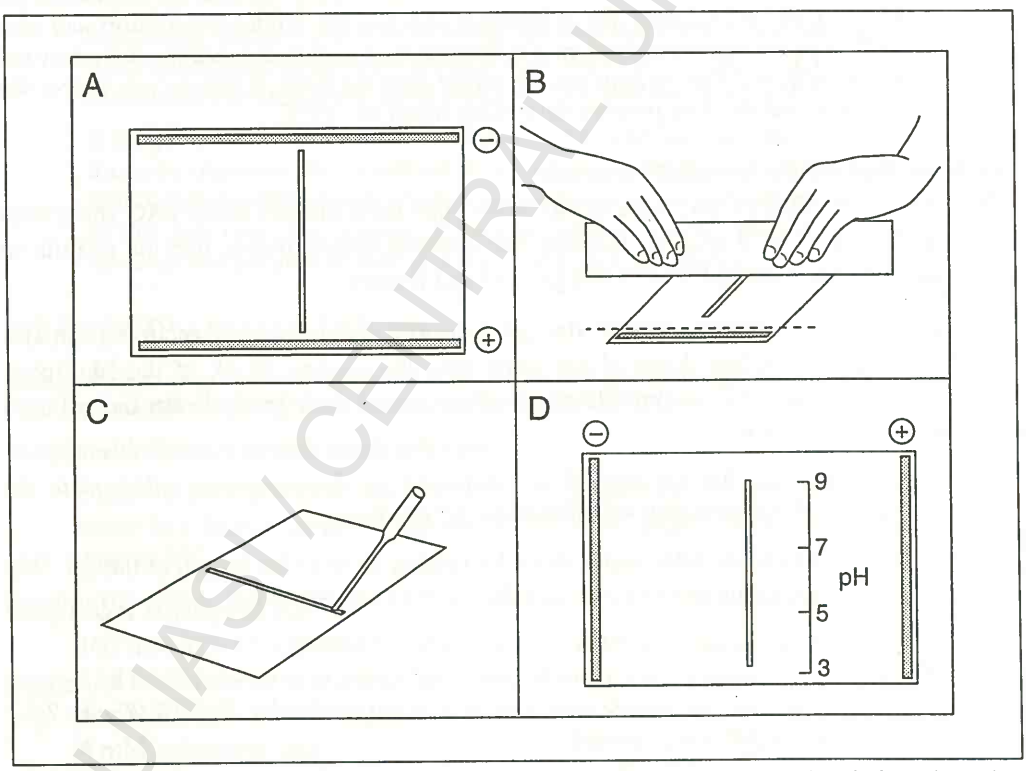

Figure 7.3.1 Experimental procedure for generating titration curves by isoelectric focusing. First the pH gradient is formed by focusing the carrier ampholyte mixture without sample (first-dimension run; **A**); the electrode strips and the gel layer underneath are then removed (**B**); the sample is applied in the trench now perpendicular to the pH gradient (**C**); the second-dimension run is performed perpendicular to the first dimension axis (**D**). From Righetti et al. (1979).

FUJIASI / CENTRAL UNIVERSITY LIBRARY

Constant-power supply (up to 3000 V, 200 mA, 20 W)
Thermostatic water bath: e.g., MultiTemp (Pharmacia Biotech)
Titration curve kit (Pharmacia Biotech)

Additional reagents and equipment for denaturing IEF in slab gels (*UNIT 10.2*)

Cast the gel

1. Cut a Gel Bond PAG sheet in half (to 12.5 × 12.5 cm) to form a gel-supporting foil. Roll the supporting foil on the glass plate of the electrophoresis unit, putting a few drops of water on the back to secure adhesion.

   The hydrophilic surface of the foil should face the operator; this is the surface designed for adhesion of the gelling layer.

2. Complete the cassette by placing the glass plate–foil sandwich between the two marks on top of the slot former and fastening them together using four clamps. Lay out the completed cassette horizontally, preferably on a levelling table.

3. Prepare 28 ml of an appropriate gel solution—e.g., containing 5%T and 4%C monomers and 2% ampholytes—from acrylamide/bisacrylamide stock solution and carrier ampholytes (see *UNIT 10.2* for details of gel casting). Degas for 5 to 10 min.

   Preparing 28 ml of solution provides a slight excess, as 25 ml will be needed to fill up the gel cassette.

4. Add 4 µl ammonium persulfate stock solution and 1 µl pure TEMED per milliliter of gelling solution; mix carefully. Immediately inject the gel solution between the slot-former and the upper glass plate (the solution will fill the cassette by capillary action). Let stand while polymerization occurs (this will be complete after 1 hr).

   IMPORTANT NOTE: *When titration curves are run under denaturing conditions (in 8 M urea), the gel solution will polymerize very quickly. High temperatures will also greatly accelerate polymerization. If polymerization occurs too quickly, there may not even be sufficient time to pour out the liquid from the flask. If this occurs, repeat the procedure and this time precool the gelling liquid to ~10°C.*

Perform first-dimension electrophoresis

5. Remove the clamps and separate the glass plate from the Gel Bond PAG sheet with a gentle twist of a spatula. Holding the cassette upside down, use the spatula to introduce air bubbles between the gel and slot former.

6. Starting from a corner, remove the gel from the plastic cover containing the slot former. Spread a few drops of kerosene onto the cooling block of the Multiphor chamber (set at 10°C) to provide good adhesion, and then gently lower the gel onto the cooling surface.

   Any trapped air bubbles should be eliminated, as their presence will lead to the formation of hot spots that will distort the pH gradient.

7. Prepare IEF electrode filter paper strips by cutting them to the length of the gel. Wet in electrode solutions and blot excess solution with a paper tissue. Apply strips to gel surface.

   For good performance, the electrode strips and platinum wires should all be parallel to one another and the sample trench should be perpendicular. Refer to Figure 7.3.1 for this and the following operation.

8. Perform first-dimension electrophoresis at 10 W constant power with voltage and current set to a maximum (typically, at steady state, the voltage should be ~1000 V).

   This focusing step is usually terminated in 50 min.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Perform second-dimension electrophoresis

9. Remove the electrode strips and use a long blade to cut away the strips of gel underlying the electrode strips (see Fig. 7.3.1B).

   This step is important, as otherwise considerable heating will occur in these regions due to high conductivity.

10. Turn the gel around 90° on the cooling plate. Prepare and apply new electrode strips, using the same electrode solutions as for the first dimension. The sample trench is now parallel to the electrode strips (see Fig. 7.3.1).

11. Apply the sample by filling the trench with ~100 µl of protein solution (typically 100 to 400 µg protein, depending on sample heterogeneity, at 1 to 4 mg/ml; see Fig. 7.3.1C).

12. Perform second-dimension electrophoresis at 600 V for 5 to 20 min (based on sample mobility).

    High levels of salts, as well as salts and buffers comprising strong acids and bases, must be strictly avoided in any focusing process. For best results, the sample should not contain more than 10 mM salt or buffer, and these should consist of weak acids and bases—e.g., Tris-acetate, but not Tris·Cl or sodium acetate.

Stain and destain gel

13. Place the gel in Coomassie blue staining solution and allow to stain 1 hr with shaking.

    Staining solution can be reused at least 10 times. Store at room temperature protected from light.

14. Replace the staining solution with destaining solution. Destain with shaking, changing solution several times until a clear background is seen.

    Destaining solution can also be stored at room temperature and reused several times if filtered through a charcoal cartridge after each use. Beware of excessive evaporation of both ethanol and acetic acid, which will weaken the destaining process.

    If the gel is over-destained, the titration curve zones will also fade away. In this case, it can be restained and destained. When too little sample is available to be visualized in this fashion, any variant of silver staining may be used (Rabilloud, 1990; UNIT 10.5). In this last case, the amount of sample can be 20 times smaller. For best results, however, the gel slab should be thinner (e.g., 0.5 mm thick).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Acrylamide/bisacrylamide stock solution

Dissolve 28.7 g acrylamide and 1.3 g *N,N'*-methylene bisacrylamide in distilled water to a final volume of 100 ml (30%T, 4%C final). Store up to 3 weeks in the dark at 4°C.

Alkylation buffer, pH 8.0

100 mM Tris·Cl adjusted to pH 8.0 with 6 M HCl or glacial acetic acid
125 mM NaCl
5 mM EDTA
4 mM iodoacetic acid
Prepare fresh just before use

Concentrated stock solutions of EDTA (sodium salt; APPENDIX 2E) and iodoacetic acid in water may be made up and kept at –20°C (stable at least 1 month). Iodoacetic acid

continued

BOSTON UNIVERSITY LIBRARY

should be bought in small amounts and should take the form of white crystals. The solid and its solutions are light-sensitive and should therefore be shielded with aluminum foil and kept protected from direct sunlight.

CAUTION: *Solid iodoacetic acid and its concentrated solutions are corrosive—wear gloves when handling these materials.*

Ammonium persulfate, 10% (w/v)

Dissolve 50 mg ammonium persulfate in 0.5 ml distilled water. Prepare fresh each time.

Cyanogen bromide, 2 mg/ml in 70% formic acid

Weigh an empty open small glass tube or vial together with its cap, and then move this container to a chemical fume hood. Add a few small crystals of cyanogen bromide, replace the cap, and then reweigh the container to calculate the amount of cyanogen bromide added. Dilute with sufficient 70% formic acid to obtain a 2 mg/ml solution. (This procedure avoids the need to use a balance inside the chemical fume hood.) Prepare fresh.

CAUTION: *Cyanogen bromide, though a solid at room temperature, is quite volatile and sufficiently toxic to have been used as a chemical warfare agent (albeit a rather ineffective one). It should be manipulated in a chemical fume hood and gloves should be worn when handling.*

Buy good-quality reagent, keep solid protected from light at 4°C to minimize degradation, and make up fresh solution as required, as otherwise contaminating free bromine will tend to oxidize Met and Trp residues, which can result in cleavage at Trp and failure to cleave at Met.

Dialysis tubing, pretreated

Obtain dialysis tubing with appropriate MWCO (molecular weight cut-off) for the protein under study—e.g., Visking 18/32, which has a cut-off after boiling of <5000—and prepare an appropriate length of tubing fresh before use by treating it as follows to remove glycerol and residues from manufacture. Bring 1% sodium bicarbonate solution to a simmer in a beaker which has no chips or cracks (as these could pierce the tubing). Place the tubing in the solution and simmer 10 min; do not boil vigorously or the tubing will protrude from the solution and become brittle. Cool by adding distilled water, then thoroughly rinse the tubing inside and out with distilled water.

Excess prepared tubing can be stored in water or buffer for a few days at 4°C if precautions are taken to avoid microbial growth (e.g., add sodium azide to 0.005%).

IMPORTANT NOTE: *Throughout tubing preparation, beware of sharp edges, including fingernails and especially pipets, which can easily damage the tube and lead to complete loss of sample during the experiment.*

Digestion buffer

10 mM Tris·Cl, pH 8.0
0.1 mM EDTA
0.02 M NH_4HCO_3
0.1% SDS (include *only* if protein is to be digested in a gel slice)
Prepare fresh

Different proteolytic enzymes and chemical cleavage agents require different digestion buffers; refer to UNITS 11.1 & 11.4 for a discussion of these requirements.

DSU IASL CENTRAL UNIVERSITY LIBRARY

Electrode solutions

Use 50 mM solutions of either weak acids (e.g., acetic acid) or weak bases (e.g., Tris) as anolyte and catholyte, respectively (strong acids and bases should be avoided). Alternatively, use 50 mM solutions of isoionic zwitterions (e.g., Asp, pI 2.77, or Glu, pI 3.22) as anolyte and 50 mM Lys (pI 9.74) or 50 mM Arg (pI 10.76) as catholyte. Store in cold room to avoid bacterial growth. Keep basic solutions tightly capped and check the pH before use. If the pH decreases ≥0.5 pH units (due to CO_2 absorption), discard the solution.

HPLC solvents for disulfide linkage analysis

RP-HPLC solvent A: Add 1 g HPLC-grade trifluoroacetic acid (TFA; Pierce or ABI) to 1 liter of HPLC-grade water (e.g., purified using a Milli-Q system, Millipore) and mix. Degas either by vacuum filtration in an all-glass device (Millipore) or by sparging with helium. The solution is good for at least 3 months when stored at room temperature, protected from dust, and degassed prior to each use.

HPLC solvent B: Add 1 g TFA to 100 ml HPLC-grade water and mix. Dilute to 1 liter with HPLC-gradient-grade acetonitrile. Degas as for solvent A except, if using vacuum filtration, employ a solvent-resistant filter membrane (e.g., Millipore). The solution is good for at least 3 months when stored at room temperature, protected from dust, and degassed prior to each use.

CAUTION: *Undiluted TFA is very corrosive: wear eye protection (preferably a face shield) and gloves. Once diluted to 1 g/liter, it presents no danger.*

HPLC solvents for peptide mapping

HPLC solvent A: 0.1% (v/v) TFA in water
HPLC solvent B: 0.07% (v/v) TFA/80% acetonitrile

Filter and degas both solvents. For best results, balance absorption of solvents A and B at 215 nm by adding TFA until absorption values are equal. Store up to 1 week at room temperature.

COMMENTARY

Background Information

Peptide mapping

The number of different digests required to characterize a recombinant protein depends on the analytical method used and on the quality of information produced. Analysis by high-performance liquid chromatography (HPLC; Basic Protocol 1) allows the use of proteolytic agents that cut proteins generally into small fragments (such as trypsin, which cuts at Arg and Lys residues; endoproteinase Lys-C, specific for Lys residues; or endoproteinase Asp-N, specific for Asp residues). Analysis by SDS-polyacrylamide gel electrophoresis (SDS-PAGE; Alternate Protocol), on the other hand, requires larger fragments (≥2 kDa in size) and thus is limited to agents that cut the protein of interest at amino acid residues that are less frequent (such as CNBr or BNPS-skatole, which cut at Met and Trp residues, respectively) or to partial digests with proteolytic enzymes (such as endoproteinases Lys-C or Asp-N, which cut at Lys and Asp residues, respectively). These proteolytic agents have very strict specificities and easily predicted patterns of digestion. Other proteases have rather broad specificities (e.g., chymotrypsin is specific for Tyr, Phe, and Trp and to a lesser extent for Leu, Met, Ala, Asp, and Glu) and therefore produce a large number of fragments. These proteases are ideal for comparing a recombinant protein to the native protein because many more sites can be probed with only one digestion. Still other proteases, such as endoproteinase Glu-C (otherwise known as *Staphylococcus aureus* V8 protease), recognize one or two sites (in this case Glu and Asp) depending on the buffer conditions used for the digestion. For a useful discussion of these enzymes, see Allen (1989) and *UNIT 11.1*.

For recombinant proteins, the investigator has the advantage of knowing the predicted amino acid sequence and can design a specific strategy based on the distribution of key amino acids that define chemical and protease cleav-

BODLEIAN CENTRAL UNIVERSITY LIBRARY

age sites. Several computer programs predict cut sites, HPLC elution patterns, and molecular weights of fragments. The Peptide Sort program from Genetics Computer Group (GCG; University of Wisconsin, Madison, Wis.) is one such program. Because many cleavage agents give rise to a combination of complete and partial digests, it is important to treat the recombinant protein and the native isolated protein (if available) under the same conditions.

If it is impossible to obtain enough native material for comparison by the methods described above, there are a number of analytical techniques that can be used to prove the recombinant protein has the correct structure. The easiest and most cost-effective method is to analyze individual peaks from an HPLC run for their amino acid compositions; this can be compared to the predicted composition for each fragment. This method is most powerful when combined with N-terminal amino acid sequencing, which can identify each fragment collected by HPLC. The intact protein can also be submitted for N-terminal sequencing. With new instruments, it should be possible to identify as many as 50 to 100 residues directly from the N-terminus. On several occasions it has been possible to sequence up to 50% of a protein from a single digest (N. Denslow, unpub. observ.).

Newer analytical methods rely on mass spectrometry to analyze the digest of recombinant protein (Langen et al., 1993; Patterson, 1994). The mass accuracy of mass spectrometers is sufficient to identify a fragment directly. The preferred technique relies on the use of electrospray ionization (ESI)–quadrupole mass spectrometers, especially if the mass spectrometer is in-line with the HPLC. ESI-MS has a mass accuracy of 0.01%. Accurate data, however, can also be obtained from a matrix-assisted laser-desorption ionization time-of-flight (MALDI-TOF) mass spectrometer, which typically has a mass accuracy of 0.03%. In this case, HPLC fractions must be collected and mixed with a matrix for analysis.

Disulfide linkage analysis

Correct formation of the disulfide linkages of a recombinant protein is at least as important for function as correct amino acid sequence, but (as can be appreciated from the complexity of Basic Protocol 2) it is sometimes more difficult to establish. The key to success generally involves digestion of the protein by chemical or enzymatic means in such a way as to cleave the polypeptide chain at least once between successive Cys residues—except where two consecutive Cys residues share a disulfide bond, when this is not necessary. This apparently simple task is often frustrated by the presence of closely spaced Cys residues, because it is not always easy to cleave between these. Some instructive examples showing the difficulties encountered when two Cys residues are very close or juxtaposed are discussed by Morris and Pucci (1985); Hojrup and Magnusson (1987); and Rose et al. (1992). Cleavage techniques are somewhat limited by the need to prevent disulfide scrambling (Hojrup and Magnusson, 1987; Rose et al., 1992). Scrambling can occur in the presence of strong mineral acid, and also in neutral to basic medium, which is why mildly acidic conditions are preferred where possible. Scrambling is catalyzed by the presence of free thiol; for this reason any unpaired Cys residues (which may be present in a small fraction of improperly refolded material) must be blocked in the first step.

It must be emphasized that people working with a recombinant protein usually have two enormous advantages over those working with a rare polypeptide isolated from natural sources—they have much more material, and they know most, if not all, of the amino acid sequence. These advantages must be exploited to the full: it is advisable to use trial amounts, change tactics if solubility problems are insurmountable, and design the fragmentation strategy around the known sequence. The method described is designed to give results as reliably and rapidly as possible with recombinant proteins, and would need extensive modification to be suitable for dealing with trace amounts of proteins derived from natural sources.

Titration curve analysis

Protein titration curves (in reality, pH/mobility curves) became suddenly popular in the late seventies after an original report by Rosengren et al. (1977), who demonstrated a simple method to force a protein to migrate across a quasi-stationary pH gradient in such a way as to trace a sigmoidal path resembling a classical potentiometric titration curve. These pH/mobility curves were found to be quite useful in a number of applications: (1) for screening of genetic mutants (Righetti et al., 1978a; Righetti et al., 1979); (2) for studying macromolecule-ligand interactions (Krishnamoorthy et al., 1978; Constans et al., 1980); (3) for demonstrating macromolecule-macromolecule interactions (Righetti et al., 1978b; Lostanlen et al., 1980; Gianazza et al., 1980); (4) for direct pK

determination of simple cations and anions and of uni-uni-valent amphoteric molecules (Righetti et al., 1979; Valentini et al., 1980); (5) for determining dissociation constants (K_d) of ligands and proteins and their pH dependence (Ek et al., 1980; Ek and Righetti, 1980); (6) for detecting protein and peptide microheterogeneity (Arnaud et al., 1980; Henner and Sitrin, 1984; Picard et al., 1987; Van Den Oetelaar and Hoenders, 1987); and (7) for choosing optimal pH conditions in ion-exchange chromatography (Fägerstam et al., 1983).

The times must have been ripe for such an idea, because at just about the same time, Creighton (1979) reported a method for studying the unfolding of proteins by running them across a urea gradient: these denaturation curves, often sigmoidal in shape, represent the transition from the folded to the unfolded state. In an analogous manner, it is possible to study the melting profiles of DNA (from double helix to single strand) by running them across a thermal gradient: these curves too are sigmoidal in shape (Riesner et al., 1991).

In general, pH/mobility curves of proteins are generated in a polyacrylamide slab gel. However, a number of modifications have been reported, including the use of: (1) cellulose acetate as support (Vickers and Robinson, 1983); (2) agarose thin layers (Troungos et al., 1982); (3) highly cross-linked (highly porous) polyacrylamide matrices (Bianchi-Bosisio et al., 1980); (4) thin-layer silica gels (Stahl and Muller, 1981)—in this last instance, however, no electric field is used and the analysis performed is a standard ascending thin-layer chromatography against a pH gradient created by buffer diffusion; (5) paper sheets as supports (Tate, 1981)—here too the pH gradient is obtained by bathing the paper sheet in a number of buffers titrated at different pH values; and (6) paper sheets in water-alcohol solvents (Jokl et al., 1979)—again, the pH gradient is obtained as in Tate (1981).

The typical gel slab size normally employed consists of a polyacrylamide plaque 12.5 × 12.5 cm and 1.6 mm in thickness. Because this is the typical plate commercially available, that is the only method described extensively in Basic Protocol 3. However, it must be emphasized that by using the Pharmacia Biotech Phast-System, titration curves can be run in a small format (typically 4 cm × 4 cm × 0.5 mm) and the entire operation (including staining and destaining) can be performed in only 50 min. Additionally, Rüchel and Trost (1981) have described a minichamber only 35 × 15 × 0.5 mm vertically inserted into two cylindrical buffer reservoirs. The gel slab is polymerized by using a two-vessel gradient mixer with two limiting solutions titrated to different pH values; thus, in this case too an artificial pH gradient (utilizing diffusion of nonamphoteric buffers) is created instead of a natural one (created by a current with the aid of a multitude of amphoteric buffers).

Critical Parameters and Troubleshooting

Peptide mapping

Excess SDS (>0.01%) is a problem for peptide mapping by HPLC (Basic Protocol 1). For samples digested in a gel slice in the presence of 0.1% SDS, the detergent must be removed prior to applying the sample to the HPLC. Otherwise, it will interfere with the resolution of fragments and the retention time on the column, and numerous artifactual peaks will be observed. SDS can be removed to a certain extent by precipitation in acidified acetone. Total removal of SDS from a protein solution requires either binding to an ion exchanger or electrophoresis. Ion-exchange precolumns that can be put in-line with the reverse phase column to remove SDS from a contaminated sample are available commercially (e.g., from The Nest Group).

Excess of either SDS or salt causes problems for high-resolution SDS-polyacrylamide gels. These factors should not be a problem if the method described in the Alternate Protocol is used. In the event that a protocol containing high salt or excess SDS is used to cleave a protein, levels of both can be reduced by precipitation with acidified acetone. Generally, proteins that are precipitated by acidified acetone in the presence of SDS are readily solubilized after precipitation, probably because a small amount of SDS adheres to the protein.

It is important to use the correct digestion buffer for each protease (Allen, 1989). If the wrong conditions are used, the enzyme is likely to lose its specificity, if it works at all. Some proteases can withstand up to 0.1% SDS or 10% acetonitrile without loosing activity. Others are sensitive to 0.01% SDS, and in these cases the conditions described here may not be suitable. Refer to *UNITS 11.1 & 11.4* for specific protocols. For best results, proteases should be of sequencing grade.

For high-resolution SDS-PAGE of proteolytic digests done in gel slices, it is crucial to

ROSWELL PARK CANCER INSTITUTE LIBRARY

separate the polypeptide fragments from the gel pieces prior to running the sample. As indicated in the protocol, this can be done easily by centrifuging the sample through a microfilterfuge. Recoveries are in the 80% range for this step. Failure to remove the gel pieces will widen each peptide band, giving rise to poor resolution in the gel.

Gels that will be silver stained should be washed with 50% methanol (four changes in 2 hr, or equilibration overnight) to remove substances that interfere with the staining process.

Disulfide linkage analysis

Most steps are critical when working with a given protein for the first time, as one can lose it by precipitation or adsorption to columns, or in various other ways! Usually, however, many properties of a protein (e.g., solubility and stability) are discovered during its isolation and purification: it is important to find out all that is already known about the protein before attempting to determine the disulfide bridge positions. Unless the protein is available in great abundance, it is advisable not to commit >0.1 to 0.2 mg to any untried step.

Blocking steps 1 to 3 must be performed whenever there is reason to suspect the presence of an unpaired Cys (e.g., an odd number of Cys residues in the sequence or reaction with thiol-specific reagents: Ellman, 1959; Thannhauser et al., 1984). These blocking steps must precede the fragmentation procedures to prevent scrambling (see Background Information).

Good HPLC technique is critical to success: the appearance of spurious peaks on chromatograms is often due to poor technique. The analytical column should be run at a flow rate of 0.6 ml/min. This column may also be used for preparative purposes with digests of up to ~0.2 mg protein: use flow rates of 0.6 ml/min when working with up to 0.1 mg digest and 1 ml/min when working with 0.1 to 0.2 mg digest. If working with larger amounts (up to ~1.5 mg digested protein), use a 25-cm × 10-mm-i.d. column filled with the same packing and operate at 3 ml/min (for 0.5 to 1 mg digest) or 4 ml/min (for 1 to 1.5 mg digest). When no longer required, columns must first be flushed with five column volumes of pure acetonitrile; flow may then be stopped. If the flow is stopped with HPLC solvent A or B present, the column will rapidly deteriorate and silica or stationary phase may block the detector when flow is restarted. It is important to prevent contamination of shared stock reagents or solutions and to avoid storing them in an inappropriate vessels—e.g., acetonitrile, trifluoroacetic acid, concentrated acetic, and formic acids may leach UV-absorbing materials from certain plastic tubes or stoppers. Use glass or polypropylene where possible, and beware of black rubber disks (even if faced with PTFE) in solvent bottle stoppers. Always start a series of runs with a blank injection of HPLC solvent A; run some standards (e.g., glucagon and insulin, obtainable from Sigma) if peaks are broad or fail to elute (expect analytical peaks that are not overloaded to have a width at half height of ~30 sec with a gradient of 2% B/min). Ask a chromatography expert for advice if problems continue.

Correct fragmentation (in general, cleavage between Cys residues, without scrambling) is crucial to success. Depending on the known or expected amino acid sequence, digestion conditions are chosen that will cleave the polypeptide chain at least once between successive Cys residues. Acidic conditions (for cyanogen bromide, see Basic Protocol 2 and *UNIT 11.4*; for pepsin, see Basic Protocol 2) help to avoid disulfide scrambling. If neutral or basic conditions must be used (see *UNIT 11.1*), it is important to keep the pH as low as possible while preserving adequate enzyme activity; keep digestion times short by using a high protein concentration and enzyme/substrate ratio; and, if possible, operate in the presence of a thiol-specific reagent to trap any transient thiols. For recombinant CD23, for example, the tryptic digestion was performed at pH 7.0 in the presence of 10 mM iodoacetic acid (Rose et al., 1992). Note that commercially available asparaginyl-endopeptidase (Pierce), in contrast with Asp-N protease (*UNIT 11.1*), requires reducing conditions and so cannot generally be used for disulfide bond assignments (Rose et al., 1992). If saving time is more important than the amount of material consumed, perform several trial fragmentations in parallel and examine them analytically by reversed-phase HPLC.

Sometimes an isolated peptide component may not be susceptible to Edman degradation: it may be N-terminally blocked (e.g., by formyl or acetyl if it is the N-terminal peptide of the protein, or by a residue of pyroglutamic acid if a Gln residue liberated during proteolysis has cyclized). This problem is easily recognized by the fact that more components are found by mass spectrometry than by Edman degradation. It can usually be solved more easily by amino acid analysis of the isolated (reduced) component than by digestion with acyl amino acid

BSU IASST CENTRAL UNIVERSITY LIBRARY

hydrolase or pyroglutamyl amino peptidase to expose an amino group for a further attempt at Edman degradation. Alternatively, sophisticated mass spectrometric sequencing techniques may be employed; however, these are not available in the average biochemical laboratory.

Titration curve analysis

Avoid overfilling the sample trench with protein solution! Sample running freely on the gel surface will produce smears and curtains. If some sample overflows outside the trench accidentally, blot it immediately with filter paper.

If condensation is seen on the glass lid supporting the electrodes, it means that too much joule heat has been generated. This could be due to too high a power setting (i.e., 10 W); if this is the case, lower the setting. Most often, however, condensation comes from electrode filter paper strips being too wet with electrode solution; this results in solution flooding the gel surface in the first-dimension run. The remedy, at this point, would be to excise a wider area of gel in front of the electrode wicks when they are removed in the passage from the first gel to the second dimension (see Fig. 7.3.1B for this operation). Occasionally, the thermostatic water bath might not have been switched on, the coolant might not be recirculating, or the water bath might be jammed (in the Pharmacia Biotech instrument, press the button release to restart the thermostat).

If, upon staining, the protein titration curves appear too wavy or excessively broad, there are three things to check. First, inspect the contact between the platinum wire and the electrode strips. The platinum wire might have been damaged or broken, or might be dislodged from its groove. Integrity, good contact, and good alignment of the platinum wire are essential for good technique. Second, check the amount of salt in the protein (if enough liquid volume is available, one can use a conductivity meter). If too much salt is present, the high sample conductivity might generate too much heat in the trench and provoke convective flows or even partial protein denaturation due to heat shock or generation of strongly acidic and/or strongly basic ion boundaries. Remember that use of salts made of strong acids or bases is an anathema to all focusing techniques. Finally, check the protein concentration. If too much protein has been applied, the titration curves will be rather broad, since diffusion is proportional to the initial sample concentration.

Anticipated Results

Peptide mapping

Note that partial digestion products are usually present in varying amounts in both chemical and enzymatic cleavage procedures. For this reason, if the recombinant protein will be compared with the native protein, it is important to treat both samples concurrently so that they can be compared directly. The large number of fragments that result are easily resolved by HPLC, giving many points of comparison between the recombinant and native proteins. In the event that native protein is not available (the most likely circumstance), then the peptide fragments of the recombinant protein must be analyzed by additional techniques, including amino acid analysis, N-terminal sequence analysis, and/or mass spectrometry.

Analyzing peptide maps by high-resolution gel electrophoresis, on the other hand, may fail to resolve all of the fragments. While Tris-tricine gels are ideal for resolving peptides in fairly tight bands down to 2 kDa (*UNIT 10.1*), the error in mass measurement can be as high as 5%. Fragments close in size may not be resolved from each other by this method. In general, several digests may be required to get a good set of data to compare with the native protein. In the event that a native protein is not available for comparison, fragments can be transferred to PVDF membranes and analyzed by amino acid analysis or N-terminal sequence analysis.

Disulfide linkage analysis

Interpretion of the pairs of chromatograms (attempted reduction and control) is usually straightforward. If no disulfide bond is present, there should be essentially no difference in retention time between the peak present in the attempted reduction and in the control. If a disulfide bond is present, then either this bond is holding two small peptide chains together or it is holding a single polypeptide chain in a loop. In the former case, two peaks should be visible on reduction, whereas in the latter case all that is observed is a small shift to later retention time (opening of the loop exposes more of the peptide chain to the stationary phase).

If the results of the analytical reduction of a fraction are very clear-cut (small shift to later retention time, or splitting into two components), it may be sufficient to submit a portion of that fraction for Edman degradation, a portion for mass spectrometry, and a portion for in

BOULARD GENERAL INSTITUTE LIBRARY

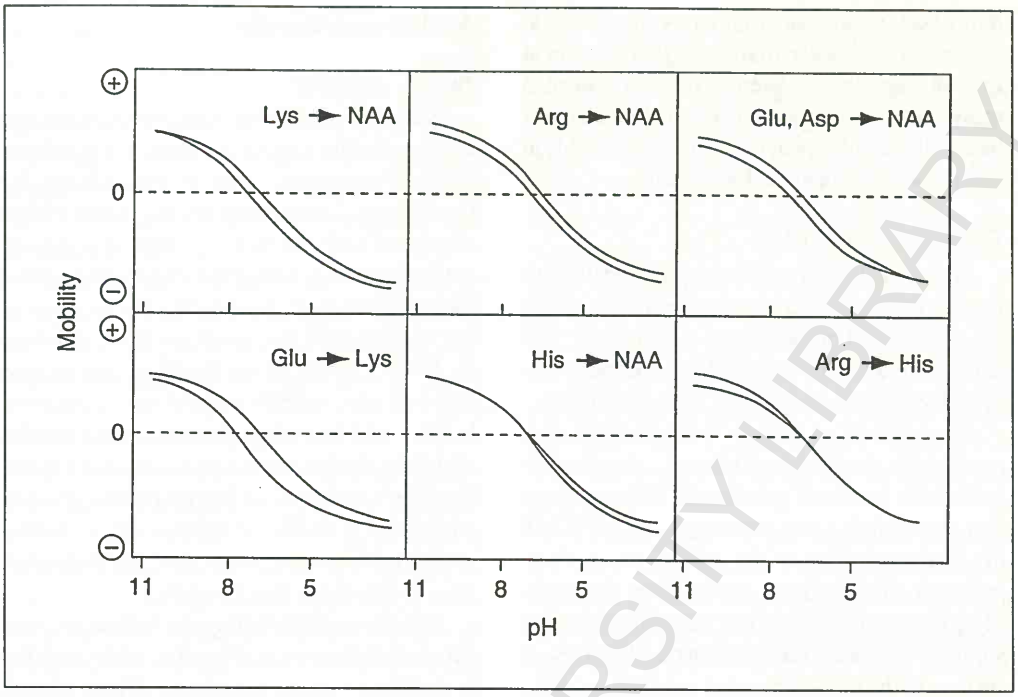

Figure 7.3.2 Theoretical titration curves of a wild-type protein and its genetic mutants in the presence of a given amino acid substitution. NAA: neutral amino acid; broken lines represent the zero-mobility plane (sample application trench); arrows indicate the direction of amino acid mutation. From Righetti et al. (1979).

situ reduction during mass spectrometry, thus avoiding the preparative reduction and HPLC step. Ask if the mass spectroscopist can perform in situ reduction: if this service is not available, then do preparative reduction, isolation, and analysis as described in Basic Protocol 2.

Titration curve analysis

Some examples of applications are presented in the figures. Figure 7.3.2 offers an example of differential titration curves obtained by mixing the presumptive mutant with the wild-type species. According to the various types of amino acid substitutions, different relative shapes will be detected, as shown. Note that only in the case of a replacement of arginine with a neutral amino acid (NAA) will the two curves run parallel all along the titration interval (typically not exceeding the pH 3 to 10 range).

Figure 7.3.3 gives a good example of affinity-titration curves obtained by incorporating a ligand into the gel matrix. In this case, a lectin from *Ricinus communis* was run in presence of increasing amounts of allyl-α-D-galactose grafted onto the gel matrix. This technique gives a unique depth of field, because not only does it permit measurement of the dissociation constant (K_d), but it also makes it possible to evaluate the variation in K_d with respect to pH (see Fig. 7.3.4).

Time Considerations

Peptide mapping. A peptide mapping experiment can be completed in ~2 days. The sample is generally digested overnight; analysis by either HPLC or high-resolution SDS-PAGE is then done on the second day. HPLC runs generally take ~2 hr each, including the pre-equilibration step for the column. Tris-tricine gels can be prepared ahead of time and stored overnight in a cold-box. Large gels generally require ~5 hr to run. Staining requires ~2 hr for Coomassie blue, whereas gels that will be silver stained should be washed with 50% methanol (four changes in 2 hr, or equilibration overnight) to remove substances that can interfere with the staining process. The silver staining process requires ~1.5 hr.

Disulfide linkage analysis. Each step (including dialysis) has been described in such a way as to make it possible to estimate how much time it will take. The time necessary for vacuum centrifugation and lyophilization steps depends somewhat on the scale, but samples containing ammonium bicarbonate must remain on the lyophilizer overnight or the salt

BU IASTRA UNIVERSITY LIBRARY

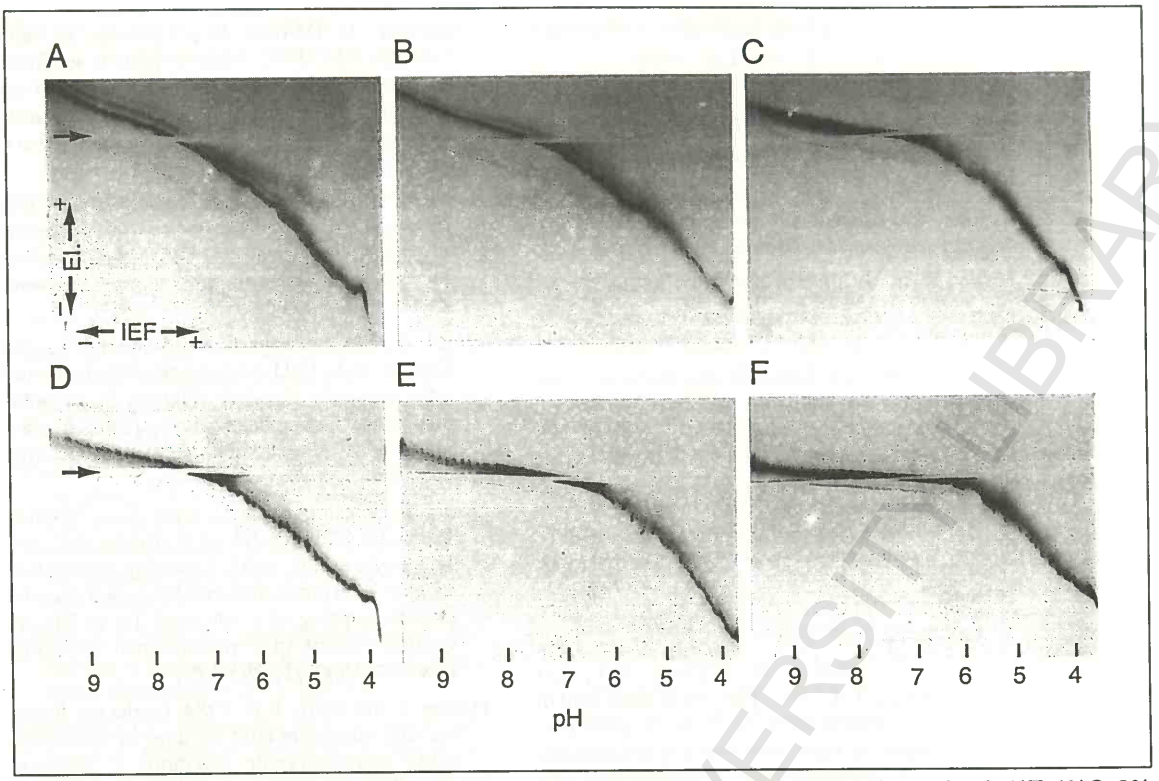

Figure 7.3.3 Affinity-titration curves of lectin from *Ricinus communis* seeds. The gel contained 6%T, 4%C, 2% Ampholine (pH 3.5 to 10), and 2 mM each Glu, Asp, Lys, and Arg. The amounts of allyl-α-D-galactose copolymerized in the gel matrix were: (**A**) 0 (no-ligand control); (**B**) 1×10^{-5} M; (**C**) 4×10^{-5} M; (**D**) 5×10^{-5} M; (**E**) 7×10^{-5} M; and (**F**) 10×10^{-5} M. The amount of protein loaded was 200 µg in 100 µl volume in all cases. The first- and second-dimension runs were 50 min at 10 W constant power and 20 min at 700 V constant voltage, respectively. The two arrows in (**A**) and (**D**) indicate the sample application trench (zero-mobility plane); the two double arrows with positive and negative symbols in (**D**) represent the direction and polarity of isoelectric focusing (IEF) and electrophoresis (El). From Ek et al. (1980).

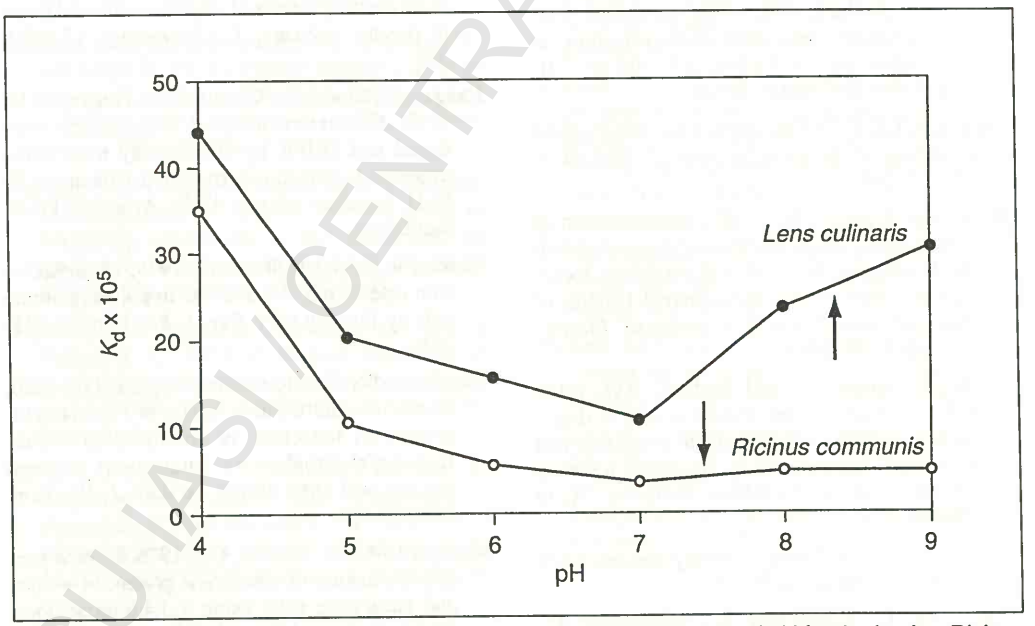

Figure 7.3.4 Variation of the dissociation constants (K_d) as a function of pH for the lectins *Ricinus communis* and *Lens culinaris*. These values were calculated from the retarded mobilities observed at different pH values in affinity-titration curves such as the one reported in Figure 7.3.3. The two vertical arrows indicate the pI of each lectin. From Ek et al. (1980).

BIBLIOTECA CENTRALE UNIVERSITÀ IASI

will not vaporize fully and some will remain with the protein. If blocking (steps 1 to 3), cyanogen bromide treatment, and enzymatic digestion must all be performed, the bonding pattern should be established within 2 weeks provided that an automatic injector is available for the HPLC.

Titration curve analysis. The titration curve analysis can be done in one day. Casting the gel requires ~1 hr. The first dimension electrophoresis takes ~1 hr, and the second dimension run requires ~30 min. Staining and destaining the gel can take ~1 to 2 hr.

Transverse Urea-Gradient Gel Electrophoresis

Monitoring the cooperative unfolding transition induced when a protein is exposed to elevated temperature or a chemical denaturant is an important strategy for characterizing the conformational properties of a globular protein. This transition may be analyzed quantitatively by a variety of spectroscopic techniques, but a simpler alternative is urea-gradient gel electrophoresis. The pattern produced in the resulting gel can be used to estimate both the free energy change for unfolding and the rate of the unfolding transition. In addition, the technique can help identify either covalent or conformational heterogeneity in a protein sample. Because urea-gradient gel patterns are sensitive to several parameters, including hydrodynamic volume, net charge, and conformational stability, the technique can be particularly useful for comparing two forms of a protein, e.g., a natural form and the product of recombinant bacteria.

Transverse urea-gradient gels are slab gels prepared with a gradient of urea concentration perpendicular to the direction of electrophoresis (Creighton, 1979). A single sample is applied to the top of the gel, and as the protein is electrophoresed, molecules at different positions across the gel are exposed to different urea concentrations. Unfolding is detected by a decrease in electrophoretic mobility, reflecting the increased hydrodynamic volume of the unfolded protein.

The gels are prepared with the glass plates rotated 90° from the orientation used for electrophoresis, which requires minor modifications of most standard electrophoresis equipment. The major requirements are spacers to fit the sides of the glass plates as oriented for casting and some arrangement for holding the glass plates in this orientation. An arrangement devised for preparing gels for the Bio-Rad Mini-Protean II apparatus is illustrated in Figure 7.4.1. The spacers and a casting box for preparing multiple gels simultaneously are available from Aquebogue. The gels are prepared using a photoactivating polymerization catalyst to allow sufficient time to prepare the gradient. After the gels

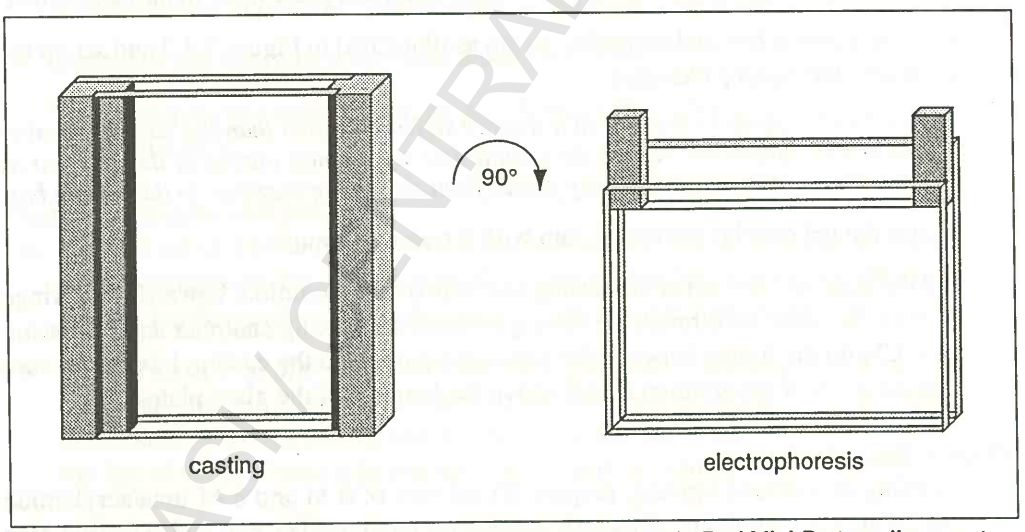

Figure 7.4.1 Spacers for preparing urea-gradient gels for the Bio-Rad Mini-Protean II apparatus. **(A)** A gel "sandwich" assembled and oriented for casting. The spacers are designed fit along the sides of the gel, as oriented for casting, and to keep the glass plates from sliding when placed in a casting box. **(B)** After the gel has polymerized, the gel is rotated 90°, the casting spacers are removed, and short spacers are placed on the sides of the gel to form a single sample well. The spacers are made to prepare gels 1 mm thick and can be constructed by machining single pieces of plastic or by glueing layers together. The standard glass plates for the Mini-Protean II apparatus are used. In the figure, the thicknesses of the spacers and glass plates have been exaggerated for clarity.

have polymerized, the spacers are removed to expose the top and bottom of the gel, as oriented for electrophoresis. The gel is then preelectrophoresed and the sample is loaded. After electrophoresis, the gel is stained and analyzed.

The following instructions assume that the total volume of the gels is 40 ml for five 10-cm-wide gels in the Aquebogue casting box. The gels are prepared so that 2 cm on the left and right side (as oriented for electrophoresis) contain 0 and 8 M urea, respectively. Volumes should be adjusted appropriately for gels of other dimensions.

Materials

Gel overlay solution: 20% (v/v) ethanol/0.002% (w/v) bromophenol blue
Urea/acrylamide gel solutions with photopolymerization catalysts (see recipes)
10× electrophoresis buffer (see recipe)
Protein samples
Acidic *or* basic protein sample buffer (see recipes)
Coomassie blue R-250 stain solution (see recipe)
Gel rinse solution: 50% (v/v) methanol/7.5% (v/v) acetic acid
Gel destain solution: 5% (v/v) methanol/7.5% (v/v) acetic acid

Gel electrophoresis tank and glass plates (e.g., Bio-Rad)
Spacers for casting gels (Aquebogue)
Gel casting box (Aquebogue)
Three-channel peristaltic pump (e.g., ISCO Tris pump)
Light source to initiate photopolymerization of gels (e.g., two 15-W blue fluorescent lamps)
Air-displacement pipettor
Gel-loading tip
Plastic boxes

Set up apparatus for casting gradient gels

1. Assemble glass plates and spacers into sandwiches and place them in the casting box.
2. Connect casting box and peristaltic pump as illustrated in Figure 7.4.2 and set up the reservoir and mixing chamber.

   Position the pump so that it is at a slightly higher elevation than the mixing chamber and slightly below the inlet to the casting box to minimize mixing of the gradient as the solution of increasing density passes from the mixing chamber to the casting box.

3. Degas the gel overlay solution 5 min with a water aspirator.
4. Fill the bottom 2 to 4 cm of the casting box with overlay solution. Use a 20-ml syringe to draw the solution through the tubing between the mixing chamber and the casing box. Clamp the tubing between the peristaltic pump and the casting box. Make sure that the level of the solution is still above the bottoms of the glass plates.

Prepare the gel solutions

5. Working in subdued lighting, prepare 30 ml each of 0 M and 8 M urea/acrylamide gel solutions containing photopolymerization catalyst. Do not add TEMED (for riboflavin polymerization) or methylene blue (for methylene blue polymerization).

   Because of the time required to prepare the gradients, it is convenient to use a photoactivated polymerization catalyst, such as riboflavin or methylene blue. The gels can be cast under subdued lighting (complete darkness is not necessary), and then exposed to direct light to initiate polymerization.

   Appropriate pH and acrylamide concentrations of gel solutions must be chosen for each protein (see Critical Parameters).

ECU IASI GENERAL UNIVERSITY LIBRARY

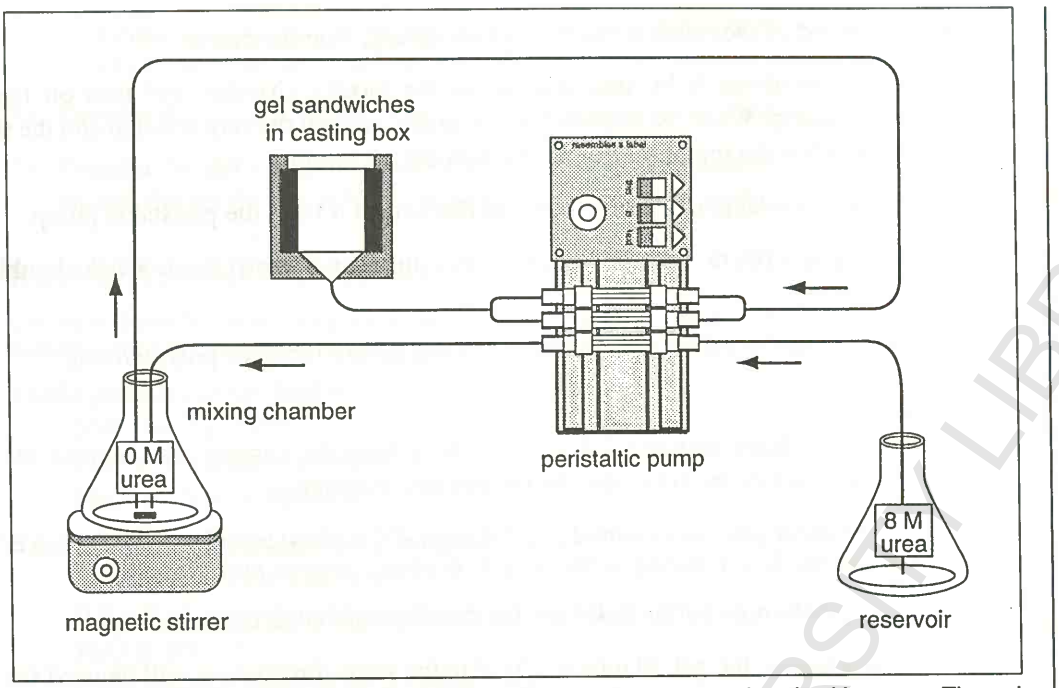

Figure 7.4.2 Preparation of urea-gradient gels using a three-channel peristaltic pump. The gel sandwiches are held in a clear plastic casting box with an inlet for the gel solution placed below the bottoms of the glass plates. Gel solutions containing 0 and 8 M urea are placed in the mixing chamber and reservoir respectively. As solution from the mixing chamber is pumped into the casting box using two channels of the pump, the 8 M urea solution is pumped into the mixing chamber using a single channel, leading to a linear increase in urea concentration in the mixing chamber. Before the gel solution is pumped into the casting box, the bottom of the box and the tubing between it and the mixing chamber are filled with gel overlay solution. The flow rate from the pump to the casting box should be ~2 ml/min.

Urea should be dissolved just prior to preparing the gels, because urea in solution breaks down to produce cyanate that can react with protein amino groups.

6. Degas the gel solutions 5 min with a water aspirator.

7. For photopolymerization, add 36 µl TEMED (for riboflavin) *or* 1.5 ml 2 mM methylene blue.

Cast the urea-gradient gels

8. Place 12 ml of 8 M urea gel solution in the reservoir. Use a 20-ml syringe to fill the tubing connecting the reservoir to the mixing chamber. Clamp the tubing in the peristaltic pump and temporarily place the outlet in the 8 M urea reservoir.

9. Place 8 ml of 0 M urea solution in the mixing chamber. Remove the clamp between the pump and the casting box. Turn on the peristaltic pump to begin pumping 0 M urea solution into the casting box at a rate of ~2 ml/min (1 ml/min per channel). When the last of the 0 M urea solution has just entered the tubing, stop the pump.

Be careful not to allow any air into the tubing.

10. Place 12 ml of 0 M urea solution in the mixing chamber and position the outlet from the 8 M urea solution in the mixing chamber. Turn on the magnetic stirrer and the peristaltic pump.

The concentration of urea in the flask will now increase linearly as the solution is pumped into the casting box.

BCU JAMES CENTRAL UNIVERSITY LIBRARY

11. When the last of the solution has entered the tubing, stop the pump.
12. Place the remaining 8 M urea solution in the mixing chamber and turn on the peristaltic pump. When the boundary between the ethanol overlay solution and the 0 M urea reaches the top of the gel plates, turn off the pump.
13. Clamp off the inlet to the casting box and disconnect it from the peristaltic pump.
14. Place the gels ~10 cm from the light source to initiate polymerization, which should take ~30 min.
15. Promptly rinse the gel solution out of the tubing before it begins polymerizing.

Set up the gel

16. After the gels have polymerized, remove them from the casting box, remove the spacers, and mount the gel in the electrophoresis chamber.

    Urea-gradient gels can be stored 1 to 2 days at 4°C without significant dissipation of the gradient. Before storing, wrap the gels in plastic wrap to prevent drying.

17. Dilute electophoresis buffer to 1× and fill the electrophoresis tank.
18. Preelectrophorese the gel 30 min at 100 V in the same direction as will be used for electrophoresis.

    For negatively charged proteins, electrophorese with the positive electrode at the bottom of the gel; for positively charged proteins, electrophorese with the negative electrode at the bottom of the gel.

    These conditions are usually adequate to remove reactive compounds resulting from the breakdown of urea or the polymerization process in a gel that is 1 mm thick and 10 cm wide.

Prepare and electrophorese samples

19. Prepare the sample for electrophoresis by diluting ~50 µg of protein to a total volume of 60 µl. Add 15 µl sample buffer appropriate for acidic or basic protein.

    Small samples of unfolded proteins in 8 M urea can be prepared by dissolving 48 mg solid urea in 63 µl aqueous solution (including the protein) to yield a total of 100 µl. It is not necessary to add glycerol to samples that contain 8 M urea.

20. Apply the sample evenly across the top of the gel using an air-displacement pipettor with a gel-loading tip.
21. Electrophorese the sample.

    The voltage and duration of electrophoresis appropriate for a given protein and set of electrophoresis conditions must be determined empirically, but 50 to 100 V for 3 to 4 hr is a good starting point.

22. At the end of the run, turn off the power supply and disconnect the electrodes. Remove the gel from the apparatus and remove the plates. Mark the orientation of the gel by cutting off one corner.

Stain and destain the gel

23. Place the gel in a plastic box containing ~50 ml Coomassie blue R-250 stain solution. Agitate gently ≥2 hr at room temperature.

    The high acid concentration of the recommended stain makes this solution particularly effective for fixing smaller proteins that are not easily precipitated by milder staining conditions. For some applications, staining solutions commonly used for SDS gel

ECU IAS / CENTRAL UNIVERSITY LIBRARY

electrophoresis—e.g., 0.1% (w/v) Coomassie blue R-250/50% (v/v) methanol/7.5% (v/v) acetic acid—may also be suitable.

24. Transfer the gel to a clean plastic box containing gel rinse solution and rinse ≤5 min.

25. Transfer the gel to a plastic box containing gel destain solution. Agitate gently and change the gel destain solution as necessary to obtain a nearly clear background.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocols steps. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acidic protein sample buffer

50% (w/v) glycerol
0.01% (w/v) bromophenol blue
Store at room temperature

Acrylamide/bisacrylamide stock solution

30 g acrylamide (30% final)
0.8 g *N,N′*-methylene bisacrylamide (0.8% final)
H_2O to 100 ml
Filter through paper or an 0.45-µm filter
Store at 4°C in the dark

CAUTION: *Acrylamide and bisacrylamide are toxic. The powders should be handled in a fume hood, and both the powder and solutions should be handled wearing gloves.*

Basic protein sample buffer

50% (w/v) glycerol
0.2% (w/v) methyl green
Store at room temperature

Coomassie blue R-250 stain solution

0.5 g Coomassie blue R-250 dissolved in ~400 ml H_2O (1 mg/ml final)
50 g trichloroacetic acid (0.61 M final)
50 g 5-sulfosalicylic acid (0.39 M final)
H_2O to 500 ml
Store at room temperature

CAUTION: *Trichloroacetic acid and 5-sulfosalicylic acid are very caustic. Wear gloves when handling the solids or stain solution.*

Electrophoresis buffer, 10×

Buffer solutions that have been used successfully for urea-gradient gels include:
0.5 M acetate-Tris, pH 4.0: 0.5 M acetic acid adjusted to pH 4.0 with Tris base
0.5 M imidazole/0.5 M MOPS, pH ~7.0
0.5 M Tris-acetate, pH 8.0: 0.5 M Tris base adjusted to pH 8.0 with acetic acid
0.5 M Tris/0.5 M Bicine, pH ~8.4
Store all buffer solutions at room temperature

Urea/acrylamide gel solutions containing photopolymerization catalysts

0 M urea/15% acrylamide gel solution for riboflavin-polymerized gels
15 ml acrylamide/bisacrylamide stock solution (see recipe)
3 ml 10× electrophoresis buffer (see recipe; 1× final)
3.75 ml 0.04 mg/ml riboflavin (5 µg/ml final)
8.25 ml H_2O

Immediately before casting gels, degas gel solution, then add 36 µl TEMED.

continued

BOSTON CENTRAL UNIVERSITY LIBRARY

8 M urea/11% acrylamide gel solution for riboflavin-polymerized gels

14.4 g solid urea
11 ml acrylamide/bisacrylamide stock solution (see recipe)
3 ml 10× electrophoresis buffer (see recipe; 1× final)
3.75 ml 0.04 mg/ml riboflavin (5 µg/ml final)
1.2 ml H_2O

Immediately before casting gels, degas gel solutio, then add 36 µl TEMED.

0 M urea/11% acrylamide gel solution for methylene blue–polymerized gels

11 ml acrylamide/bisacrylamide stock solution (see recipe)
3 ml 10× electrophoresis buffer (see recipe; 1× final)
1.5 ml 20 mM sodium toluene sulfinate (1 mM final)
1.5 ml 1 mM diphenyliodonium chloride (50 µM final)
11.5 ml H_2O

Immediately before casting gels, degas solution and add 1.5 ml 2 mM methylene blue (100 µM final).

8 M urea/7% acrylamide gel solution for methylene blue–polymerized gels

14.4 g solid urea
7 ml acrylamide/bisacrylamide stock solution (see recipe)
3 ml 10× electrophoresis buffer (see recipe; 1× final)
1.5 ml 20 mM sodium toluene sulfinate (1 mM final)
1.5 ml 1 mM diphenyliodonium chloride (50 µM final)
4.4 ml H_2O

Immediately before casting gels, degas solution and add 1.5 ml 2 mM methylene blue (100 µM final).

COMMENTARY

Background Information

One of the most general properties of folded globular proteins is the tendency to undergo a cooperative unfolding transition when exposed to elevated temperature or to chaotropic agents such as urea or guanidinium chloride (Tanford, 1968). The unfolding transition for a particular protein under defined conditions is characterized by several thermodynamic properties, including the free energy change for unfolding, the enthalpy change, the entropy change, and, even more fundamentally, whether or not the transition is sufficiently cooperative that only fully folded and fully unfolded molecules are present at equilibrium. The free energy change for unfolding, ΔG_u, is a particularly important parameter that represents the net stability of the folded conformation relative to the unfolded state and is widely used for comparing the stabilities of related proteins. Unfolding-refolding transitions are also characterized by their kinetic properties, including their rates and the accumulation of any transient intermediates.

The thermodynamics and kinetics of protein unfolding and refolding reactions have been studied extensively using a variety of different biophysical methods, including spectroscopic and calorimetric techniques. These studies have led to important advances in understanding the physical interactions that stabilize folded proteins and the mechanisms by which these structures form (Schellman, 1987; Privalov, 1989; Kim and Baldwin, 1990; Creighton, 1992; Matthews, 1993). Although spectroscopic techniques and calorimetry have been mastered in a growing number of laboratories specializing in protein stability and folding, these measurements are quite technically demanding and require equipment and expertise that is not always found in typical protein biochemistry laboratories.

Urea-gradient gel electrophoresis was developed by T.E. Creighton (1979) as a simple alternative to spectroscopic methods for studying protein folding and unfolding. In this procedure, a single sample is applied across the top of a polyacrylamide slab gel containing a horizontal gradient of urea concentration. As the sample is electrophoresed through the gel, molecules at different positions across the gel are exposed to increasing urea concentrations.

ECU IASH CENTRAL UNIVERSITY LIBRARY

Those molecules that unfold have a larger hydrodynamic volume than the folded protein molecules and therefore migrate more slowly. After electrophoresis, the stained gel produces a graphic representation of the unfolding transition. As discussed later (see Anticipated Results), the pattern generated can provide information about whether or not the protein undergoes a urea-induced unfolding transition, information about the presence of significantly populated intermediate states in this transition, and semiquantitative information about the net stability of the folded protein and the rates of interconversion between the native and unfolded states.

Although the data obtained from urea-gradient gels are not generally as quantitative as those derived from spectroscopic or calorimetric measurements, the electrophoretic method offers a number of advantages for many applications. In addition to being relatively simple to implement, urea-gradient gel electrophoresis requires only small amounts of protein—a 50-μg sample is sufficient for detection with Coomassie blue, and even less can be used with more sensitive detection methods (*UNIT 10.5 & 10.6*). Furthermore, heterogeneous samples may often be used, because different components are likely to be separated during electrophoresis (Hollecker and Creighton, 1982). Indeed, urea-gradient electrophoresis is a particularly sensitive method for detecting heterogeneity, because molecules that differ in their electrophoretic mobilities in either the native or unfolded form can be distinguished, as can molecules that differ only with respect to the urea concentration at which they unfold.

In addition to being convenient, urea-gradient gels can often provide information about protein-folding transitions that is complementary to the information obtained from more conventional biophysical methods. Most spectroscopic techniques—e.g., UV absorbance (*UNIT 7.1*), fluorescence, and circular dichroism—measure only the averaged properties of a sample. As a consequence, it is often difficult to determine if, for instance, the signal measured at an intermediate urea concentration arises exclusively from a mixture of fully unfolded and fully native molecules or if a partially folded species may be present. Separation techniques such as gel electrophoresis can sometimes help resolve such ambiguities, particularly if different conformational states interconvert relatively slowly on the time scale of the separation.

The most useful applications of urea-gradient gels are often those where a qualitative comparison of different proteins is required, as in comparing the protein produced in recombinant bacteria with that obtained from a natural source. If the recombinant-produced protein has the same covalent structure and has folded to the same conformation as that of the natural protein, the two samples should display identical electrophoresis patterns. If, on the other hand, the two proteins differ in their covalent structure, this might be reflected in differences in the mobilities of either the native or unfolded forms, particularly if there are differences in net charge. If the conformations of the folded proteins are different, this may lead to differences in the mobilities of the native form or in the urea concentration at which the proteins unfold. Other applications include screening protein variants for differences in folding thermodynamics and kinetics (Klemm et al., 1991; Creighton and Shortle, 1994) and carrying out preliminary experiments to define conditions for more detailed studies using spectroscopic methods.

Critical Parameters

Because the behavior of a protein during urea-gradient gel electrophoresis depends on several properties of the particular protein, including its hydrodynamic volume, net charge, and conformational stability, there are more parameters that must be considered than for SDS gel electrophoresis, for instance. These parameters include pH, direction of electrophoresis, gel composition, and duration of electrophoresis.

pH

Because electrophoresis depends on the intrinsic net charge of the protein, the pH must be sufficiently far from the isoelectric point to maintain a significant net charge, usually 5 to 10 charge units (the charge of a proton or electron). For proteins with extremely high or low isoelectric points, it will probably be necessary to work below or above the isoelectric point, respectively, but proteins with isoelectric points near neutrality can be electrophoresed under either acidic or basic conditions. Although it may be desirable, in general, to use a pH close to physiological, in some cases it may be necessary to use more extreme conditions. For instance, it may be necessary to use a higher or lower pH to maintain a large enough net charge on the protein for electrophoresis or to

BYU CENTRAL UNIVERSITY LIBRARY

keep the protein soluble, because many proteins are least soluble close to their isoelectric points. In addition, pH can be used as a means to manipulate the stability of the folded protein. Many proteins are too stable to be unfolded in 8 M urea at neutral pH, but can be unfolded by urea under alkaline or acidic conditions.

Several different buffers have been used successfully for urea-gradient gels (see Reagents and Solutions). Ideally, the ionic strength of the buffer solution should be as low as possible to minimize the heat generated during electrophoresis. Meeting this condition can be facilitated by using buffers in which both the anionic and cationic component provide buffering capacity; several buffer systems of this type have been described by McLellan (1982). The direction of electrophoresis is determined by the pH chosen. If the pH is above the isoelectric point, the protein will have a net negative charge and will migrate towards the anode in the electrophoresis tank, as in SDS–polyacrylamide gel electrophoresis. If, on the other hand, a pH below the isoelectric point is used, the orientation of the electrodes must be reversed.

Gel composition

As in other forms of electrophoresis, the gel composition must be chosen to match the hydrodynamic volume of the protein of interest, with larger proteins requiring lower acrylamide concentrations. The sieving properties of the gel and, therefore, the choice of acrylamide concentration also depend on the presence of urea in the gel and the method of polymerization used. For reasons that have not been fully characterized, urea in a polyacrylamide gel decreases the electrophoretic mobility, so that even in the absence of an unfolding transition there will be a progressive reduction of mobility across a urea-gradient gel. This can be largely compensated for by incorporating an acrylamide gradient so that there is a lower acrylamide concentration at the high-urea side of the gel. In his original protocol, Creighton (1979) used a 15% to 11% (w/v) acrylamide gradient (photopolymerized with riboflavin) superimposed on the 0 to 8 M urea gradient, and these conditions have worked well for a variety of monomeric proteins, including bovine serum albumin, with M_r = 66,000. Larger proteins, however, are likely to require lower acrylamide concentrations.

Gel sieving is also greatly influenced by the conditions used for polymerization. The two catalysts that have been most widely used to polymerize acrylamide gels are ammonium persulfate and riboflavin, the latter used for photoactivation. Both are used in conjunction with *N,N,N′,N′*-tetramethylethylenediamine (TEMED). Photopolymerization is particularly convenient for preparing gradient gels, because the timing of polymerization can be easily controlled. A major drawback to the use of riboflavin, however, is that polymerization is not as complete as when ammonium persulfate is used. Although this is not a serious difficulty for gels prepared at slightly acidic pH, at neutral or alkaline pH the gels may be very soft or the solution may not gel at all. The efficiency of photopolymerization can be increased by adding a small amount of ammonium persulfate, but it can be very tricky to find a concentration that will stimulate photopolymerization without also causing early polymerization. More recently, a procedure for photopolymerizing gels using methylene blue has been described, and it appears that this catalyst leads to much more efficient polymerization than riboflavin does (Lyubimova et al., 1993). Urea-gradient gels containing 11% to 7% (w/v) acrylamide and polymerized with methylene blue have been reported to have sieving properties similar to those of 15% to 11% (w/v) acrylamide gels polymerized with riboflavin (Creighton and Shortle, 1994).

Sample size

For urea-gradient gels ~10 cm wide, a sample volume of 75 µl is appropriate. This is large enough to apply evenly across the top of the gel and small enough to give reasonably narrow bands. It should be possible, in principle, to use discontinuous buffer systems with a stacking gel, but this does not appear to be necessary. Even in the absence of a discontinuous buffer system, there is usually some stacking effect when a macromolecular sample enters a gel, because the first molecules to enter the gel are retarded and accumulate near the top of the gel while the rest of the molecules enter the gel. The difference between the mobilities of molecules above and within the gel can be enhanced by making the ionic strength of the sample lower than that of the electrophoresis buffer.

Duration of electrophoresis

The time required for electrophoretic separation depends on the voltage applied to the gel, and this parameter can be manipulated according to the type of information desired. As discussed later (see Anticipated Results), the elec-

ECU IASTATE UNIVERSITY LIBRARY

trophoresis pattern generated depends to a large degree on whether the interconversion between native and unfolded states is rapid on the time scale of the electrophoresis. In particular, if the two forms interconvert many times during the electrophoresis, then a smooth, continuous band of protein should be generated, and the position of the observed transition can be used to estimate the thermodynamic stability of the protein. On the other hand, if the two forms interconvert slowly, a discontinuous or blurred band will be generated, and under favorable conditions it is possible to estimate the rate of the transition from the appearance of the bands and the duration of electrophoresis. Significant separations have been observed after as little as 8 min of electrophoresis (Creighton, 1980), but times as long as 10 hr have been used to generate smooth patterns for relatively slow transitions (Klemm et al., 1991).

An additional parameter that can be manipulated to advantage is the presence of other molecules or ions in the gel that influence the unfolding transition by binding selectively to either the native or unfolded forms. For instance, the influence of a divalent cation can be examined by comparing the patterns observed when the ion is present in the electrophoresis buffers with the patterns obtained when EDTA is added to the buffers. This approach is limited, of course, to compounds that do not interfere with either gel polymerization or electrophoresis. Thiol reagents, for instance, react with free radicals generated during polymerization, and high salt concentrations lead to very high temperatures during electrophoresis.

Troubleshooting

The difficulties most likely to arise in using urea-gradient gel electrophoresis are the formation of protein aggregates or covalent modifications either before or during the electrophoresis. Aggregation is likely to lead to smearing of the protein bands or a complete failure of the protein to enter the gel. It may be possible to minimize aggregation by choosing a different pH or ionic strength for electrophoresis or by decreasing the concentration of protein applied to the gel. Covalent modifications are likely to cause multiple protein bands, particularly if they lead to changes in net charge. Such modifications may arise from residual free radicals from the polymerization reaction or from cyanates generated by hydrolysis of urea. To minimize these reactions, the urea solutions should be prepared immediately before casting the gels, and the gels should be pre-electrophoresed before applying the sample.

Anticipated Results

The simplest patterns generated by urea-gradient gel electrophoresis arise when the native (*N*) and unfolded (*U*) forms of the protein are in rapid equilibrium and there are no significant populations of partially folded intermediates. In these cases, a simple sigmoidal band is produced (see Fig. 7.4.3).

If the two forms are in rapid equilibrium on the time scale of the electrophoresis, the band should remain sharp through the transition region, and the same pattern should be obtained whether native or urea-unfolded protein is applied to the gel. Provided that only the native

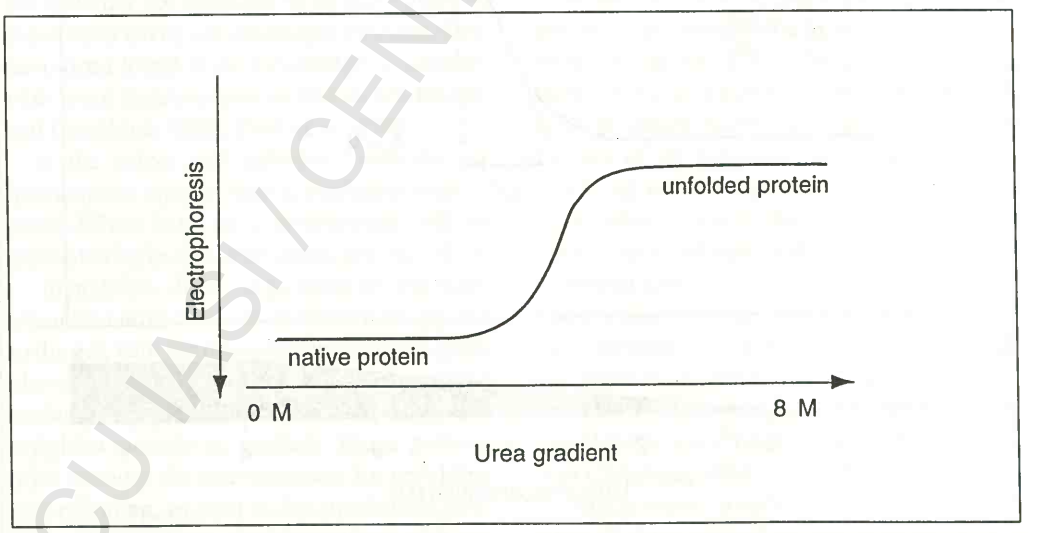

Figure 7.4.3 Diagram of an unfolding curve produced by urea-gradient gel electrophoresis of a protein undergoing rapid interconversion between the folded and unfolded states.

CHITIE
BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

and unfolded forms are significantly populated, the observed mobility at the intermediate urea concentrations will reflect the relative concentrations of N and U ([N], [U]), and the pattern can be interpreted as a plot of the fraction of protein unfolded versus urea concentration.

Although urea-gradient gels are used primarily for qualitative analysis of protein unfolding transitions, they may also be used to obtain an estimate of the conformational stability of a protein, provided that the conditions described above are met. The free energy change for unfolding is given by

$$\Delta G_u = -RT \ln \frac{[U]}{[N]}$$

where R is the gas constant and T is the absolute temperature. The value of ΔG_u will depend on the urea concentration, becoming more negative at higher concentrations. Because ΔG_u can only be measured at urea concentrations where N and U are both detectable, i.e., in the transition zone, it is usually necessary to extrapolate values measured near the middle of the transition to 0 M urea in order to estimate the stability under physiological conditions. Numerous studies of protein unfolding transitions have shown that the dependence of ΔG_u on denaturant concentration can usually be well described by a simple linear relationship,

$$\Delta G_u = m \cdot (C - C_m)$$

where C_m is the urea concentration at the transition midpoint (i.e., where $\Delta G_u = 0$, and the average mobility is midway between that of the native and unfolded forms), C is any other urea concentration and m is an empirical parameter (Schellman, 1978; Pace et al., 1989).

Hollecker and Creighton (1982) have shown that m is proportional to the derivative of the fraction unfolded (f_u) with respect to urea concentration evaluated at the midpoint according to the relationship:

$$m = -4RT \frac{df_u\,(C_m)}{dC}$$

This derivative can be estimated from urea-gradient gel patterns by drawing a line tangent to the gel band at the midpoint and measuring the change in urea concentration, ΔC, associated with the extrapolated change in f_u from 0 to 1. This procedure is illustrated in Figure 7.4.4.

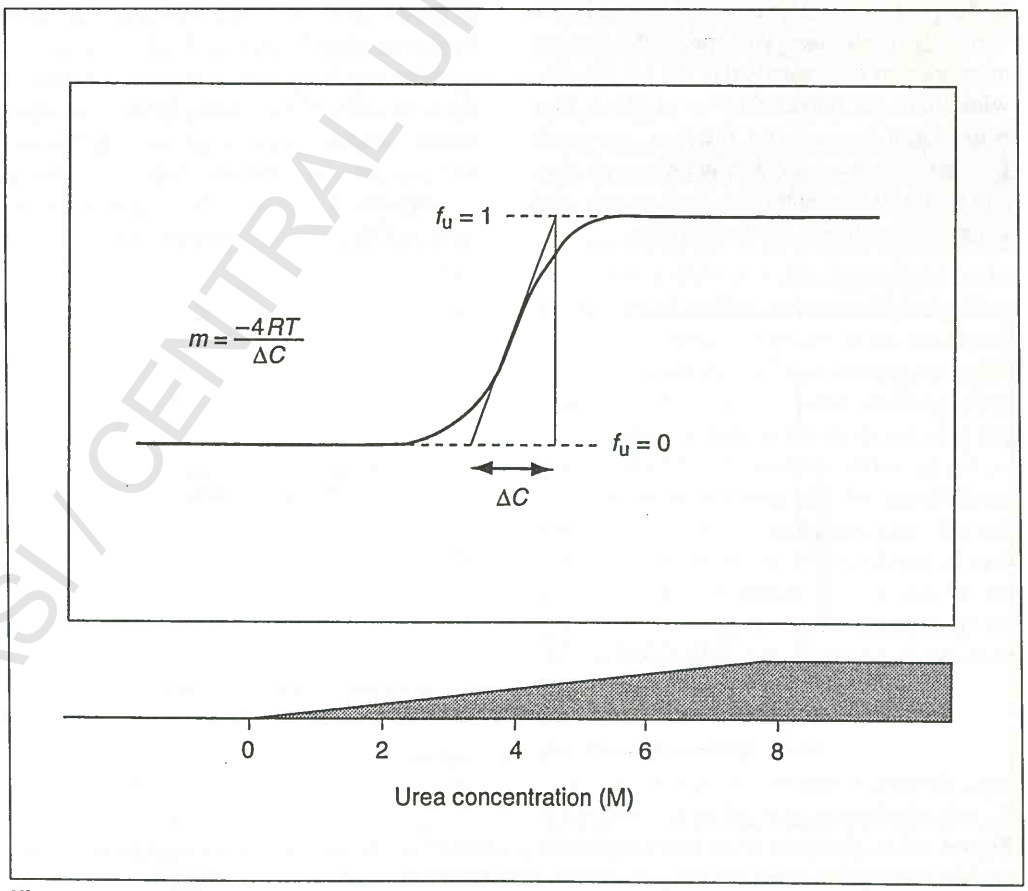

Figure 7.4.4 Estimating the parameter m from a urea-gradient gel. See text for details.

ECU IASI / CENTRAL UNIVERSITY LIBRARY

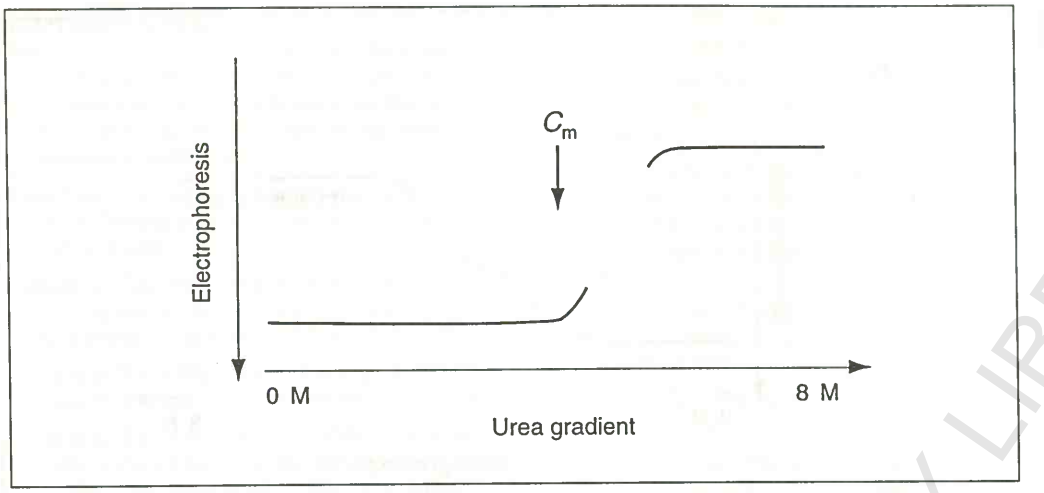

Figure 7.4.5 Urea-gradient gel pattern produced by a protein that slowly interconverts between the native and unfolded states when native protein is applied to the gel.

The derivative is simply $1/\Delta C$, and m is calculated according to:

$$m = \frac{-4RT}{\Delta C}$$

From the value of m and C_m, the value of ΔG_u can be calculated for any other urea concentration, including 0 M, where $\Delta G_u = -mC_m$ (Hollecker and Creighton, 1982; Klemm et al., 1991).

Quantitating urea-gradient gel results in this manner requires knowing the urea concentration at different positions across the gel, which can be estimated from the dimensions of the gel and from the known volumes of the linear gradient and the two bordering segments containing 0 and 8 M urea. Although values of C_m, m, and ΔG_u estimated from urea-gradient gels are certainly not expected to be as accurate as those obtained by spectroscopic methods, they have been found to be surprisingly consistent with more rigorous measurements (Hollecker and Creighton, 1982; Pace et al., 1989).

If the native and unfolded forms do not interconvert rapidly during electrophoresis, a more diffuse band or a discontinuity will be generated in the transition zone (see Fig. 7.4.5).

In addition, different patterns are expected when the native and unfolded forms are applied to the gel, with the transition appearing slightly above the equilibrium midpoint (C_m) when native protein is applied and below C_m when unfolded protein is applied. These patterns arise because the rate constants for unfolding and refolding, as well as the equilibrium constant, vary with urea concentration, with unfolding rates increasing and folding rates decreasing at higher urea concentrations. When native protein is applied to the gel, it remains in its initial state at low urea concentrations both because this state is thermodynamically favored and because unfolding is very slow. At urea concentrations near the equilibrium midpoint, the native conformation does not predominate thermodynamically, but at least a fraction of the molecules remain in this state simply because they do not have time to unfold during the time of electrophoresis. At urea concentrations somewhat above the midpoint, the unfolding rate is fast enough that most or all of the molecules unfold during the electrophoresis. When unfolded protein is applied to the gel, the opposite effect is seen, with a fraction of the molecules remaining unfolded even at urea concentrations below the equilibrium midpoint.

When the unfolding and refolding rates are not fast compared to the time of electrophoresis, the patterns cannot be used to estimate thermodynamic parameters, but it may be possible to obtain some information about the kinetics of the transition. If the half-time for unfolding (or folding) at the midpoint is approximately equal to the time of electrophoresis, a smeared band will be generated in the transition zone, and slower transitions will give rise to a discontinuity, as described above. The rate constants can be estimated by comparing the observed patterns with those predicted by numerical simulations, as discussed in greater detail elsewhere (Creighton, 1979; Goldenberg and Creighton, 1984; Goldenberg, 1989).

Much more complicated gel patterns can arise if there are additional species present either at equilibrium or accumulating as transient kinetic intermediates. If there is a partially

EDINBURGH UNIVERSITY LIBRARY

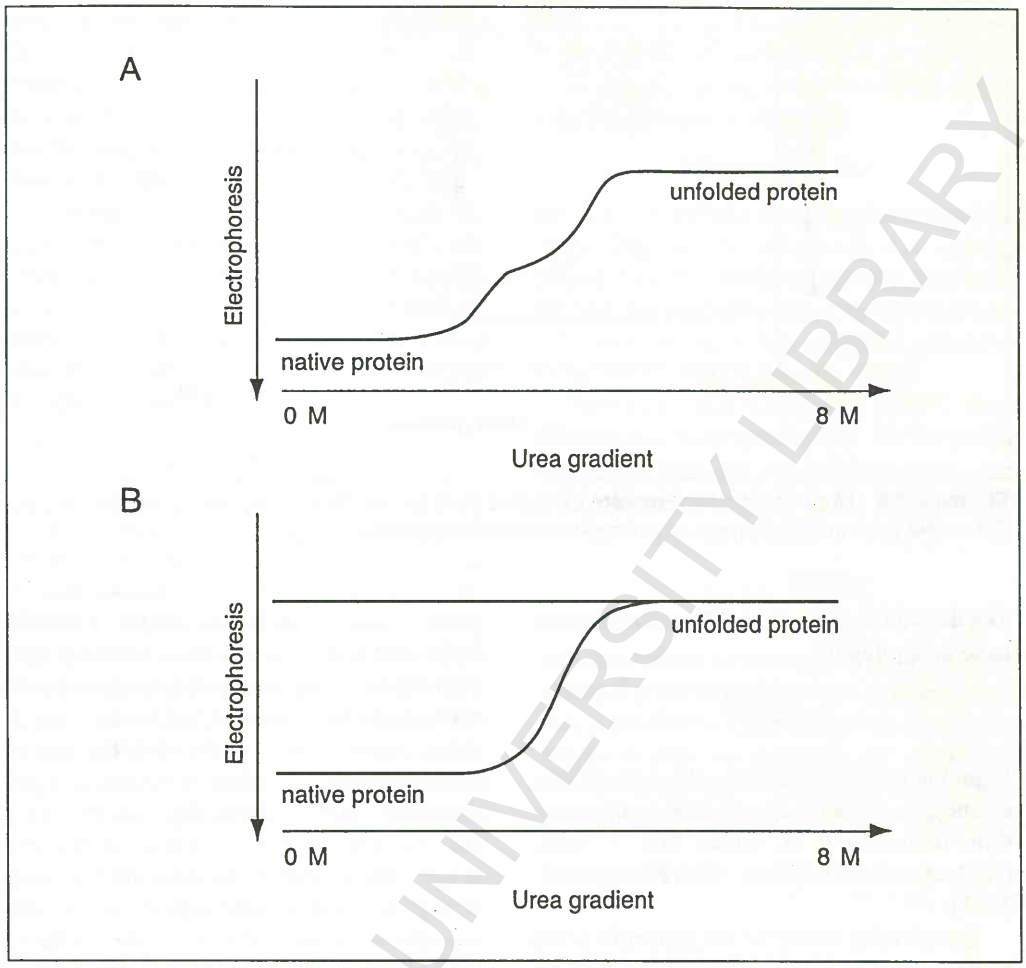

Figure 7.4.6 Urea-gradient gel patterns produced by proteins with additional species. **(A)** A protein with a partially unfolded species that predominates at intermediate urea concentrations. **(B)** A protein with two unfolded species, one of which refolds very slowly.

unfolded species that predominates at intermediate urea concentrations, a two-step transition may be observed (see Fig. 7.4.6A).

A frequently observed type of conformational heterogeneity is one in which there are multiple unfolded forms that refold at different rates. Multiple unfolded forms can arise from isomerization of prolyl peptide bonds (Brandts et al., 1975) and can give rise to the pattern depicted in Figure 7.4.6B when unfolded protein is applied to the gel (Creighton, 1980). This pattern is generated because some of the unfolded molecules can rapidly refold and establish an equilibrium with the native protein, but others do not have time to refold during the electrophoresis and remain unfolded even at urea concentrations at which the native protein is thermodynamically preferred. At the lowest urea concentrations, some of the slowly refolding form may have time to fold to the native form, giving rise to a blurred or discontinuous transition. Also, the slowly folding form may equilibrate with partially folded forms, giving rise to a downward curvature in the upper band. When native protein is applied to the gel, only the lower, sigmoidal, band is expected, because the slowly refolding form is generated relatively slowly after the protein unfolds. Other complexities in the patterns may arise from multiple folded forms, intermediates that convert slowly with the native or unfolded protein, or oligomeric proteins that undergo dissociation either prior to or in concert with unfolding.

Time Considerations

Most urea-gradient gel electrophoresis experiments can easily be completed in 1 day. A few hours should be allocated for preparing the gels, and electrophoresis may take as little as 20 min or as long as several hours. Once prepared, the gels can be kept at least 2 days at 4°C without apparent changes in their properties.

Analytical Ultracentrifugation

Analytical ultracentrifugation is the grandfather of biochemical methods, with a 70-year history of development and application (Svedberg and Pederson, 1940; Schachman, 1959). Recently, the attention of protein scientists and molecular biologists has been drawn to macromolecular interactions, an area where analytical ultracentrifugation excels, resulting in a renewed interest in this technology (Harding et al., 1992; Ralston, 1993; McRorie and Voelker, 1993; Schuster and Laue, 1994). As this unit will describe, analytical ultracentrifugation is one of the most powerful, though as yet underexploited, techniques available to molecular biology and biochemistry.

Two different but complementary methods of sample analysis are possible using an analytical ultracentrifuge: sedimentation velocity and sedimentation equilibrium (Table 7.5.1). Each encompasses a range of techniques suitable for characterizing everything from crude mixtures to highly purified proteins. Sedimentation velocity provides such hydrodynamic information as size, shape, and, when combined with diffusion measurements, molecular weight. Sedimentation equilibrium provides thermodynamic information about molecular weight, stoichiometry, association energy, and nonideality.

Both sedimentation methods are understood from first principles. Thus, no standards are

Table 7.5.1 Methods of Analytical Ultracentrifugation

Method	Category	Information obtained and notes
Velocity	Direct fitting to transport equations	Modern way to obtain *s* (and the diffusion coefficient) for a single solute. When combined with molecular weight, *s* yields information concerning the size and shape of the protein (Philo, 1994).
	g(*s*)–particle size distribution analysis	Powerful method for analyzing complicated mixtures of molecules. Holds promise for analyzing associating systems (Stafford, 1992; Stafford, 1994). By increasing the gravitational field over the course of an experiment, fractionation of incredibly complicated mixtures may be achieved (Mächtle, 1988).
	Differential sedimentation	Sensitive means of detecting small (0.005%) differences in sedimentation due to conformational changes (Richards and Schachman, 1957).
	Active enzyme sedimentation	Means of characterizing an impure enzyme (Cohen et al., 1971) using a chromophoric assay and monitoring the movement of color development as the enzyme sediments.
	Van Holde and Weischet extrapolation	Graphical means of removing the effects of diffusion, thus improving resolution of a paucidisperse solution (Van Holde and Weischet, 1978).
Equilibrium	Short-column analysis (750 µm, 15 µl samples)	Useful for quick surveys of molecular weight, association properties, and nonideality (Yphantis, 1960; Laue, 1992).
	Longer-column analysis (3 mm, 110 µl samples)	Provides higher precision than short-column; useful for low-molecular-weight solutes and analysis of heterogeneity (Yphantis, 1964).
Miscellaneous	Extinction coefficient	Combines absorbance and refractive optical reading for precise measurement of extinction coeffiecient. Sensitive test for sample homogeneity.
	Tracer sedimentation	Very sensitive and selective for characterizing interactions between purified proteins.
	Diffusion coefficient	Obtained at low speed.

required to interpret data and the same values should be obtained for parameters (e.g., molecular weight and $s_{20,w}$) from preparation to preparation and from laboratory to laboratory. Of the two methods, sedimentation velocity provides a greater degree of sample fractionation, and it is uniquely suited to particle size distribution analysis (see Anticipated Results for definitions and further discussions). The standardized sedimentation coefficient ($s^0_{20,w}$; measured in Svedberg units, S) is a constant for a given molecule; it therefore is often used as a species descriptor (e.g., 30S subunit, 5S RNA).

The reasons behind the revival of analytical ultracentrifugation reveal many of its virtues. Fundamental information concerning sample purity, native molecular weight, association energies, and molecular size and shape are all readily obtainable using this technique. The methods are not fussy with regard to solvent conditions, and can be applied to any sort of protein (fibrous or globular, large or small) over an enormous range of molecular weights (<100 to >10,000,000 g/mol). Relatively small quantities of materials are required for analysis and, because the techniques are nondestructive, samples can be recovered afterwards. Moreover, great experimental precision can be anticipated, even by a novice experimenter.

The disadvantages of sedimentation analysis are different for the velocity and equilibrium methods. Sedimentation velocity analysis requires relatively large sample volumes (450 µl) and, being a broad-zone method, exhibits poor sample fractionation when compared with various chromatographic and electrophoretic methods (Table 7.5.2). Subtle changes readily apparent upon electrophoresis may not be revealed by sedimentation. Another consequence of the technique's broad-zone nature is that only the slowest-sedimenting species can be examined in a pure state; all other boundaries will be composed of mixtures of components.

The interpretation of sedimentation equilibrium data requires that highly purified proteins be used. For the analytical ultracentrifuge, relatively high concentrations of proteins (0.1 to 1.0 mg/ml) are required for detection (Table 7.5.3). Even if these criteria are met, complicated association schemes (e.g., highly nonideal monomer:dimer:tetramer:octamer associations) are difficult to analyze in great detail. Finally, neither sedimentation velocity nor sedimentation equilibrium is suitable for kinetic analysis.

Even with these disadvantages, sedimentation analysis compares favorably with alternative methods (Table 7.5.2). There are three classes of methods that can be compared with sedimentation: (1) other primary methods (light scattering and osmotic pressure), (2) spectroscopic analysis for obtaining thermodynamic information, and (3) secondary methods built around electrophoresis and column chromatography. Both light scattering and osmotic pressure are well-grounded in thermodynamics and provide accurate estimates of molecular weight. However, neither affords any fractionation of the solution and neither provides hydrodynamic information equivalent to that from sedimentation velocity. Both are subject to problems with contamination (osmotic pressure from small particles and light scattering from large ones), though this sensitivity can be useful for detecting such contaminants. Finally, both require larger quantities and higher concentrations of sample than does sedimentation.

Spectroscopic methods—e.g., fluorescence, absorbance, circular dichroism (CD), nuclear magnetic resonance (NMR), and electron spin resonance (ESR)—are often useful for examining sample purity and for conducting binding studies. For sample purity, these methods are usually applied to detect the presence of specific contaminants (e.g., detecting protein in a DNA sample by absorbance). The concentrations needed to conduct a study range from quite low (fluorescence) to rather high (NMR). In addition to sample purity, spectroscopy often is used phenomenologically to monitor associations, including macromolecular interactions. Because of their respective sensitivities, the concentration range accessible to these methods is quite variable. All spectroscopic methods suffer from certain common problems. First, because they are phenomenological, it is not guaranteed that binding will lead to the production of an appropriate signal. Hence, it is possible for an interaction to occur that gives rise to no measurable spectroscopic change. Moreover, if the stoichiometry of binding is >1, it is possible for different binding events to give rise to proportionately different signals. In these cases, the stoichiometry of binding will be nearly impossible to determine and estimates of the strength of binding may be seriously in error.

There are several chromatographic and electrophoretic methods available for making measurements similar to those from sedimentation. These fractionate the sample and therefore are extremely useful for detecting contam-

BCU IASI - CENTRAL UNIVERSITY LIBRARY

Table 7.5.2 Alternative Analytical Methods

Class	Method	Notes
Primary methods No standards required; data interpretation grounded in physical first principles; no sample fractionation.	Scattering	Light and low-angle X-ray can yield molecular weight and radius of gyration. For mixtures, weight-average molecular weights and *z*-average radii are obtained. (Laue, 1995; Yphantis, 1964). Sensitive to large contaminants. Small cuvettes reduce sample volume, but sensitivity is limited to relatively high concentrations (>1 mg/ml). Particle scattering (e.g., neutrons) is very expensive but yields details about particular aspects of structure.
	Osmotic pressure (other colligative methods)	Useful for determining molecular weights of small molecules. For mixtures, number-average molecular weights are obtained. Sensitive to low-molecular-weight contaminants. Relatively high concentrations (>1 mg/ml) are required. Vapor pressure osmometers require small sample volumes.
Spectroscopic methods Primarily useful phenomenologically; sample size and sensitivity vary from method to method; no sample fractionation.	Absorbance	Useful for detecting particular contaminants. Simple to use. Sensitivity to contaminants depends on their extinction coefficient at the wavelength of interest. Changes in absorbance with binding can be used to monitor macromolecular interactions with varying success.
	Fluorescence	Very sensitive. Both luminescence and quenching of fluorescence useful for detecting contaminants. Changes in fluorescence can be used to monitor macromolecular interactions with varying success.
	Circular dichroism	Not generally as useful as other spectroscopic methods for detecting contaminants. Can be used to monitor macromolecular interactions with varying success. Instrumentation expensive.
	Nuclear magnetic resonance, electron spin resonance	Not generally as useful as other spectroscopic methods for detecting contaminants. Can be used to monitor macromolecular interactions with varying success. Requires high concentrations of material and instrumentation expensive.
Secondary methods Require standards for interpretation; can be particularly useful for detecting contaminants; most are used as "thin-zone" methods, which limits their usefulness in characterizing interactions.	Column chromatography	Depending on column matrix, can be sensitive to size, charge, or specific binding. In studying binding, useful qualitatively but less so for quantitative work. Fractionation can be excellent. Ability to measure contaminants depends on detector used to monitor effluent, but can be exquisitely sensitive. A modified detector in which the matrix is attached to the detector is at the heart of the Pharmacia Biotech Biacore and related devices.
	Electrophoresis	Several methods based on electrophoretic mobility exist (e.g., gel electrophoresis, capillary zonal electrophoresis, and isoelectric focusing). Fractionation is usually superb; sensitivity depends on detector. Because of the high degree of sample fractionation, only limited, qualitative information about macromolecular interactions is obtainable.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Table 7.5.3 Methods of Solute Detection

Method of detection	Use[a]	P[b]	A[c]	S[d]	D[e]	Notes
Absorbance	A, P	G	F	G	F	Sensitivity depends on solute's extinction coefficient. Discrimination depends on separation between absorbances.
Refractive	A	E	E	G	P	Accuracy and precision cannot be matched by other techniques. Method of choice for nonabsorbing solutes or buffers that absorb in the UV.
Fluorescence	P	F	F	E	E	Specific labels can provide excellent sensitivity and superb discrimination, but the linearity of the concentration determination is subject to several types of error.
Enzyme assay	P, A	F	F	E	E	Excellent discrimination and sensitivity. Can be used to determine which form of an enzyme is active. Precision and accuracy can be quite good or rather poor, depending on the assay. A band sedimentation method for the analytical ultracentrifuge works quite well, but requires that a suitable colorimetric assay be available.
Radiolabel	P	G	F	E	E	Superb discrimination and sensitivity can be attained. Accuracy of the concentration determination can range from very good to very poor depending on the particulars of the radiolabeling.
Other	P	—	—	—	—	Any assay (RIA, ELISA, bioassay) that yields a signal proportional to the concentration may be used for determining molecular weight and $s_{20,w}$. Of particular interest are methods in which the sample is fractionated (e.g., by gels or HPLC) subsequent to sedimentation, which allows detection of interactions between components in extremely complicated mixtures. Typically, the accuracy of these methods is not sufficiently high to allow further analysis (i.e., determination of association constants).

[a]Designates the instrument that may be used: A, analytical ultracentrifuge; P, preparative centrifuge with subsequent microfractionation. Where both types of instruments may be used, the better of the two is listed first. In general, the analytical ultracentrifuge offers improved accuracy in the determination of radial position and concentration, which is necessary for determining accurate association constants and stoichiometries. The preparative centrifuge offers lower cost and, in general, greater solute sensitivity and discrimination, but lower precision and accuracy.

[b]Precision of detection. Usually given as a standard error of replicates, the precision of a detection scheme may be very high, yet the accuracy may be poor if systematic error is present. E, excellent; G, good; F, fair; P, poor.

[c]Accuracy of detection. This depends on the lack of systematic errors (e.g., nonlinearity of the response of the detector with concentration).

[d]Sensitivity to solute.

[e]Discrimination between solutes.

inants. Most of these methods are now highly refined, are easy to use, and can examine a wide range of sensitivities. However, with regard to sample characterization, they are less rigorous than sedimentation. This stems from the fact that all are secondary methods, requiring standards for calibration and comparison. For example, gel permeation chromatography is often used to estimate molecular weights, radii, and stoichiometries. However, if a protein does not conform to the properties of the standards (e.g., if the unknown is asymmetric and the standards are all spherical), erroneous conclusions may be reached with this approach. A second, more fundamental, problem arises when these methods are used to examine macromolecular interactions. Both chromatography and electrophoresis usually entail the monitoring of thin zones of material. Because the concentration in the zone varies both spatially and with time, it is impossible to relate the zone shape or position to any association parameters in a rigorous fashion.

PLANNING AN EXPERIMENT

The principle measurement obtained in any sedimentation experiment is the concentration as a function of radial position. Knowledge of the concentration distribution, along with the rotor speed and temperature, is needed to obtain a molecular weight or an $s_{20,w}$. There are several means of determining the concentration distribution (Table 7.5.3). Analyses may be conducted using either a preparative or an analyt-

BCU IAS/CENTRAL FIRST LIBRARY

ical ultracentrifuge. It is worth taking a moment to consider which instrument will be most useful for elucidating a particular problem. To do this, it is necessary to have a clear notion of what information is being sought from the centrifugation experiment. If all that is needed is a rough estimate of the molecular weight to confirm a stoichiometry, then a preparative centrifuge will be sufficient. On the other hand, if association constants or accurate sedimentation coefficients are needed, an analytical ultracentrifuge will be required.

The biggest difference between an analytical and a preparative ultracentrifuge is the analytical instrument's ability to monitor the concentration distribution as a sample is spinning. To do this, a special cell and rotor are used that permit light to pass through the sample. Light sources and detectors are arranged to monitor the cell contents throughout an experiment. Data acquisition is automated, and a large number (500 to 2000) of data points are available across the cell (1.5 cm), yielding the high radial resolution needed for the analysis of interacting systems. At present, absorbance and refractive detection are available for the XLA analytical ultracentrifuge (Beckman), and prototype fluorescence optics are under development. Data acquisition requires 5 to 30 sec per cell, and up to four cells may be used.

The ability to acquire data rapidly and with high radial resolution has led to improvements in both sedimentation equilibrium and velocity analysis. For sedimentation equilibrium, there has been a resurgence of interest in short-column methods (Yphantis, 1960; Laue, 1992), whose small sample volumes (15 µl), rapid equilibrium (typically ~1 hr), and large throughput (up to 16 samples simultaneously) are well-suited to addressing biochemical problems. The development of time-derivative sedimentation velocity has improved the sensitivity of the refractive optical systems nearly 100-fold, and promises to revolutionize the range of systems suitable for sedimentation analysis. Experimental protocols in which the rotor speed is accelerated over the course of an experiment (i.e., gravitational sweep sedimentation) have been described (Stafford, 1992; Machtle, 1988) for analyzing and characterizing polydisperse samples. The fractionation range and accuracy of this method far exceed those of any other technique presently available.

A good preparative ultracentrifuge (either a floor or tabletop model) may also be used for analytical ultracentrifugation, as confirmed by the long-time success of sucrose gradient analysis. In many cases, these methods offer great advantages because the sample is analyzed after centrifugation by taking fractions (i.e., radial slices) from the centrifuge tube. Because of this, any detection scheme may be used to determine the concentration distribution. This means that unparalleled sensitivity and selectivity are afforded by schemes that use the preparative ultracentrifuge. Moreover, each fraction may be further fractionated—e.g., by high-performance liquid chromatography (HPLC) or gel electrophoresis—yielding good analytical sedimentation data for complicated mixtures. Detailed protocols for sedimentation velocity and sedimentation equilibrium in a preparative ultracentrifuge are available, and a superb microfractionator is available (from Brandel) specifically for conducting sedimentation analyses (Attri and Minton, 1986).

However, it must be recognized that the information obtained from a preparative centrifuge is a snapshot of the cell at the time of deacceleration (assuming no mixing occurs during deacceleration). This precludes the use of the elegant time-derivative methods that have been developed for the analytical machine. Moreover, the time delay between stopping the run and sampling the cell allows diffusion to distort the concentration gradient, leading to inaccuracy in its determination. This problem becomes severe when steep gradients are involved. In general, the radial resolution for the preparative techniques is not as high as with the analytical ultracentrifuge.

The concentration of protein needed for an experiment depends on what question is being addressed. If one merely seeks the molecular weight or sedimentation coefficient of a solute, then any convenient concentration may be used. However, if one is interested in knowing the association state of a sample under particular conditions (e.g., at concentrations found in vivo, or in an assay), the choice of detection scheme may become critical. In this case, one must work out what concentration is needed and what detection schemes are suitable for the concentration range, and match this to an entry in Table 7.5.3. It is essential to realize that any experimental protocol must examine the sedimentation behavior over a range of concentrations to take account of thermodynamic nonideality (sedimentation equilibrium) and hydrodynamic effects (sedimentation velocity; Laue et al., 1992).

The stability and accuracy of the temperature is a critical experimental parameter. The

BCM LIBRARY

XLA ultracentrifuge can be operated at temperatures between 0° and 40°C. Although this is convenient for most biochemical work, there are some studies (e.g., thermal denaturation) where a wider range is desired. In this case, one is limited to using an appropriately configured preparative centrifuge. Regardless of the temperature used, temperature stability is important in preventing convection. The accuracy of the temperature measurement is also important, particularly for sedimentation velocity analysis, where adjustment of a measured sedimentation coefficient (s) to standard conditions (20°C and water; the $s_{20,w}$) must be made. Methods for making these adjustments are well established and have been automated (Laue et al., 1992).

The rotor speed should be chosen carefully, as the gravitational field (g) increases as its square ($g = \omega^2 r$, where $\omega = \pi \times \text{rpm}/30$ and r is the rotor radius). Different criteria are used to choose the rotor speed for sedimentation velocity and for sedimentation equilibrium analyses. For a sedimentation velocity experiment, two options can be considered: (1) gravitational sweep, in which the rotor speed is increased periodically throughout the experiment, and (2) s, where a single rotor speed is chosen for the analysis. Gravitational sweep is particularly useful for the initial characterization of a system where it is useful to get a general idea of how broad the particle size distribution is. In this method, the rotor is accelerated to a low speed (e.g., 3000 rpm) and several (six to ten) concentration distributions are collected to determine if there are any fast-moving boundaries. Next, the rotor speed is accelerated twofold, and data collection again undertaken. This process is continued until the maximum rotor speed (60,000 rpm) is attained, following which data are acquired until all boundaries have sedimented at least three-quarters of the way down the cell. Using this scheme, a sample can be "scanned" for the presence of an extraordinarily broad range of particle sizes (from greater than 1000S to ~1S).

The second method of analysis acquires data at a fixed rotor speed. This is useful for samples that have one or only a few types of proteins with similar sizes (within an order of magnitude). If one is trying to resolve two proteins of similar size, the highest rotor speed that allows a sufficient quantity of data to be obtained should be used (i.e., such that the fastest boundary takes ~30 min to travel the length of the cell). The time-derivative data analysis routines work best with large numbers of data sets closely spaced in time, so data should be acquired frequently throughout a run.

Multiple rotor speeds should be used for sedimentation equilibrium analysis. Choosing appropriate rotor speeds is relatively simple if the molecular weight of the largest species is known ($\text{rpm} \approx 2 \times 10^6 \sqrt{M^{-1}}$), and a practical scheme for choosing an initial rotor speed is available for other cases. Low speeds are useful for detecting aggregates and high speeds are useful for detecting proteolytic fragments. In general, rotor speeds should be used that keep the reduced molecular weight, σ, between 2 and 12. An estimate of σ can be calculated from the molecular weight:

$$\sigma = M(1 - \bar{v}\rho)\,\omega^2/RT$$

where $\bar{v}$ is the partial specific volume (~0.72 ml/g is a good rough estimate), ρ is the solvent density (1 g/ml for the dilute aqueous buffers usually used in biochemistry), ω is the rotor angular velocity (see above), R is the gas constant (8.31×10^7 erg/mol°), and T is the absolute temperature. Even a crude estimate of σ will suffice. The range of rotor speeds used in an analysis should vary σ over a 4-fold or greater range, if possible. The experimental protocol should involve incrementing rather than decrementing the rotor speed, as (because of diffusion) it takes much longer for a rotor to reach equilibrium when approaching it from a higher speed. There are many other practical tips for choosing the rotor speed, estimating σ, and designing an appropriate experimental protocol (Ralston, 1993; Laue, 1992).

In general, conducting an experiment with an analytical ultracentrifuge is very simple. The usual cause of difficulty is the sample, either in terms of its purity (for experiments trying to extract thermodynamic details) or its behavior (for previously uncharacterized biochemical systems). Problems often encountered for either sedimentation velocity or sedimentation equilibrium, along with suggestions for resolving them, are discussed in Table 7.5.4.

ANTICIPATED RESULTS

Different, yet complementary, information is obtained from sedimentation velocity and sedimentation equilibrium experiments. For sedimentation velocity, the rate of movement of the boundary yields the sedimentation coefficient, s. Straightforward adjustment of this measured value provides $s_{20,w}$, the expected sedimentation coefficient for the molecule if it were sedimented in pure water at 20°C (Laue et al., 1992). A second adjustment is made by

BCU IAS CENTRAL UNIVERSITY LIBRARY

Table 7.5.4 Troubleshooting Guide for Analytical Ultracentrifugation

Problem	Possible cause	Solution
Velocity method		
No boundary or very broad boundary	Convection	May be caused by thermal instability or mechanical instability (rotor vibration)
	Sample heterogeneity (aggregates or fragments)	Clean sample by gel filtration
	Loss of sample to cell walls	Use centerpiece made of different material.
	Interacting system (concentration-dependent; may show pressure dependence)	Analyze by sedimentation equilibrium
Too few data points; boundary reaches base in <30 min	Rotor speed too high	Shake cell and rerun at lower rotor speed
Boundary that moves too slowly	Rotor speed too low	Shake cell and rerun at higher rotor speed
	Presence of proteolytic fragments	Fractionate sample by gel filtration
	Improper sample dialysis	Buffer component not equilibrated in sample and reference channels
Equilibrium method		
Decrease in molecular weight with increased concentration	Nonideality; little dependence of rotor speed on molecular weight	Use a nonideal model in nonlinear least squares analysis; extrapolate to zero protein concentration. Information about molecular size and charge available.
	Sample heterogeneity; molecular weight also decreases with increased rotor speed	Fractionate sample
Increase in molecular weight with increased concentration, but little change as rotor speed is varied	Mass-action association	Characterize by nonlinear least-squares analysis
Somewhat higher molecular weight than expected; slow loss of material	Slow aggregation; flocculant formation (data are often noisier than usual; inconsistent molecular weights are obtained from one sample to the next)	Use sedimentation velocity analysis to detect this as a fast boundary or sloping plateau concentration. Only cure is to find buffer conditions that stabilize protein solubility. For intracellular proteins, be sure a reducing agent (2-ME or DTT) is present.
Somewhat lower molecular weight than expected	Proteolysis (e.g., molecular weight drops with time)	Use protease inhibitors in sample; refractionate by gel filtration.
	Improper dialysis of sample prior to analysis	Be sure sample and reference buffers are at dialysis equilibrium prior to run. Use centrifugal gel filtration for rapid equilibration.

measuring the sedimentation coefficient of the boundary at several different protein concentrations, then extrapolating the values of $s_{20,w}$ to zero protein concentration to get $s^0_{20,w}$. For a nonassociating protein, $s^0_{20,w}$ decreases with increasing concentration; this decrease occurs gradually if the protein is spherical (by ~1% per mg/ml) and more strongly if it is asymmetric. In addition to gaining insight into the shape of a protein, there are three reasons for adjusting to standard conditions. First, $s^0_{20,w}$ is a practical, descriptive constant for a protein that can be used to compare preparations made under different conditions or in different laboratories. Second, determination of $s^0_{20,w}$ provides a first-principle means of detecting changes in the hydrodynamics of the protein (see below). Third, an increase in $s^0_{20,w}$ with increasing concentration is a useful diagnostic for mass action association of a protein.

Sedimentation velocity is also useful for characterizing more complicated mixtures of molecules (Stafford, 1992). In these cases sedimentation coefficient profiles are obtained. For samples containing only a few boundaries (paucidisperse samples), appropriate extrapolation of the data to infinite time provides higher precision and improved resolution of the

BRANDEIS CENTRAL UNIVERSITY LIBRARY

boundaries (Van Holde and Weischet, 1978; Stafford, 1994).

In addition to $s^0_{20,w}$, the Stokes radius, R_S, of a particle may be obtained from sedimentation analysis (Laue et al., 1992). Models can be applied in which R_S is analyzed in terms of either the extent of hydration or the degree of asymmetry (Laue et al., 1992). Such analyses often provide the first insight into the shape of a protein.

Equilibrium sedimentation provides thermodynamic information about a sample. Analyzed in the simplest way, the data can be used to obtain the molecular weight. For a mixture of molecules, various average molecular weights (number, weight, and z) may be calculated (Yphantis, 1964; Laue, 1995). By measuring the molecular weight in a denaturing solvent (e.g., 6 M guanidine·HCl; *APPENDIX 3A*) and in a physiological solvent, the stoichiometry of the native molecule can readily be determined (Laue, 1992). More detailed analysis of the concentration distributions can provide energies of assembly and nonideality coefficients (McRorie and Voelker, 1993).

TIME CONSIDERATIONS

For a typical run with the XLA ultracentrifuge involving three cells per rotor, sample preparation and cell loading requires ~1 hr. For sedimentation velocity analysis, a run requires ~2 hr (once the rotor is at the desired temperature). Gravitational sweep analysis requires somewhat longer. The time required to conduct a sedimentation equilibrium analysis is discussed below. In any case, operation of the centrifuge, including data acquisition, is completely automated. After the run, sample recovery and cell cleaning require ~1 hr. For maximum efficiency, it is worthwhile to have two complete sets of cells so that one may be cleaned and loaded while the other is being run. Data analysis for sedimentation velocity experiments is computerized and rather straightforward, and usually requires <1 hr.

The time required to conduct a sedimentation equilibrium experiment depends a great deal on the particulars of the experimental setup. The number of samples that can be analyzed simultaneously depends on the choice of centerpieces, so that up to sixteen samples may be analyzed simultaneously. Cell loading still only requires ~1 hr. The time needed to reach sedimentation equilibrium depends on the solvent viscosity, the diffusion coefficient of the protein, and the distance between the meniscus and the base of the solution column. In general, the time increases linearly with the viscosity, as the cube root of the molecular weight, and as the square of the column height of the solution. Shorter solution columns can be accommodated in any of the centerpieces. For a typical aqueous buffer and a 50,000-molecular-weight protein, the time needed to reach equilibrium is ~9 hr for a 3-mm solution column (~110 µl of sample) and ~1 hr using a short column centerpiece (~15 µl of sample). Because a typical experimental protocol requires equilibrium at three or four rotor speeds, a full 1 or 2 days are needed to complete data acquisition.

Computer programs have automated equilibrium data analysis. Even so, the time needed to analyze equilibrium data depends on the level of detail of the scrutiny. If only an average molecular weight is required, this can be accomplished in a few minutes. On the other hand, determination of both the stoichiometry and energetics of a self-associating protein may require several days of analysis if no previous characterization has been done. Both the level of detail required to answer a biological question and the experience of the researcher will affect the time needed to complete an analysis.

For either velocity or equilibrium sedimentation, there are no time-critical steps once the centrifuge run has started. Zealots often begin data analysis during the centrifuge run. Although this is not strictly necessary, it is particularly useful when examining a previously uncharacterized system as it allows adjustment of the experimental conditions to maximize the quality of the data.

Methods using a preparative centrifuge can handle a larger number of samples in a run (depending on which rotor is used). Likewise, the time required for preparation will vary, though it will be on the same order of magnitude as for the XLA. Unlike with the XLA, data acquisition is not fully automated in that the radius of each fraction must be calculated on the basis of its volume and the sample-tube geometry (Attri and Minton, 1986). Likewise, assaying the fractions may or may not require considerable time.

HELP FOR THE NOVICE

It is widely recognized that undertaking sedimentation analysis for the first time can be a daunting task. Fortunately, the most difficult parts—including data acquisition, data analysis, and data interpretation—have been automated. Commercial computer programs for these tasks are available from Beckman Instru-

RCU IASI CENTRAL UNIVERSITY LIBRARY

ments. In addition, there is an Internet bulletin board (rasmb@bbri.eri.harvard.edu) where analytical sedimentation is discussed and a wide variety of computer programs are available free of charge. Often, though, it is not the process of conducting analytical ultracentrifugation that is a problem for biochemists, but rather their uncertainty about the solution physical chemistry of proteins. Fortunately, the cadre of researchers working with the ultracentrifuge welcome the opportunity to help newcomers to the field. Determining the CD Spectrum of a Protein

There are two requirements for a molecule or group of atoms in a molecule to exhibit a circular dichroism (CD) spectrum. The first is the presence of a **chromophore**—i.e., a group that can absorb radiation by virtue of the electronic configuration of its resting or ground state at room temperature. The energy absorbed results in a transition to a higher-energy or excited state, which has a different distribution of electrons around the nucleus. It can therefore interact with its environment in a way that differs from the ground state. In proteins, tryptophan, tyrosine, and phenylalanine are the main chromophores in the near-UV (240- to 320-nm) region; the peptide bond is the main chromophore in the far-UV (180- to 240-nm) region. Disulfide bonds and histidine residues are two other chromophores whose contribution to CD are, in general, less marked. Most chromophores exhibit more than one transition (e.g., see Fig. 7.6.1, Fig. 7.6.2, and Table 7.6.2) and their spectra are a composite of several absorption bands. It is an important feature of CD that, unlike optical rotation, the wavelength region within which spectra are observed is limited strictly to the wavelength region of the individual absorption bands. This confers greater specificity on spectra and allows a certain degree of assignment to particular chromophores.

The second requirement for CD is that the chromophore be in, or closely associated with, an **optically asymmetric environment**. The chromophores in proteins are themselves not chiral and exhibit no optical activity. The phenolic group of tyrosine, for example, exhibits a CD spectrum only because it is connected to an optically asymmetric carbon atom. However, when the same group is packed in a folded protein in an environment that is asymmetric with respect to polarity, or is interacting through the phenolic hydroxyl, it exhibits a different CD spectrum that is specific to the particular environmental influences acting on the chromophore. In practice, the latter spectrum is usually much more intense than that for free tyrosine and may also differ in shape. When the peptide-bond chromophore is part of a regularly folded structure, with particular backbone angles and hydrogen-bond interactions as in an α-helix or β-sheet, it becomes closely associated with a conformationally asymmetric structure—i.e., one that cannot be superimposed on its mirror image. A CD spectrum for the protein will be generated that is a composite of the individual spectra corresponding to each of the peptide-bond absorption transitions (Fig. 7.6.1). The intensity of the spectrum may be further affected by interaction between neighboring chromophores (Bayley, 1980).

Plane-polarized radiation comprises two circularly polarized vectors of equal intensity, one right-handed and the other left-handed (Fig. 7.6.3A), which are separately measured in the CD spectrometer by means of a photoelastic modulator. A chromophore situated in an optically symmetrical environment will normally absorb the two components equally so that, when recombined after passing through a solution of the chromophore, they result once again in radiation oscillating in a single plane. A chromophore situated in an optically asymmetric environment, however, will absorb each of the two components to a different extent, the difference being ΔA. When recombined, the resultant vector describes an ellipse (Fig. 7.6.3B), the ratio of whose major and minor axes determines the **ellipticity.** The value of ΔA, and hence that of ellipticity, can be positive or negative depending on the nature of the asymmetric environment. This is exemplified by the contribution of the tyrosines in IL-1β (Fig. 7.6.4A) and of the tyrosines and tryptophans in GM-CSF (Fig. 7.6.5).

It is a general consequence of the above principles that CD spectra of molecules in solution are located in the same wavelength region as their absorption bands. For proteins this means the far-UV and near-UV regions, as well as regions extending into the visible and near infrared. These regions have their origin in and provide information about the

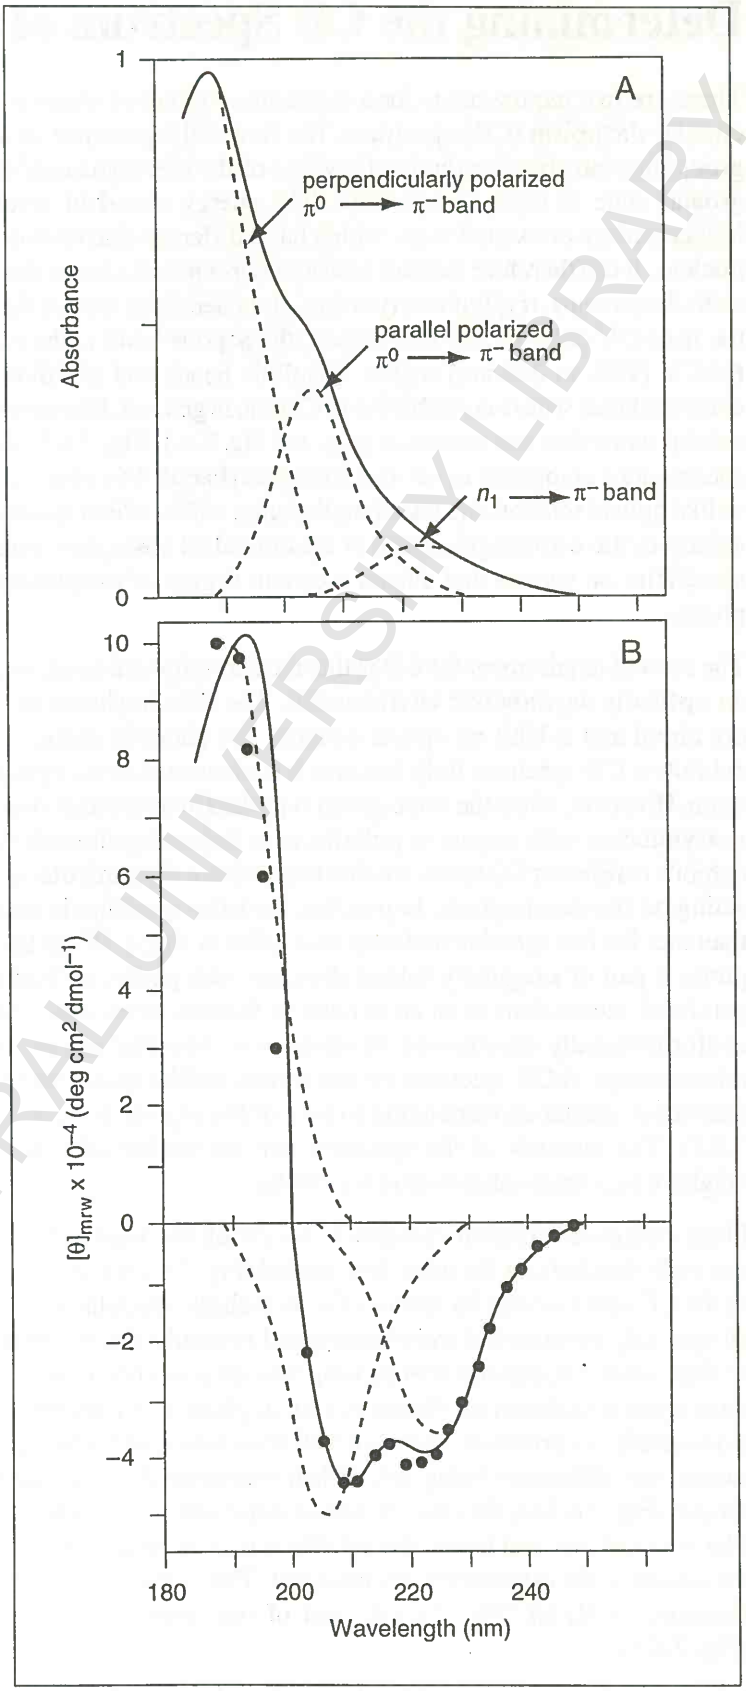

Figure 7.6.1 Relation between absorbance and circular dichroism for a polypeptide chain in the helical conformation. **(A)** The absorbance spectrum of poly-γ-methyl-L-glutamate in the α-helical form, with an assignment of its three constituent transitions. **(B)** The far-UV CD spectrum of the same compound, deconvoluted on the assumption that the shapes of the absorbance and dichroic bands are directly related (broken lines). The solid line is the observed spectrum and the filled circles the sum of the three bands. In general, the sign of a CD band may be either positive or negative, and its intensity does not necessarily follow that of the absorbance band. (From Holzwarth and Doty, 1965.)

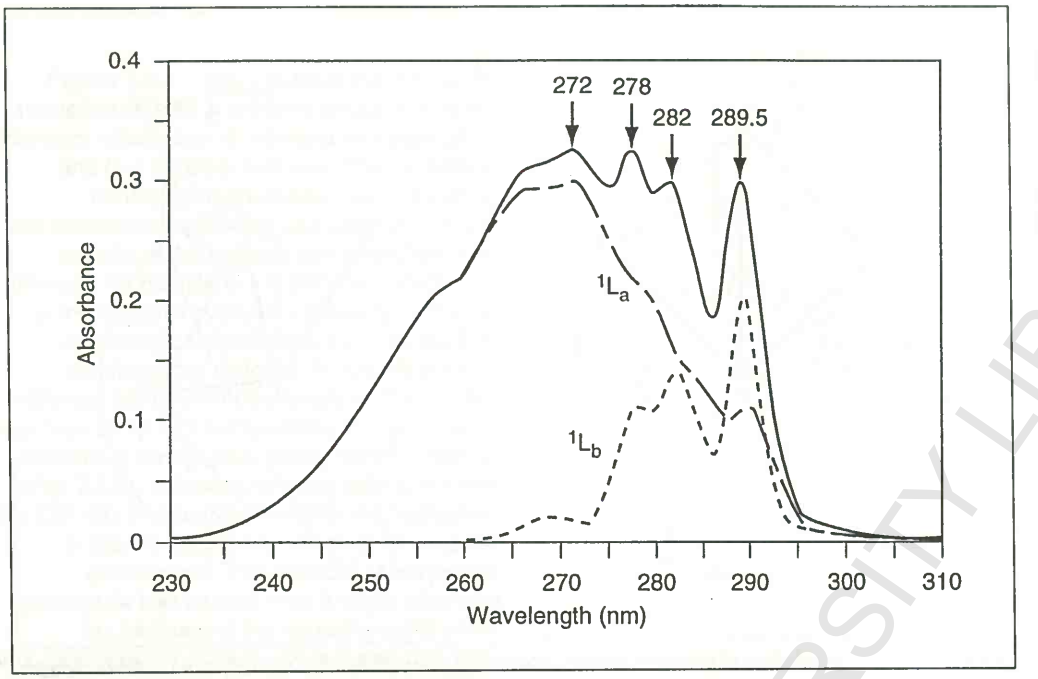

Figure 7.6.2 The two near-UV absorbance transitions for tryptophan. The near-UV absorption spectrum for *N*-stearyl tryptophan *n*-hexyl ester dissolved in methylcyclohexane at 24°C (solid line) has been resolved into the ^1L_a and ^1L_b bands. (Drawn from Strickland, 1974.)

polypeptide backbone and its conformation (far-UV), the aromatic amino acid residues and their environments (near-UV), and bound ligands such as heme and cofactors (visible and near infrared). Experimentally, the near-UV and the visible and near-infrared regions can be treated together and the protocols in this unit will therefore refer explicitly only to the collection of far- and near-UV spectra.

In both the far- and near-UV regions, CD spectra can be used empirically as "fingerprints" of a particular protein, with the spectrum resulting from the aromatic residues being rather more specific and hence diagnostic. The far-UV spectra, however, can provide information about the protein conformation in terms of its secondary structure. As for fluorescence spectroscopy or any spectroscopic method, the sample needs to be chemically pure and homogeneous.

The output of CD spectrometers is in two alternative but related types of unit. The difference in absorbance with respect to left- and right-handed circularly polarized radiation ($A_L - A_R = \Delta A$) is measured in absorbance units; ellipticity (θ) is measured in millidegrees (mdeg). These units are related by the expression $\theta = 33{,}000 \times \Delta A$ (see Fig. 7.6.3A).

Ellipticity is usually used for far-UV measurements. Because essentially every residue in a protein is associated with a peptide bond, spectra in this region can be directly compared for different proteins by calculating the mean residue ellipticity,

$$[\theta]_{mrw} = \frac{\theta \times M_{mrw}}{10 \times c \times 1}$$

where c is the protein concentration in mg/ml, l is the cell path length in cm, and M_{mrw} is the mean residue molecular weight—i.e., protein formula weight/number of residues. The dimensions of $[\theta]_{mrw}$ are deg cm^2/dmol, and the quantity is independent of molecular weight. M_{mrw} is in the range 110 to 115 for most proteins.

BOJIAN / CENTRAL UNIVERSITY LIBRARY

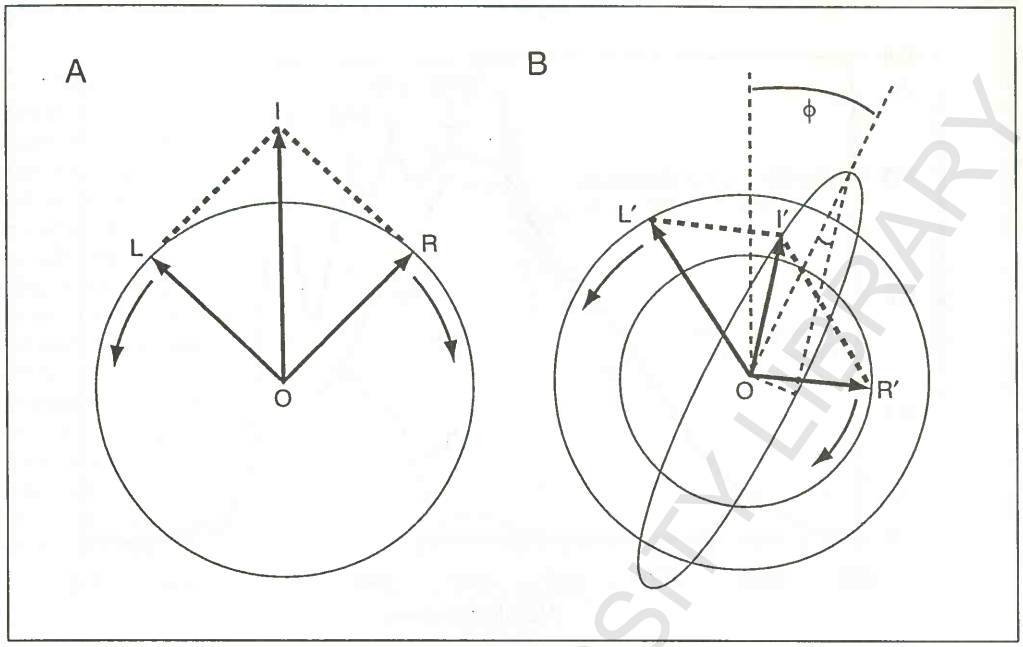

Figure 7.6.3 The relation of ellipticity to the differential absorption of circularly polarized radiation. The oscillating radiation sine wave, **OI**, is proceeding out of the plane of the paper towards the viewer. **(A)** Plane-polarized radiation is made up of left- and right-handed circularly polarized components, **OL** and **OR**, respectively. Absorption by a chromophore in a nonchiral environment results in an equal reduction in intensity of each component, whose resultant is a vector oscillating only in the vertical plane—i.e., plane-polarized radiation. **(B)** Interaction of the radiation with a chiral chromophore leads to unequal absorption, so that combination of the emerging vectors, **OL'** and **OR'**, leads to a resultant that describes an elliptical path as it progresses out of the plane of the paper. The ratio of the major and minor axes of the ellipse is expressed by tan θ, thus defining ellipticity. The major axis of the ellipse makes an angle (ϕ) with the original plane, which defines the optical rotation. This figure thus demonstrates the close relation between optical rotation and circular dichroism.

For example, for serum albumin (see Fig. 7.6.6), the ellipticity measured at 209 nm using a 1-mm path-length cell for a solution containing 0.361 mg/ml is –61.7 mdeg. Taking a mean residue molecular weight of 110, $[\theta]_{mrw} = -18.8 \times 10^3$ deg cm^2/dmol.

For small molecules, such as aromatic amino acids and model compounds, the molar difference absorption coefficient is frequently used. By analogy with absorbance spectroscopy, this quantity is given by $\Delta\varepsilon = \Delta A/(c \times l)$, where c is the concentration in mol/liter, l the path length in cm and $\Delta\varepsilon$ has the units liters/mol/cm (or cm^2/mmol). However, in the case of proteins, near-UV CD spectra are made up of contributions from tryptophan, tyrosine, and phenylalanine residues—the content of all of which vary from protein to protein. It is therefore confusing—and achieves no useful end—to present results in terms of mean residue ellipticity. Instead, dichroism should be presented as values of ΔA. For a given protein, different samples may be compared by calculating $\Delta A/(c \times l)$, with c in mg/ml.

Owing to the variety of units found in the literature and in software—e.g., mdeg and deg for ellipticity, and mm, cm or dm for path length—it is necessary to take care that experimental parameters be entered in the units requested by the machine software.

The Strategic Planning section deals with considerations regarding instrumentation and reagents for CD spectrometry. The Basic Protocol outlines the steps in recording a CD spectrum. The two support protocols explain the interpretation of CD spectra—Support Protocol 1 deals with near-UV spectra and Support Protocol 2 with far-UV spectra.

PCU IASRI CENTRAL UNIVERSITY LIBRARY

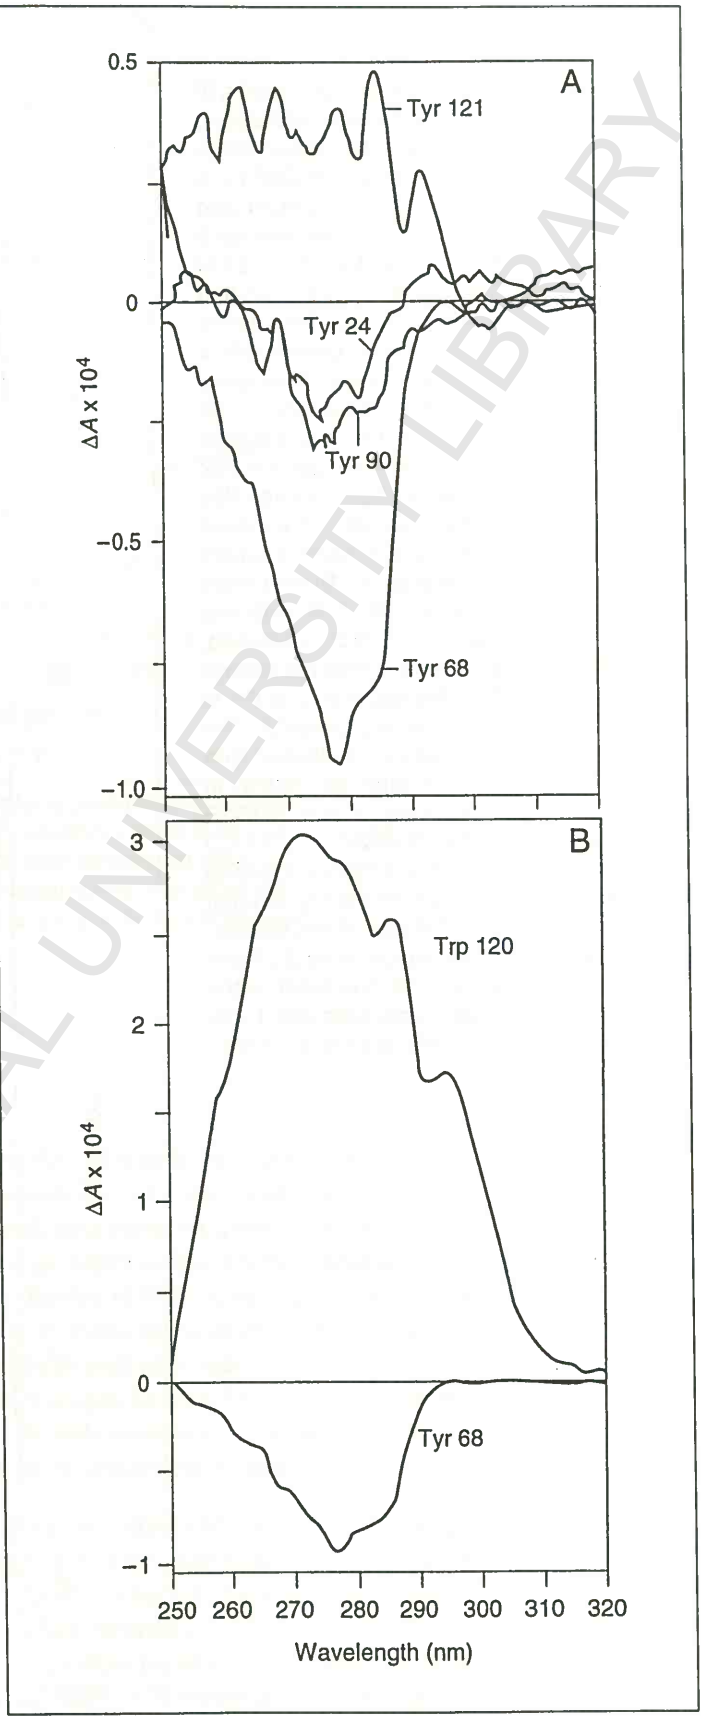

Figure 7.6.4 The contributions of different aromatic residues in a folded protein to circular dichroism. Interleukin 1β contains one tryptophan and four tyrosine residues. Their individual contributions have been resolved using site-directed mutagenesis. (**A**) The near-UV CD spectra of the tyrosine residues show that, although Tyr 68 makes a significant contribution to the negative ellipticity, indicating its buried, asymmetric environment, the contributions resulting from residues 24 and 90 are little different from that of free tyrosine. The derived spectrum of Tyr 121 is interesting in that it clearly contains a contribution arising from tryptophan (Fig. 7.6.2), indicating its close interaction with Trp 120. (**B**) The contribution from the tryptophan is seen to dominate, reflecting its nonpolar environment. The intensity of the protein spectrum is less intense than it might otherwise be, because of the opposing signs of the individual spectra. Spectra were measured using a 1-nm bandwidth (Craig et al., 1989).

BCU IASI / CENTRAL UNIVERSITY LIBRARY

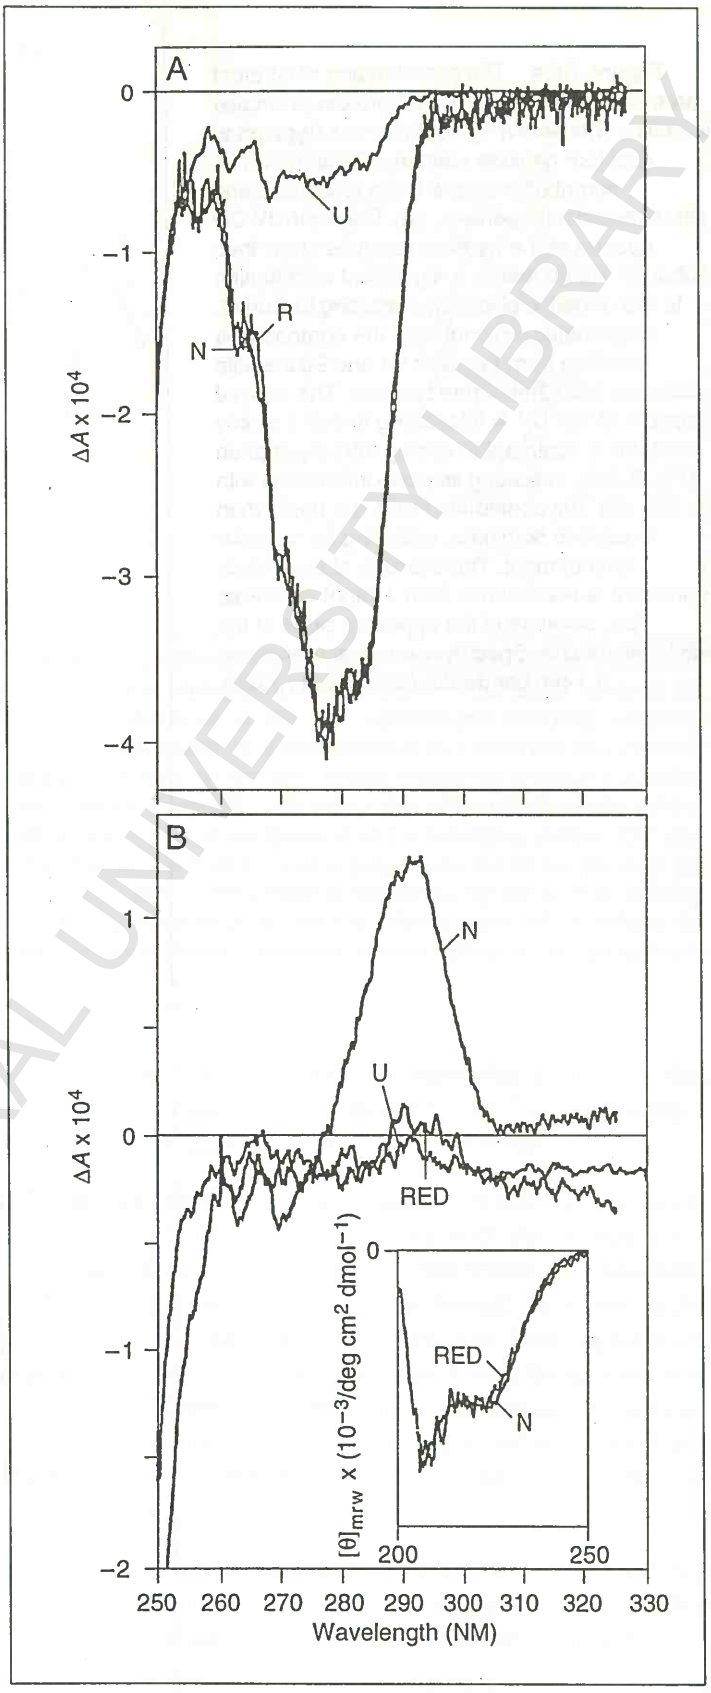

Figure 7.6.5 The near-UV CD spectra of granulocyte/macrophage-colony stimulating factor (GM-CSF). (**A**) Comparison of the spectrum of the native (N) murine GM-CSF (with one tryptophan residue, which is exposed, and four tyrosine residues, 2.5 of which are exposed) with those for the protein unfolded in 3.25 M guanidine·HCl (U) and refolded from this solution (R) by dialysis against 3 M urea. The intense negative spectrum of the folded protein, with a maximum at 278 nm, is characteristic of tyrosine, with contributions from phenylalanine. The intensity is probably a result of the interaction of Tyr 81 and Tyr 82. The absence of a band at 292 nm shows that the Trp 14 makes little contribution, as expected from its exposed location. Refolding restores the detailed tertiary structure of the native protein. (**B**) Reduction (RED) of native human GM-CSF (with two tryphtophan residues, one of which is exposed, and two tyrosine residues, which are buried) reduces the ellipticity of the native protein (N) to that of the fully unfolded protein (U). The secondary structure is however, unaffected (see inset for far-UV CD spectra). Notice that, in contrast to the murine protein, human GMCSF exhibits a less intense, but positive, near-UV CD band at 290 nm with little fine structure, implying a contribution from a ^1L_a transition of Trp 123 and indicating the buried nature of this residue. Spectra were measured using 0.01-mm path-length cells and 2-nm bandwidth in the far-UV, and 10-mm path-length cells with 1-mm bandwidth in the near-UV (Wingfield et al., 1988).

ACU IASI / CENTRAL UNIVERSITY LIBRARY

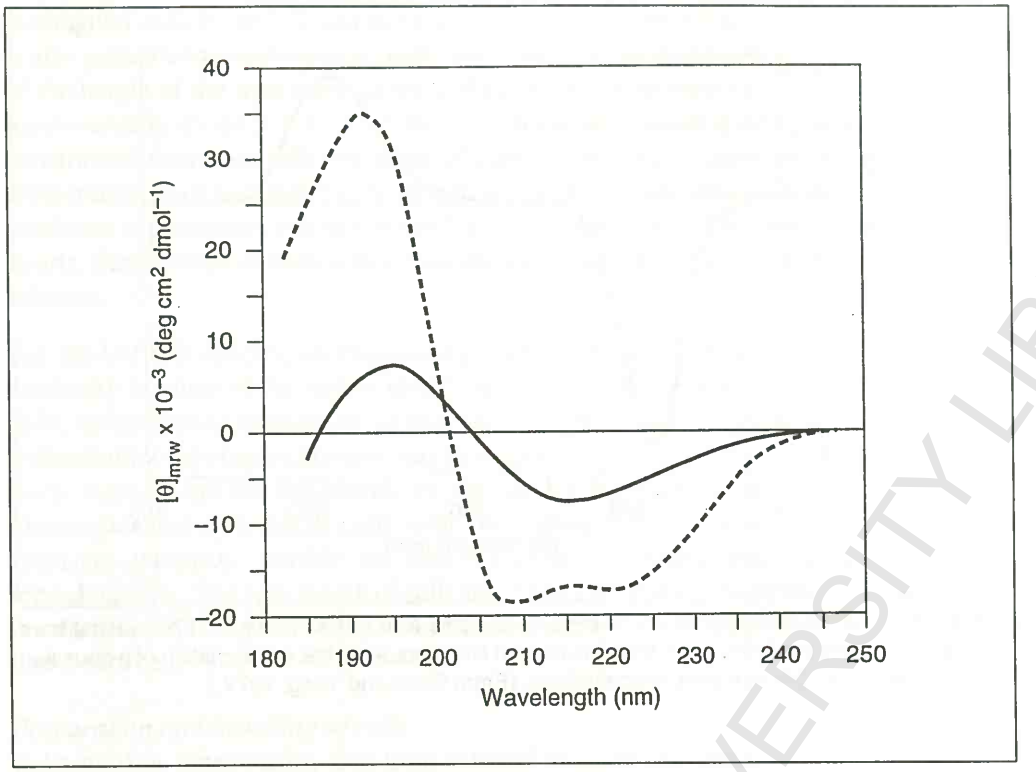

Figure 7.6.6 Characteristic far-UV CD spectra of proteins containing high contents of helix (dotted line) and β-sheet (solid line) structures. Protein concentrations were 0.36 mg/ml human serum albumin and 0.03 mg/ml immunoglobulin G. Spectra were determined using a 1-mm path-length cell. Each spectrum is the smoothed average of four repeat scans, measured with 1-nm bandwidth, reading ellipticity every 1 nm with an averaging time of 5 sec—i.e., at a scan speed of 12 nm/min.

STRATEGIC PLANNING

CD Spectrometer

CD spectra are measured using a CD spectrometer, of which there are three different makes on the market (AVIV Associates, Instruments SA, and Jasco; see *SUPPLIERS APPENDIX*). These instruments are fitted for control, data collection, and data handling by computer. The principles of how they function are generally outlined in the manufacturers' manuals and a good general account is given in Bayley (1980). A supply of high-purity nitrogen is essential to displace oxygen, in order to avoid degradation of the mirrors by ozone generated by the high-power xenon sources as well as to reduce absorbance from oxygen bands below 200 nm (see discussion of Nitrogen Supply, below). A satisfactory means of thermostatting cells is essential for work with proteins (see discussion of Cells, below), using a water-circulation system or the more convenient Peltier thermostat.

The CD spectrometer is usually required to work near the limits of sensitivity—e.g., reading ΔA values of $\leq 10^{-4}$ at a total absorbance of 1. Thus, particular care needs to be taken with cleanliness and orientation of cells and with settings of scan rate, time constant, and bandwidth. It is also important, especially when recording far-UV spectra, that the lamp is not old and that the mirrors are not clouded from radiation and traces of ozone. Because the spectrometer is a single-beam instrument, it is essential always to watch carefully for evidence of instrumental drift during measurements of sample and baseline.

BOSTON UNIVERSITY LIBRARY

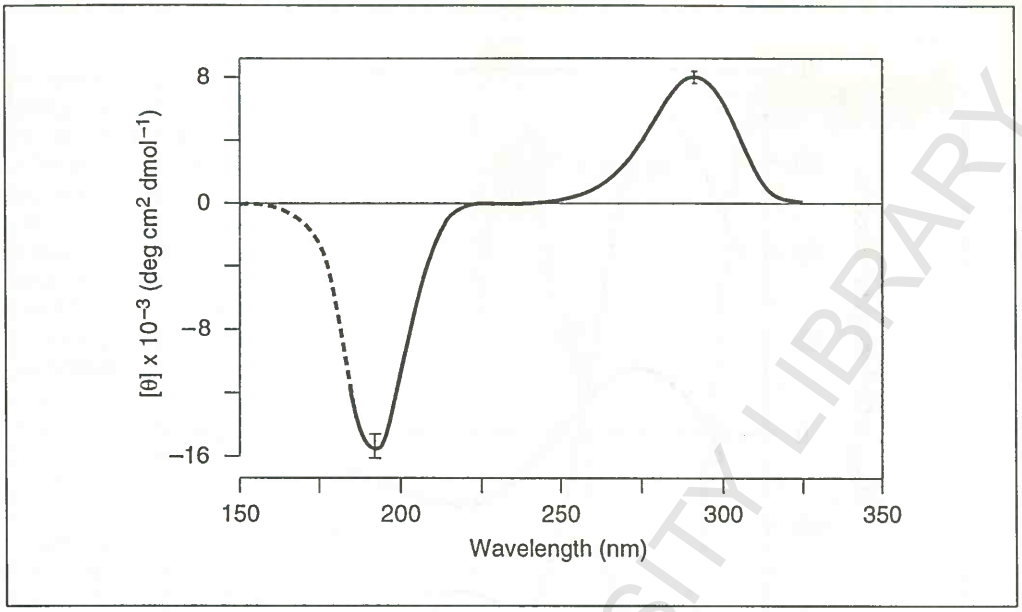

Figure 7.6.7 CD spectrum of D-(+)-10-camphorsulfonic acid (CSA) in water. The vertical bars represent variations of ±1.5% and ± 5%. The broken line represents the extrapolation of a gaussian band. Commercial CSA was twice recrystallized. (From Chen and Yang, 1977.)

Calibration of the Spectrometer

Depending on the make of the spectrometer, wavelength calibration may require the use of a mercury lamp and the services of an engineer, or the use of a holmium oxide solution with a simple computer-operated adjustment. It is unlikely to vary significantly during the lifetime of a xenon lamp. Calibration of ellipticity, on the other hand, must be carried out regularly—at least monthly, if the machine is in regular use—using a purified compound of known absorbance and ellipticity. D-(+)-10-camphorsulfonic acid (CSA) is the substance of choice (Fig. 7.6.7), but care must be taken to purify it from optically active impurities. Crystallization from ethyl acetate is recommended. CSA is hygroscopic; hence, although a stable monohydrate can be prepared (Yang et al., 1986), the concentration of the aqueous solution (~1 mg/ml) should be determined from $A_{285}^{1\ mg/ml} = 0.149$ using a high-quality spectrophotometer. Calibration of the spectrometer is carried out according to the maker's instructions, using $\theta = 33.5$ mdeg at 290.5 nm for a solution of 1.00 mg/ml anhydrous CSA in a 1-mm path-length cell. CSA exhibits a second peak at 192.5 nm where $\theta \approx -67.0$ mdeg for the same solution. If the value of the ratio of ellipticity at the two wavelengths falls below 2.0, this indicates a loss of performance of the spectrometer. Epiandrosterone, at 304 nm, and D-(−)-pantoyllactone, at 219 nm, have also been used for calibration (Schmid, 1989). The peaks of the spectra scanned for calibration are sufficiently sharp to provide a check on the wavelength calibration.

Cells

Choice of cells

Quartz windows can exhibit dichroism, which is due to strain either remaining after the annealing process during manufacture or induced by distortion caused by heating or pressure. It is important for measurement of CD that the optical faces of the quartz QS cuvettes have low strain and exhibit low dichroism. In the near-UV region—where path lengths ≥5 mm are required—rectangular cells, in their standard, semimicro, or micro forms, are normally used. These are not only more economical with regard to protein than the cylindrical type, but allow mixing to be carried out in the cell. Testing a number of

ACU IASI PERPUSTAKAAN UNIVERSITY LIBRARY

rectangular cells in the CD spectrometer usually yields one or two with low dichroism; it is also possible to purchase cells with certificates of low dichroism. Careful observation of the height of the light beam at the cell allows the minimum volume of solution to be used—usually <1 ml in a 10 × 10–mm cell. Because standard quartz (Suprasil) cells are constructed from two different types of glass, differential expansion of the faces with temperature leads to a significant change in cell dichroism. At least for temperature-dependence experiments, it is recommended to use cells with all four faces made from fused quartz. Semimicro cuvettes with 1-cm path length are available; these require ~300 µl of solution.

For far-UV CD spectra, short-path-length cells—from 1 mm down to 0.01 mm—are necessary because of the higher absorbance and ellipticity in this region. Demountable cells, cylindrical or rectangular, of this size are easily cleaned, but require practice to fill without allowing evaporation and may be subject to solvent loss over long periods of time. Such leakage can be minimized by the use of Parafilm on the edges of the cells. Quartz-jacketed cylindrical cells with two filling holes, available from Hellma (see *SUPPLIERS APPENDIX*), provide the best economy of protein, temperature control, and reproducibility. The path length of cells should be checked by absorbance measurements. A solution of 300 mg/liter of potassium dichromate in 0.05 M KOH gives an A_{280} of 0.705 in a 1-mm cell.

C H I M I E

Preparation and handling of cells

Cells must be reproducibly free from external and internal contamination. Not only will contamination make a contribution to the measured ellipticity, but dirty surfaces cause bubbles to be trapped in short-path-length cells, leading to additional artifacts. Cleaning should always be repeated if there are any signs of "tailing." The short-path-length cells, being inaccessible to mechanical cleaning, have to rely on effective soaking and rinsing. Cuvettes must be thoroughly and reproducibly cleaned by soaking in a proprietary cuvette cleaning fluid such as Hellmanex II (Hellma), an alkaline liquid concentrate, or RBS-35 Detergent Concentrate (Pierce), following the makers' instructions. The makers of Hellma cuvettes caution against the use of ultrasonics as a means of boosting cleaning efficiency. 50% nitric acid is also effective, but requires care and a fume hood. Detergents frequently contain fluorescent material and, if used, should be removed from cuvettes with acid (2M HCl) followed by water. After the final rinse with copious amounts of high-quality distilled water, the cells are best dried using suction through a Pasteur pipet protected with a small length of fine plastic tubing. This is safer than using acetone or alcohol, which can leach out fats from fingers and deposit them on the cuvette. The faces of cuvettes must not be touched after cleaning. Filling, emptying, and rinsing between measurements of spectra must be done using pipets, to avoid spillage onto the outer faces. A Pasteur pipet protected with fine plastic tubing is satisfactory. The baseline scans, with buffer in the cell, must be examined as a constant check on the reproducibility of the state of the cell.

Buffer Solutions

Buffers must be optically inactive and have the lowest possible absorbance in the desired spectral region. Most buffers in common use are essentially transparent above 230 nm, which is fine for near-UV CD. For far-UV CD using a 1-mm pathlength cell, 0.01 M sodium phosphate buffer (*APPENDIX 2E*), is generally acceptable as a solvent for most purposes, and will still have a reasonably low absorbance between 190 and 185 nm—the lower the pH, the more transparent the buffer. NaCl should be avoided in the far-UV range. Solutions of 0.01 M $NaClO_4$, NaF, KF, or boric acid are all transparent down to the present range of commercial instruments, but are not frequently used except for vacuum UV measurements. The absorbance of 20 mM Tris·Cl is acceptable down to 190 nm. Buffers

in common use, together with their absorbances, are listed by Schmid (1989). Urea or guanidine·HCl solutions (high-purity spectroscopic grades must be used) absorb very strongly below 220 nm; even in the shortest-path-length cells, they are opaque below 205 nm.

Bubbles form readily in the cell and can distort the CD. It is important therefore to degas the buffer before filling the cell by applying vacuum in a suitable container, such as a Buchner funnel, and swirling.

Clarification of Solutions

Protein solutions must be freed from the turbidity that results from dust and aggregated protein. Turbidity will reduce the sensitivity of the measurements and can also cause artifacts in both the intensity and the shape of the CD spectrum, particularly in the far-UV (Swords and Wallace, 1993). Many proteins can be filtered, usually as a stock solution, using a 0.22-μm filter (ideally of the grade special for proteins) fitted to a syringe. If the protein is adsorbed by filters, the solution may be clarified by centrifugation; 10 min in a refrigerated microcentrifuge is convenient and usually effective. Note that the protein concentration must be measured *after* clarification. Buffer solutions are filtered on a larger scale, using a 0.22-μm filter.

It is essential to monitor clarification if artifacts are to be avoided. Indicators of adequate clarification that should be adopted for spectroscopic characterization are available from the procedures basic to the measurement of CD. First, determination of protein concentration requires an absorbance spectrum to be recorded on a good quality spectrophotometer from 240 to 350 nm. Aromatic amino acid residues do not absorb above 320 nm, so the spectrum between 320 and 350 nm should be only marginally above baseline. The presence of turbidity will result in a sloping spectrum in this region. From the absorbance spectrum obtained in this manner, the ratio A_{max}/A_{min} is calculated, where A_{min} is the absorbance in the trough in the region of 240 to 250 nm. This ratio will be specific for a given protein and should be measured for a sample that has been carefully and reproducibly clarified. Because of the strong wavelength dependence of scattering, the ratio is a very sensitive indicator, decreasing sharply with turbidity, and can be used as a semi-quantitative check on the clarity of subsequent solutions of the protein.

For membrane proteins in membrane fragments, the intrinsic turbidity offers special problems, which should be addressed by instrumental modifications. A useful discussion of the problems involved can be found in Swords and Wallace (1993).

Nitrogen Supply

Oxygen-free nitrogen can be obtained from cylinders, but must be filtered to remove oil contaminants. Liquid nitrogen provides a better supply of gas, but impurities accumulate at the bottom of the Dewar flask, so that the bottom 10% should not be used (Johnson, 1990). Accessories to monitor and purify nitrogen gas are available commercially.

BASIC PROTOCOL

RECORDING A CD SPECTRUM

Simple comparison of the CD spectra of a protein in buffer and in 6 M guanidine·HCl will immediately tell whether the protein has achieved some degree of folding. However, for the purpose of determining whether a sample of recombinant protein is correctly folded, the CD spectrum can provide a complex fingerprint that can be compared with that of a specimen that has been well authenticated as being native and functional. This constitutes an empirical, but powerful means of characterization, with the near-UV spectrum usually being more sensitive than its far-UV counterpart. There are, for example,

PCU IASI - CENTRAL UNIVERSITY LIBRARY

many well-documented cases where partially unfolded proteins exhibit a major change in the aromatic region accompanied by relatively minor changes in the far-UV CD (e.g., see Fig. 7.6.5)—the classical molten globule being an important example (Ptitsyn, 1992). For these reasons, it is important to obtain good quality near-UV spectra, paying particular attention to details of any fine structure that may exist.

Materials

CD spectrometer (calibrated), nitrogen supply, cells, buffer solution, and clarified protein solution for analysis (see Strategic Planning)

1. Set up the CD spectrometer by purging the optics with nitrogen in the manner designated in the manual, turning on the cooling water, and finally switching on the lamp. Allow to warm up for the recommended period of time, usually 30 min. Regulate the thermostat system to the desired temperature.

   Particular attention must be paid to the procedure in the manual for switching on and warming up the spectrometer. Failure to purge with nitrogen can lead to rapid and irreversible degradation of the optics.

   CD spectra, particularly in the near-UV (see Support Protocol 1) reflect the dynamics of the chromophore and may therefore show dependence on temperature. It is important to stabilize the temperature reproducibly. Accurate temperature control is particularly important in denaturation experiments to determine protein stability.

2. Enter the settings required for the scan.

   Careful optimization of the settings is necessary to achieve the lowest-noise spectra consistent with total time spent in data collection. To check that optimal settings have been achieved, a small sample region of the spectrum can be scanned.

   Table 7.6.1 is a rough guide for scanning a protein solution with A_{280} = ~1. Settings will differ according to the sample and the spectrometer.

   a. Set wavelength.

   For near-UV spectra, the scan should be from 240 to 340 nm, in order to cover contributions from tryptophan, tyrosine and phenylalanine. Although little or no dichroism will be found above 320 nm, it is advisable to extend the scan to 340 nm to ensure that both sample and baseline scans coincide at zero ellipticity in the region where there is no dichroism. This provides assurance that the cell and buffer are optically identical for the two scans (see Fig. 7.6.8).

   For far-UV spectra, it is usual to scan between 250 nm—where the ellipticities of the baseline and sample effectively coincide, given the scale of ellipticity being used—and

Table 7.6.1 Rough Guide for Scanning a Protein Solution with A_{280} = ~1

	Far-UV	Near-UV
Cell path length (cm)	0.01–0.05	1
Wavelength (nm)	250–180	340–250
Bandwidth (nm)	0.5–1	0.2–0.5
Averaging time (sec)	1	1–5
or		
Time constant (sec)	2–8	8
Repeat scans	1–2	2–4
Step size (nm)	0.5–1	0.2–0.5
Resulting time per scan (min)	70–140	3–37

BCU LRC CENTRAL UNIVERSITY LIBRARY

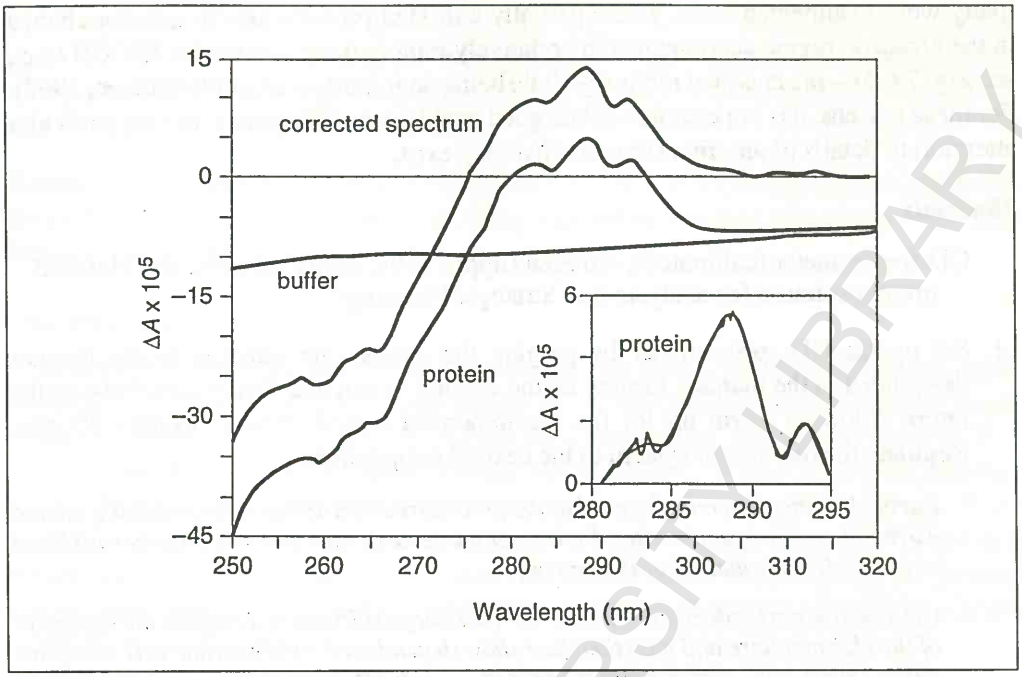

Figure 7.6.8 Obtaining the corrected near-UV CD spectrum for hen egg white lysozyme. The protein and baseline spectra were collected using a 10-mm cylindrical cell and 0.5 mg/ml protein in 0.067 M phosphate buffer, pH 6.0. Instrument settings were 1-nm bandwidth, 0.2-nm step size, scan speed 2 nm/min, time constant 8 sec (scan speed × time constant = 0.27 nm). Protein solution and buffer were scanned once each. The spectra were smoothed, a sample of the fit being shown in the inset. Reproducibility of the instrument and of the state of the cell are demonstrated by the coincidence of the ellipticity above 300 nm. The corrected spectrum was obtained by subtraction, using the instrument software.

as near to 180 nm as the absorbance of the solution will permit. The lower limit may be dictated by the absorbance of the sample or buffer, as indicated by the value of the dynode voltage (see step 2e).

b. Set bandwidth.

The radiation passing through the sample comprises a spread of intensities distributed around the selected wavelength (Fig. 7.6.9). The bandwidth (in nm) of this spread is determined by the spectrometer slit width (in mm) and is the width of the distribution at half the maximum intensity. For proteins exhibiting broad CD bands, including most far-UV and many near-UV spectra, a wide setting (2 nm) will have little effect on the shape or intensity of the spectrum. For bands with fine structure, including some near-UV spectra, a more narrow bandwidth is necessary to avoid smoothing of narrow peaks and reduction in peak intensity. The largest bandwidth that causes no distortion of the spectrum should be used, in order to maximize the signal-to-noise ratio. To optimize the slit-width setting, preliminary scans should be made at a series of slit widths over a critical region of the spectrum.

c. Set averaging time or time constant, scan speed, and number of accumulations.

The time constant determines the time that the spectrometer takes to respond to changes in signal. The reason for setting it is to obtain the best signal-to-noise ratio consistent with the time spent scanning. When the signal is strong, the time constant need only be small. The appropriate time constant for a signal of 500 mdeg is 0.25, that for a signal of 100 mdeg is 0.25 to 0.5, that for a signal of 10 mdeg is 0.5 to 0.8, and that for a signal of 2 mdeg is 2 to 30.

The faster the scan speed (with economies in operator time), the smaller the time constant must be in order to allow the instrument to respond fully to changes in ellipticity. However, less time is then available for collecting data at a given wave-

PCU IASLIC LIBRARY UNIVERSITY LIBRARY

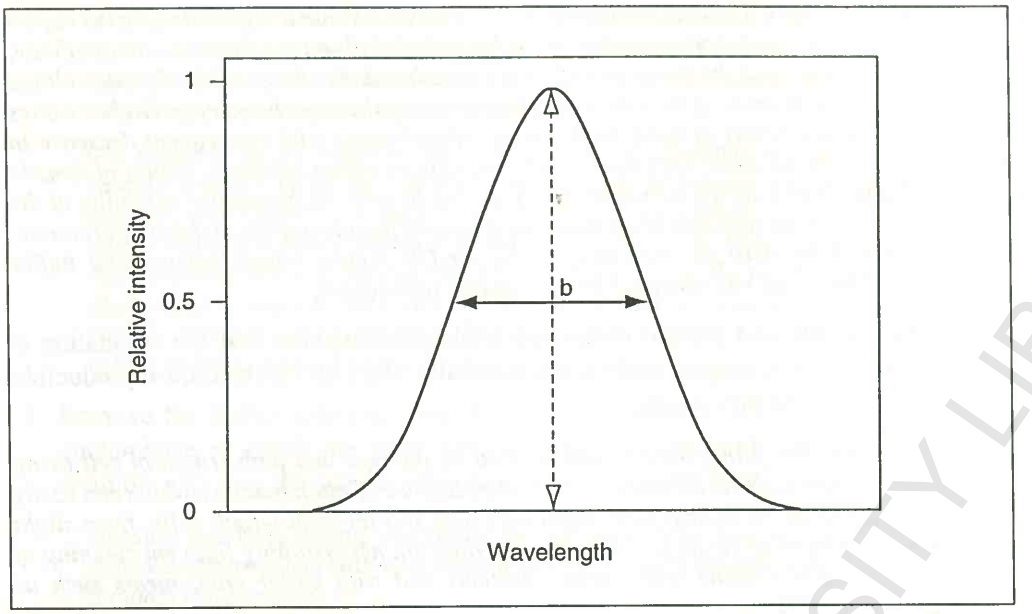

Figure 7.6.9 The distribution of intensity of radiation passing through the sample cell. Radiation emerging from a monochromator set at a wavelength corresponding to the peak maximum will contain components at other wavelengths, with intensities described by the curve. The bandwidth (b) is the width of the distribution curve at half the peak height. Its magnitude will depend on the exit slit width. The setting of the slit width is usually programmed to change during scanning, so as to give a constant bandwidth and hence constant spectral resolution.

length, so the noise is greater. Scan speed and time constant are thus interdependent, and their product should not exceed 0.33 nm. For example, a time constant of 2 sec is recommended for a scan speed of 10 nm/min. Some instruments, in the wavelength scan mode, specify an averaging time, which takes the place of a time constant setting; this is simply the time spent collecting data at each wavelength.

The signal-to-noise ratio can be enhanced either by increasing the time constant or averaging time or by accumulation of a number of scans. The latter technique is preferable to using long scan times because the effect of instrument drift will be to distort the spectrum from a single long scan, whereas the average of quicker, repeat scans will lead to a more uniformly shifted spectrum. The latter can then be corrected using the average of buffer baselines measured before and after the sample scans.

The problem of optimizing signal-to-noise ratio is greater in the case of samples possessing a low ellipticity. An all-β protein, for example, will demand more repeat scans than an all-helix protein at the same concentration.

There are realistic time limits to the degree of enhancement of signal-to-noise ratio, as the latter is proportional to the square root of both the time constant and the number of scans (see Yang et al., 1986).

d. Set step size.

The step size (in nm) between successive data-collection wavelengths, together with the scan speed, defines the number of data points collected per nm. Spectra with more fine structure require higher resolution. For far-UV spectra, which are smooth and relatively featureless, a step size of 0.5 nm is adequate. For some, near-UV spectra, but not all, a resolution of 0.2 or 0.1 nm is advisable. For a given scan speed, the greater resolution gained by using a small step size will result in more noise, so it is more economical of time to use as large a step size as possible.

e. Note dynode voltage.

Dynode voltage cannot be preset, but its value can be controlled within limits by adjusting the protein concentration and/or cell pathlength, so it is appropriate to

BOSTON COLLEGE UNIVERSITY LIBRARY

consider it here. The photomultiplier detector operates with a high voltage in the region of 1000 V across the anode and cathode. When light falls on the photosensitive cathode, current flows and the potential difference is reduced. Readings of the dynode voltage thus give a measure of the intensity of light passing through the sample. Higher values indicate low levels of light (high sample absorbance) with consequent decrease in signal-to noise-ratio; very high values indicate incorrect readings. Values of dynode voltage should always be noted during a scan in order to assess the reliability of the ellipticity measurements. Most instruments record this parameter as a matter of course. Special care must be exercised in the far-UV region, where sample and buffer absorbance can rise sharply with decreasing wavelength.

3. Fill the cuvette and place it in the cell holder, making sure that the orientation is reproducible both longitudinally and rotationally. Mark the cell to allow reproducible orientation in the light beam.

   Techniques for filling the cell will depend on the type and path length of cell being used. It is essential in all cases to avoid the presence of small bubbles, which can easily be trapped at the optical face, especially with shorter-path-length cells. Even slight contamination of the faces will make this difficult, necessitating frequent cleaning of the cell after contact with certain proteins and with buffer components such as guanidine·HCl.

   For rectangular-type cuvettes, the volumes of solution required are approximately 2.5 ml (for 1-cm standard), 1 ml (for 1-cm semimicro), 300 µl (for 0.1-cm standard) and 25 µl (for 0.01-cm demountable). Volumes for cylindrical-type cells are somewhat larger, depending on the type.

   Choice of path length will depend on the available concentration of the protein solution. If the absorbance of the buffer is unavoidably high, it will be advantageous to use a shorter path length and a higher protein concentration. As a general guide, for a protein solution with $A_{280} = 1$, path lengths of 0.01 to 0.05 cm for the far-UV and 1 cm for the near-UV make suitable starting points.

   Rectangular cells have the advantages over cylindrical cells of having smaller sample volume and better temperature control with available cell holders. Good temperature control with cylindrical cells requires the use of jacketed cells. For shorter (<0.1-cm) path lengths, where rectangular cells are currently demountable, the rigid cylindrical cells have the advantage of avoiding leakage over prolonged periods of time.

4. Scan the baseline using the same cell and buffer as required for the sample, as well as the same instrument settings.

   Preliminary scans of the samples should be carried out to assess whether valid measurements can be made in the required wavelength region or whether it is necessary to adjust the sample concentration or the cell path length. The wavelength is lowered, noting the point at which the photomultiplier voltage exceeds the value corresponding to low light intensity—i.e., to an absorbance of 1 to 1.5. Experience will indicate the value above which noise becomes excessive. It is helpful, however, to get a more objective assessment by noting the voltage at a series of low wavelengths and then measuring the actual absorbance of the same cell using a quality spectrophotometer.

   When recording spectra for a series of samples, buffer scans should be recorded at least twice (at the beginning and end of the series) in order to check for instrument drift, especially when the lamp is beginning to age.

   A convenient procedure when scanning a number of samples is to scan air blanks—i.e., with no cell in the light path—at appropriate intervals between samples. This saves additional cell filling, washing, and drying operations. A single scan (S) of the cell containing buffer accompanied by a scan of the air blank then allows correction of all the protein spectra for solvent baseline, according to the expression:

$$\{S_{protein} - S_{air}\} - \{S_{solvent} - S_{air}\} = \{S_{protein} - S_{solvent}\}.$$

ACU IASI CENTRAL UNIVERSITY LIBRARY

Ideally, the buffer scan should be run before the protein sample, as this requires less rigorous washing of the cell between the two runs and hence better assurance that the optical surfaces will be identical for both. This however requires prior knowledge of the settings appropriate to the particular sample.

It is tempting to use water in place of buffer on the grounds that both are optically inactive and, for water, the cell needs only to be dried between scans. This is unwise, however, particularly for buffers with higher concentrations of solutes and hence higher refractive index. Because in most instruments the light beam is not parallel when passing through the cell, the area and position of the photomultiplier surface illuminated is likely to vary with the refractive index of the solution, which may give slightly different voltage readings. This may result in significant errors when the signal is low, as in the case of near-UV CD.

5. Remove the buffer solution, rinse the cell with water and dry, taking care not to contaminate or touch the outer surfaces, refill the cell with the clarified sample solution, and scan the sample using the same instrument settings as for the buffer.

Because washing, drying, and filling the cell takes time, it is advisable to work with two cells alternately (both with solvent blanks properly determined) when processing a number of samples.

The protein concentration should be as high as possible, consistent with the absorbance in the cell not exceeding 1.0 to 1.5, and must be accurately determined by UV absorbance. Values of mean residue ellipticity and secondary structure content results are both affected by uncertainties in protein concentration.

In spectral regions such as the far-UV, where absorbance varies markedly with wavelength, the spectrum may have to be recorded in overlapping regions, at appropriate concentrations or cell path lengths.

A good test for the absence of artifacts that can arise at higher absorbances is to run a blank with a non–optically active molecule, such as 3-methylindole or a DL–amino acid, at the same absorbance as the test samples. The scan should be indistinguishable from the solvent blank.

6. Subtract the baseline from the sample scan.

The ellipticity of the spectrum corrected for baseline should be close to zero above 320 nm for near-UV and above 250 nm for far-UV spectra (see Fig. 7.6.6 and Fig. 7.6.8). Significant differences usually indicate problems with reproducibility of the buffer or cell and must be remedied for quantitative characterization of samples.

Depending on the level of noise, spectra and baselines can be smoothed using the instrument software. Smoothed and raw spectra should be compared directly by overlaying on the computer screen in order to avoid the distortion that can arise from overenthusiastic smoothing.

INTERPRETATION OF NEAR-UV CD SPECTRA

SUPPORT PROTOCOL 1

CD spectra reflect, in different ways, the detailed conformational environment of individual chromophores in a protein. To the extent that the transitions for the different types of chromophore differ in wavelength, the spectra can be assigned to particular types of residue and, in the case of the peptide bond, to different conformations or types of secondary structure. A brief account of the interpretation of near- and far-UV spectra is therefore pertinent.

Near-UV CD spectra provide evidence of tertiary structure and dynamics. The CD of chromophores absorbing in the near-UV region is associated with the π–π^* electronic transitions. Relevant transitions for the aromatic amino acids are listed in Table 7.6.2. Tryptophan, tyrosine and phenylalanine possess partial or complete planes of symmetry, so that their dichroism arises almost entirely as a result of interaction of the transitions

BOURNEMOUTH UNIVERSITY LIBRARY

Table 7.6.2 Transitions of Aromatic Amino Acid Side Chains[a]

Amino acid	Electronic transitions	Peak wavelengths (nm)	$\Delta\varepsilon_{max}$ (M^{-1} cm^{-1})[b]
Phenylalanine	^1L_b	262, 268	±0.3
Tyrosine	^1L_a	far UV	
	^1L_b	277, 283	±2.0
		268, 289 (shoulders)	
Tryptophan	^1L_a	266	±3
		~295-303[c]	
	^1L_b	285, 292, 305[d]	±2.5

[a]Data from Strickland (1974).

[c]May be seen as a low intensity shoulder or peak from a Trp in a nonpolar environment.

[d]Unusual; observed with, e.g., lysozyme.

with neighboring groups. Dipole-dipole interactions, especially with other aromatic rings and with the π–π^* transition of peptide bonds, make a major contribution to CD and are relatively long-range, being effective up to ~1 nm. Electric-magnetic coupling also has an influence on the CD, but is very short-range and makes a relatively minor contribution. In contrast to the aromatic residues, the disulfide bond has no plane of symmetry and is, as a result, intrinsically optically active, particularly around a dihedral angle of 90°.

These interactions of the environment with transitions of aromatic residues result in dichroic bands that are either positive or negative so that statistically the more such residues there are, the less intense the resultant ellipticity is likely to be. An intense signal frequently indicates the presence of one particularly strong interaction that overrides other minor contributions—such as the strong band at 292 nm seen in aspartic proteinases (Fig. 7.6.10), and the contributions of the one tryptophan and four tyrosine residues to the CD spectrum of interleukin 1β (Fig. 7.6.4).

The ^1L_b transition for **phenylalanine** resembles that for benzene (Strickland, 1974), but the CD signal is of relatively low intensity, so that it is seen only as shoulders or minor peaks to the low-wavelength side of tyrosine and tryptophan bands (Fig. 7.6.10). As a result of the high degree of symmetry in the side chain, the presence of these peaks is an indication of a highly specific and well-packed environment and can act as a marker for native folding.

The ^1L_b transition for **tyrosine** (the ^1L_a transition lies in the far-UV) is more intense than that for phenylalanine and overlaps the two transitions for tryptophan (Strickland, 1974). It can result in a significant contribution to the near-UV CD (e.g., see Fig. 7.6.4 and Fig. 7.6.5) but is not always easy to assign in the presence of tryptophan. Hydrogen bonds to peptide carbonyl, carboxylate (C=O), and imidazole (–N=) groups contribute significantly to its CD, as do the presence of neighboring polar groups. The direction of the optical transition is in the plane of the ring and perpendicular to the axis of symmetry (Fig. 7.6.11) so that interaction with neighboring groups makes the CD very sensitive to rotation of the residue and to the dynamics of the protein in general.

The two transitions for **tryptophan** exhibit distinct features, which lead to quite different CD bands. The ^1L_a transition is broad, relatively featureless, and intense (Fig. 7.6.2). The ^1L_b transition is weaker but exhibits fine structure (Fig. 7.6.2) similar to that of tyrosine. It can be masked by or superimposed on the ^1L_a transition. Interactions similar to those listed for tyrosine strongly affect the peak wavelengths and intensities. The presence of

PCU IASI/CENTRAL UNIVERSITY LIBRARY

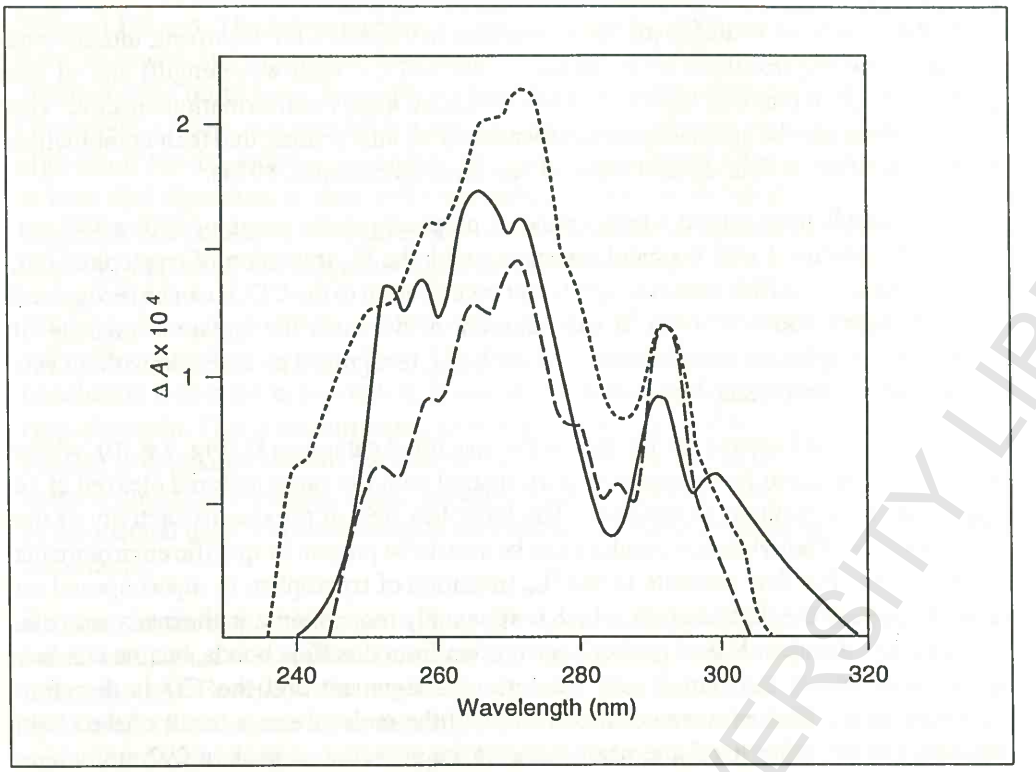

Figure 7.6.10 The near-UV CD spectra of cathepsin D. The solid line represents the porcine enzyme and the dashed line represents the bovine enzyme, each cleaved into two chains which remain associated; the dotted line represents the bovine intact enzyme. The spectra were recorded using 10-mm- and 20-mm-path-length cells, with enzyme concentrations of 0.8 to 0.4 g/liter. The far-UV CD and fluorescence spectra of the cleaved and intact enzymes are not significantly different (Pain et al., 1985).

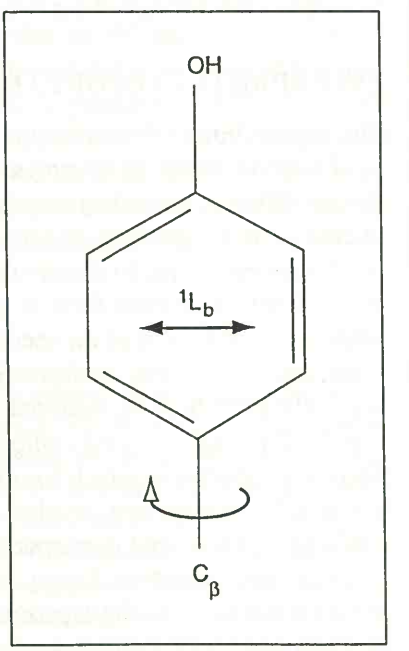

Figure 7.6.11 The near-UV absorbance transition dipole moment of the tyrosine side chain. The ^1L_b transition is seen to be perpendicular to the axis of rotation of the phenolic ring. Interactions of the transition with the environment, expressed as an enhanced CD band, will be sensitive to rotation of the side chain around this axis.

BCU IASI / GENERAL UNIVERSITY LIBRARY

bands above 285 nm is diagnostic for tryptophan in a specific environment; interactions that cause the ^1L_b transition to be shifted to the red (or high-wavelength) end of the spectrum result in bands as high as 310 nm which are highly conformation-specific. The two transitions may be affected quite independently by interactions, and their combination can thereby result in four distinct types of spectrum (Strickland, 1974).

Disulfide bonds may exhibit a broad band of ellipticity in the range of 240 to 350 nm. This can be confused with the band associated with the ^1L_a transition of tryptophan but, in cases where a disulfide makes a significant contribution to the CD, it can be recognized by its ellipticity above 320 nm. It can augment or diminish the apparent intensity of tryptophan and tyrosine contributions without being recognized as such and without fine structure necessarily being lost.

Some of the above features can be seen in the spectra of cathepsin D (Fig. 7.6.10), where the intact single-chain bovine enzyme is compared with the same material cleaved at an exposed loop but without dissociation. The latter has 50% of the specific activity of the intact molecule. Phenylalanine residues can be seen to be present in specific environments in both forms. The fine structure of the ^1L_b transition of tryptophan is superimposed on the broad peak of the ^1L_a transition, which is apparently more intense in the intact enzyme. Alternatively, there could be a greater contribution from disulfide bonds, but the absence of ellipticity above 320 nm favors the former assignment and the CD is therefore consistent with a limited increase in dynamics of the molecule as a result of the chain cleavage. On the other hand, the persistence of the pronounced peak at 292 nm, where the contribution of the ^1L_a transition is low, indicates that the interaction responsible for this band is unchanged by cleavage. Coupled with the fact that both far UV CD and fluorescence spectra are identical for the two forms, it is concluded that the overall conformations are structurally similar, differing mainly in their packing and dynamics. Comparison with the spectrum for porcine cathepsin D demonstrates the conformational similarity expected from sequence homology, as evidenced in particular by the persistence of the interaction responsible for the appearance of the ^1L_b band with its intense peak at 292 nm. Differences in the relative intensities of the minor bands provide a sensitive fingerprint for distinguishing two proteins with strong sequence homology.

SUPPORT PROTOCOL 2

INTERPRETATION OF FAR-UV CD SPECTRA

The peptide bond exhibits intense circular dichroism bands when it is located in regular, rigid conformations of the protein backbone chain. It is not surprising therefore to find that the different secondary structures—helix, pleated sheets, and β-turns—each give rise to characteristic spectra (see Fig. 7.6.6). In principle it should be possible, knowing the spectra for each type, to deconvolute the far-UV spectrum for a particular protein to give the proportions of each form of secondary structure in the folded conformation. Early work involved the use of the spectra of polyamino acids as models for α-helix, β-pleated sheet, and random coil conformations. These turned out to be inadequate models for the relatively short helices, distorted intramolecular β-sheets, and aperiodic—but far from statistically random—coil conformations found in the average globular protein. The alternative approach, which forms the basis of most estimations and avoids the need to define reference spectra, involves the use of a database of CD spectra (see Yang et al., 1986, for listings) and corresponding secondary structure contents derived from X ray structure determination. Linear combination of these spectra is carried out to give a resultant that best fits the experimental spectrum for the test protein. The two algorithms that have been most commonly used are those of Provencher and Glöckner (1981) and of Johnson and coworkers (Johnson, 1990). The former used a bank of 16 proteins with spectra measured between 240 and 190 nm. Using a different statistical approach, Johnson and coworkers provided an algorithm that uses 15 reference spectra measured between

PCU IASI CENTRAL UNIVERSITY LIBRARY

260 and 178 nm. The latter, together with a more recent development of the method, has been reviewed and compared with the Provencher and Glöckner algorithm (Johnson, 1990) and the underlying assumptions have been critically discussed (Manning, 1989). Greenfield (1996) has provided a useful and comprehensive review of all the main algorithms for determining secondary structure. Commercial CD spectrometers include at least one algorithm in their software, although it is worth installing the two original programs independently so that results from each can be compared. Copies are available from the authors of the programs and from Dr. Greenfield.

Attempts have been made to assess the success of different algorithms in deriving secondary structure content from CD spectra (see Yang et al., 1986). The general conclusion is that the helix content is usually estimated well, regardless of the structural type of protein. This is not surprising given the high intensity of the helix spectrum. β-sheet content is estimated well in the case of "all-β" proteins, but in mixed α and β proteins there is greater uncertainty. Some proteins, such as subtilisin, perform badly regardless of the method used. The estimation of the content of β-turns is similarly subject to greater uncertainty.

Reasons for these problems are various. First, estimations are dependent on the correct values of mean residue ellipticity, which depend critically on determination of the protein concentration. Second, it is reasonably claimed that the further down in wavelength spectra are recorded, the better the estimate of structure (Johnson, 1990). It is not possible with all proteins to obtain reliable spectra below 185 nm with commercial instruments—inability to use the appropriate buffer and intrinsic scattering from larger proteins are limiting factors, although loss of optimal instrument performance as a result of insufficient maintenance is frequently the main cause of the problem. Third, there is uncertainty about the degree of contribution of aromatic and cystine residues in the far-UV (see Chaffotte et al., 1992, for references and discussion). Aromatic residues are probably significant when the residues are located in clusters, and cystine residues when the dihedral angle is of the order of 90°. Fourth, criteria vary for defining the secondary structure content from the three-dimensional coordinates of structures.

In conclusion, the analysis of spectra properly recorded to 185 nm, or lower where possible, can give useful estimates of secondary structure content, but the content of turns and of β-structure should be interpreted with caution. In principle, Fourier transform infrared spectroscopy should provide better estimates of the latter. Secondly, when using the results of far-UV CD determination to characterize reproducibility of folding for different samples, it is important first to compare the spectra visually and to look for possible trends or factors that may explain small differences, rather than to rely solely on comparison of derived secondary structure contents.

COMMENTARY

Background Information

CD spectra in the near-UV are of much lower intensity than those in the far UV, in part as a result of the much lower concentration of the chromophore, but can be measured reproducibly with due care. They are very important in characterizing the degree and correctness of folding of recombinant proteins and their mutants.

Near-UV CD depends critically on the atomic environment and closeness of packing of the aromatic residues, including their accessibility to solvent. Although the structural information is limited strictly to the immediate neighborhood of the relatively few aromatic residues, the generally cooperative nature of protein conformation means that changes in aromatic CD frequently reflect more widespread changes in conformation and dynamics. A slight loosening of a protein structure may not result in any change in solvent accessibility to aromatic residues and therefore will not change the maximum fluorescence wavelength of tryptophan. Such a change may also be

RESTRICTED / CENTRAL UNIVERSITY LIBRARY

outside the resolution of X-ray crystallographic analysis. The resulting change in dynamics of the residue, and hence in the asymmetry and detailed interactions with the immediate protein environment, will however affect the near-UV CD spectrum, usually quite markedly (see Fig. 7.6.5 and Fig. 7.6.12).

Changes in the far-UV CD spectrum resulting from slight changes in conformation or partial unfolding will not in general be so marked as in the near-UV region, so that the value of the former for the detailed characterization of correct folding is not as great as that of the latter. It is, however, applicable to proteins with little or no aromatic content. The fact that the far-UV CD arises from the transitions of a single type of chromophore—i.e., the peptide bond—and that the backbone conforma-

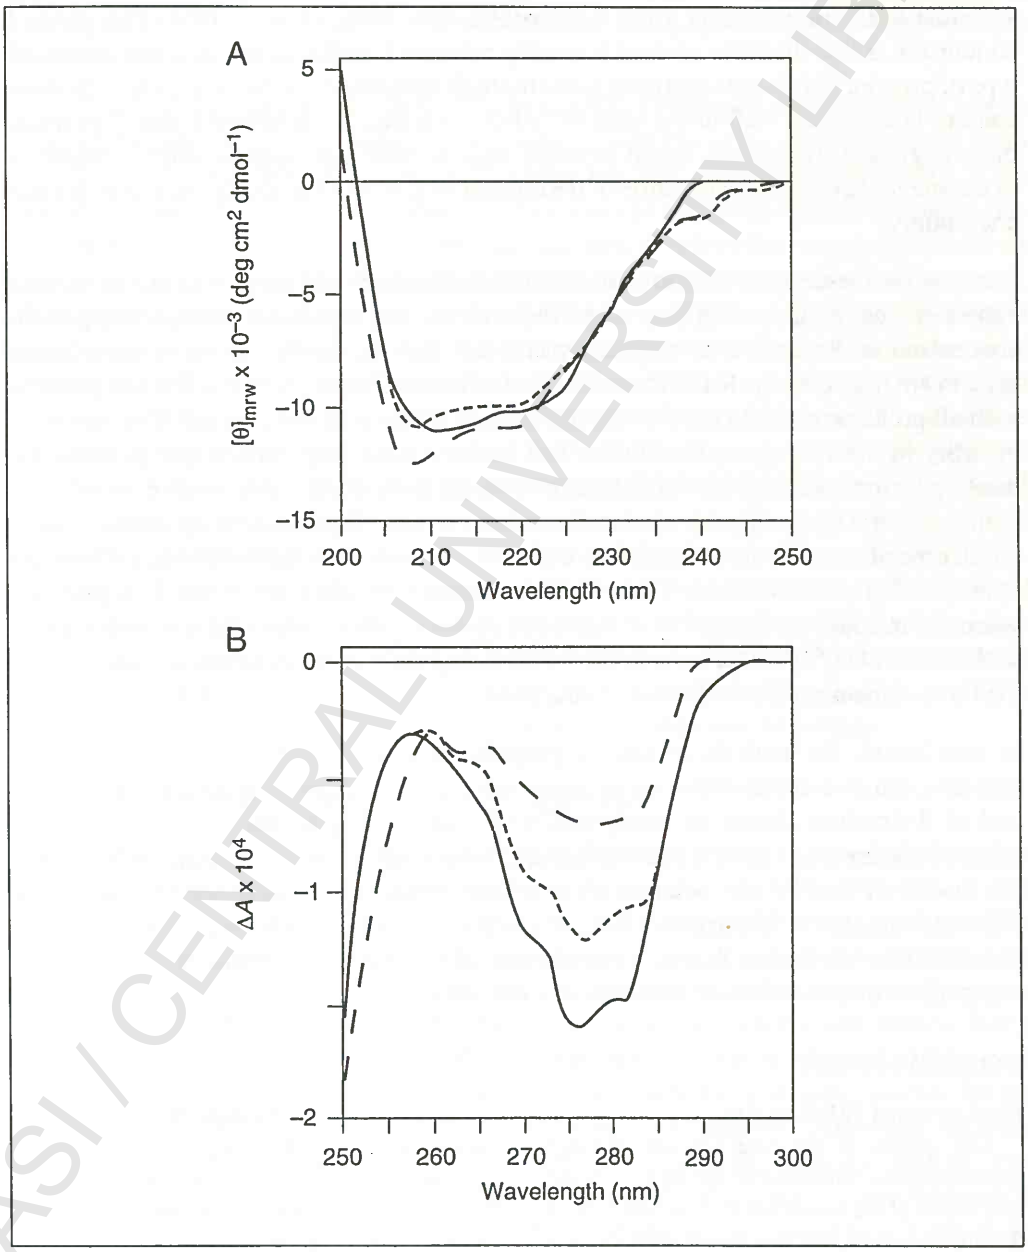

Figure 7.6.12 Effect of mutations detected by CD. The far-UV CD spectra (**A**) show that the secondary structure of β-lactamase PC1 (solid line) from *Staphylococcus aureus* is essentially unaffected by point mutations P2 (Thr 140→Ile; dashed line) and P54 (Asp 146→Asn; dotted line). The crystallographic structure of P54 (Herzberg et al., 1991) confirms that, apart from a loop region, the main body of the molecule that contains the thirteen tyrosine residues is very closely similar to that in the wild-type enzyme. The intensity of the tyrosine ellipticity (**B**) is, however, markedly decreased in each of the mutants, the lower thermodynamic stabilities of which support the interpretation of increased dynamics (Craig et al., 1985).

ACU IASI / CENTRAL UNIVERSITY LIBRARY

tion constitutes the main influence on its dichroism, means that this region is good for identifying family relationships between proteins.

CD in general is a useful tool for examining proteins made by site-directed mutagenesis for structure-function studies, where it is important to know to what extent the conformation has been affected by the mutation. The far-UV spectrum will tell whether the mutant has folded with a backbone conformation similar to that of the wild-type protein, whereas the near-UV spectrum will detect many minor changes in conformation or dynamics (Fig. 7.6.12).

CD complements fluorescence as a technique for characterizing the folded conformation in solution and for providing, in a single spectrum, a highly specific fingerprint for the native state. It requires only modest amounts of protein and measurements are relatively quick to make. Like fluorescence, its use as a comparative method requires a control spectrum from a carefully characterized sample of the natural or recombinant protein, recorded under defined and optimal conditions, using a spectrometer in good condition.

Critical Parameters

Many of the critical experimental parameters for CD spectrometry are the same as those for measuring fluorescence. Spectra will only be as reliable as the protein solution, the machine, and the operator. Cells must be scrupulously clean, solutions must be well-clarified, and buffers must have a low absorbance. In addition, not only must the protein concentration be known precisely but, together with the path length, must be chosen to optimize the absorbance in the region of interest. This will sometimes require recording a spectrum in overlapping sections. Preliminary experiments to optimize the instrumental parameters are important. Lastly, it is essential that the spectrometer be well-maintained and up to specification. The useful life for a lamp is on the order of 800 to 1000 hr, but performance in the far-UV may start to fall off before this.

Troubleshooting

The problem most frequently met (though a casual scan of the literature shows that it is not so frequently recognized) is the loss of light intensity at low wavelengths. Under such conditions, many spectrometers will produce traces that are smooth, giving the appearance of being valid spectra, but which are in fact artifacts. The example of such an artifact shown in Figure 7.6.13 provides a cautionary tale. In this case, the glutamine absorbs light in the far-UV on account of its side-chain amide group. The increasing concentration of glutamine results in a progressively longer wavelength at which light is cut off, to which this particular spectrometer responded by returning to zero dichroism, giving the impression of a peak with a maximum at increasing wavelengths. To avoid such artifacts, it is essential to monitor the photomultiplier high voltage during a scan. Similar problems can arise from using too high a protein concentration or too long a light path, from too much absorbance by the buffer, from turbidity in the protein solution, from a dirty cell, or—below 200 nm—from absorption by oxygen that results from incomplete purging with nitrogen.

A further problem that is sometimes encountered is that the spectrum obtained after baseline subtraction does not return to zero above 320 nm (in near-UV CD) or 250 nm (in far-UV CD). If, above these wavelengths, the spectrum runs parallel to the zero base, a provisional spectrum may be derived by subtracting the difference in ellipticity, as a constant, from the whole spectrum. For quantitative assessment of a sample, however, the spectrum should be redetermined, paying attention to the correct buffer blank, cell reproducibility, and instrumental drift (see Strategic Planning).

Care must be taken to rectify all of the above mentioned problems if meaningful spectra are to be obtained for reliable characterization.

Anticipated Results

Several examples of near- and far-UV CD spectra are given in the figures included in this unit. With current instruments the final spectra exhibit low noise and—provided that the instrument and sample parameters have been optimized—should be true and reproducible within the limits of protein-in-buffer absorbance of <1. The most frequent source of nonreproducibility of intensity in spectra is the difficulty of determining the protein concentration, particularly of larger proteins that scatter more and of those with a greater tendency to aggregate.

What constitutes a significant difference between two spectra? When the differences are small, the answer depends on sample preparation and sample stability as well as accuracy of concentration determination, identification of and compensation for drift in the spectrometer, correct baseline correction, absence of bubbles

BOLAS/BETRAN UNIVERSITY LIBRARY

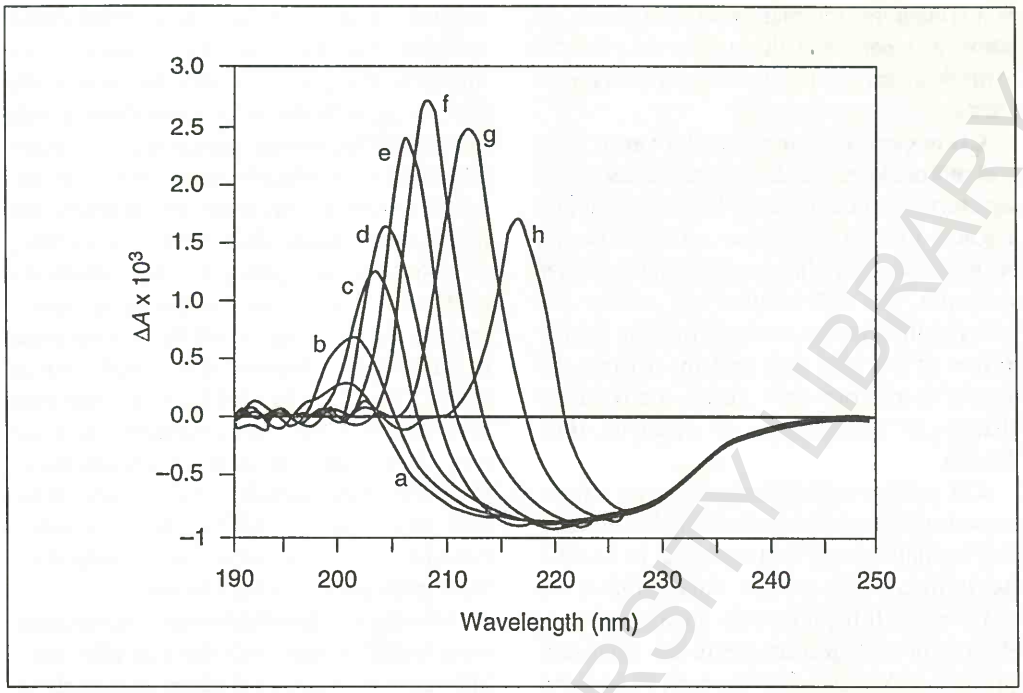

Figure 7.6.13 A convincing artifact. In an attempt to study the conformational consequences of adding an acceptor, D-glutamine, to a DD-peptidase, far-UV CD spectra were recorded for the enzyme in the presence of increasing concentrations of glutamine: a = 0 mM, b = 3 mM , c = 7 mM, d = 10 mM, e = 20 mM, f = 30 mM, g = 50 mM, and h = 95 mM. The enzyme concentration was 0.1 mg/ml, equivalent to ~10^{-3} M peptide bond, in 10 mM sodium phosphate pH 7.2. A 2-mm cell path length was used.

in the sample, reproducible cleanliness of the cuvette, and the level of general handling procedures. Ultimately, an assessment of significance depends on the experience, competence, and confidence of the operator.

As CD is very sensitive to small changes in conformation and dynamics, wild-type and mutant proteins will frequently give spectra that differ slightly in intensity rather than shape. If the dihedral angle for a disulfide bond is such as to yield an intense contribution, small conformational perturbations in a mutant protein may further affect the spectrum. Hence, there is the need to examine proteins by a number of different spectroscopic, hydrodynamic, and functional probes in order to assess correct folding of mutant proteins.

Time Considerations

A single spectrum, with associated baseline, will require ~1 hr, including the time needed to fill and clean the cuvette. Up to an additional hour may be needed for optimizing instrument parameters if the sample is unfamiliar. For a number of samples, economies of time can be effected (see Basic Protocol).

Determining the Fluorescence Spectrum of a Protein

Fluorescence spectra provide a sensitive means of characterizing proteins and their conformation. The spectrum is determined chiefly by the polarity of the environment of the tryptophan and tyrosine residues and by their specific interactions. The diminution of intensity of the fluorescence by added "quenchers" provides a measure of the degree to which these residues are buried in the protein structure or exposed to solvent.

One of the main values of fluorescence as a technique for probing protein conformation is that it is highly sensitive and very economical of material. This means, however, that small traces of fluorescent impurities in the solvent or on the cell are readily detected and, if care is not taken, can lead to misinterpretation of the spectra. The essential aim in using this technique, therefore, must be to obtain a fluorescence emission spectrum for the recombinant protein that is guaranteed free from all too easily generated artifacts.

STRATEGIC PLANNING

The following points are essential to obtaining reproducible spectra for reliable comparison between samples.

Fluorescence Spectrometer

Fluorescence spectra are measured with a fluorescence spectrometer (spectrofluorimeter), of which there are a variety of models on the market. For protein characterization, a xenon light source and optics that ensure low levels of stray light are essential. Spectrometers with dual holographic gratings in the excitation monochromator are preferred. There are two main types of fluorescence detection available: analog and photon counting. The latter counts individual photons, which enables high sensitivity and stability, but limits the range of intensities over which a linear response is obtained. Analog spectrometers provide high-precision measurements over a wide range of intensities. Stability is generally high, but is improved by the presence of a reference photomultiplier. In general, the photon-counting spectrometer is for more specialized use and the analog type of instrument is more widely used for the kind of work described in this unit.

A thermostatted cell holder—either one connected to a good circulating thermostat bath or one of the Peltier controlled type—is essential. The latter controls the temperature by electrical means, the advantages being that no water needs to be brought into the spectrometer and, secondly, that the temperature can be raised and lowered very quickly. The spectrometer should incorporate shutters that protect the sample and the photomultiplier from radiation when scanning is not in progress. A magnetic stirrer incorporated into the cell holder is useful to facilitate mixing and to minimize artifacts due to photochemical degradation. Careful attention must be paid to the manufacturer's instructions in order to achieve the optimum settings for measurement.

Calibration of Spectrometer

In order to ensure reproducibility, the wavelength setting should be correct within ±0.5 nm. This will generally not be a problem, but it is just as well to check, most readily with a mercury lamp inserted into the cell compartment. The procedure described by Lakowicz (1983) is recommended. Calibration of intensity can be more difficult, and it is always more reliable to scan samples in parallel with a solution of a known, stable compound, be it the protein in question or a model compound such as *N*-acetyl-L-tryptophanamide.

Cells

Choice of cells

The fluorescence cuvettes best used for reliable characterization of proteins are either the standard 10 × 10–mm fluorescence quartz cuvettes (with all four faces polished), taking 2 to 3 ml of solution, or semimicro cuvettes, taking ~0.7 ml. In order to ensure reproducible positioning of the cuvette, it should be placed in the cell holder with the inscription facing the incident light beam.

Preparation and handling of cells

Cuvettes must be thoroughly and reproducibly cleaned by soaking in a proprietary cuvette-cleaning fluid such as Hellmanex II (Hellma), an alkaline liquid concentrate, or RBS-35 Detergent Concentrate (Pierce), following the manufacturer's instructions. The manufacturers of Hellma cuvettes caution against the use of ultrasonics as a means of boosting cleaning efficiency. Fifty percent nitric acid is also effective, but requires greater care and a fume hood. Detergents frequently contain fluorescent material and, if used, should be removed from cuvettes with 2 M HCl followed by water. After the final rinse with copious amounts of high-quality distilled water, the cells are best dried using suction through a Pasteur pipet protected with a small length of plastic tubing. This is safer than using acetone or alcohol, which can leach out fats from fingers and deposit them on the cuvette. The faces of cuvettes must not be touched after cleaning. Filling, emptying, and rinsing between measurements of spectra must be done using pipets, to avoid spillage onto the outer faces. A Pasteur pipet protected with fine plastic tubing is satisfactory. The baseline scans, with buffer in the cell, must be examined as a constant check on the reproducibility of the state of the cell.

The cleanliness of the cuvette can be checked by filling with distilled water and scanning the appropriate wavelength region of the spectrum. If there is no contamination by fluorescent material, the spectrum should be flat, save for the Raman band (see Fig. 7.7.1) on the high-wavelength side of the excitation wavelength, λ_{max}.

Buffer Solutions

Buffers should have low absorbance and low fluorescence in the regions of excitation and emission. Absorbance will usually be expected to be <0.1 and fluorescence close to zero. This will normally be the case for standard buffers made from analytical-grade reagents or materials of equivalent purity but they should, nevertheless, be routinely checked for fluorescence. If a fluorescent component is added to the solution—e.g., as a ligand—it should be checked that the fluorescence observed arises solely from that component. The actual buffer solution used to dissolve or to dialyze the protein should be used for the fluorescence blank. Plastic containers (and stirring bars) may contribute fluorescent agents; if these are used, appropriate blanks should be carefully monitored for fluorescence.

Clarification of Solutions

Protein solutions must be freed from the turbidity resulting from dust and aggregated protein. Many proteins can be filtered (preferably as a stock solution) using a 0.22-μm filter—ideally of the grade special for proteins such as Durapore (Millipore)—fitted to a syringe. Alternatively, if the protein is adsorbed by filters, the solution can be clarified by centrifugation. A microcentrifuge operated at maximum speed for 10 min at 4°C provides reliable clarification for the majority of proteins that do not sediment appreciably under these conditions. Buffer solutions are filtered on a larger scale, using a 0.22-μm filter.

It is essential to monitor clarification if artifacts are to be avoided. There are three indicators of the completeness of clarification, each available from the standard procedures that should be adopted for spectroscopic characterization.

PCU IASST / CENTRAL UNIVERSITY LIBRARY

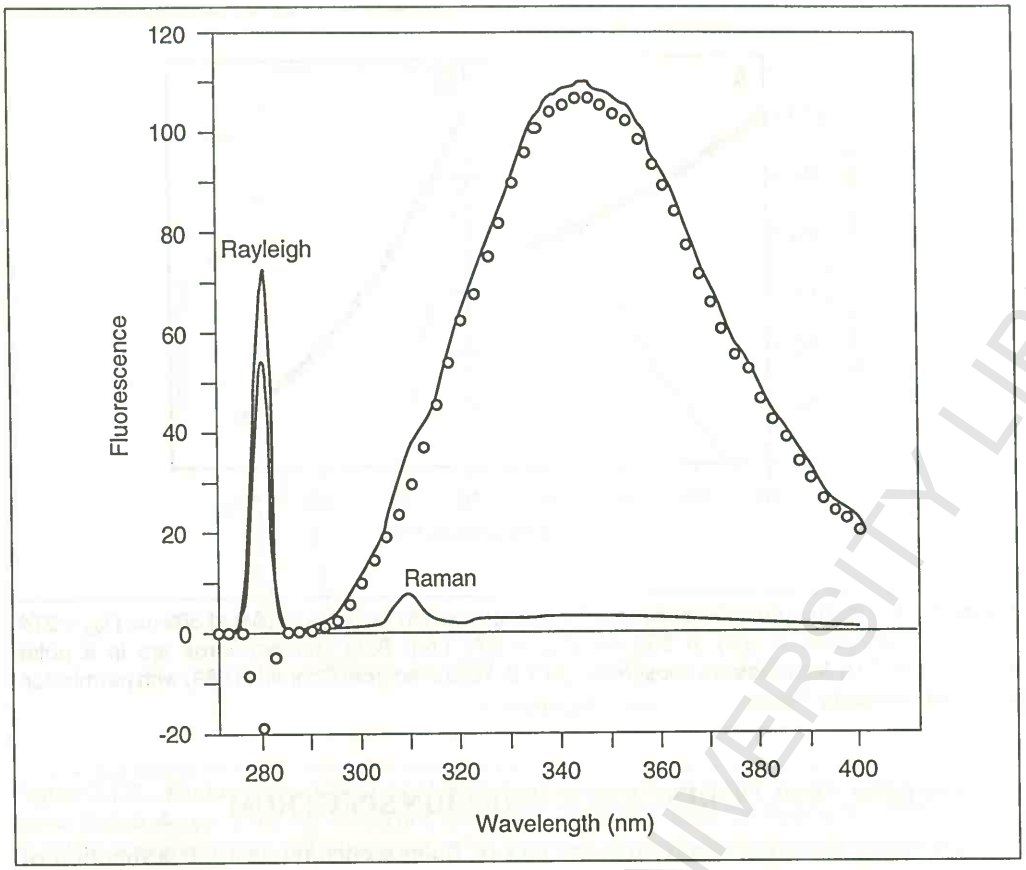

Figure 7.7.1 Fluorescence spectrum of hen egg white lysozyme (EWL). The Rayleigh and Raman bands are seen in the scans for the solvent baseline and protein solutions (solid lines). Circles represent the spectrum of EWL with baseline subtracted. Parameters: EWL $A_{280} = 0.05$; $\lambda_{ex} = 280$ nm; excitation and emission bandwidths, 2.5 nm; scan rate, 100 nm/min; five scans accumulated. Spectrum was measured using a Perkin Elmer LS50B fluorescence spectrometer.

1. Determination of protein concentration (*UNIT 7.2*) requires an absorbance spectrum to be recorded on a good quality spectrophotometer from 240 to 350 nm. Aromatic amino acid residues do not absorb above 320 nm, so the spectrum between 320 and 350 nm should be only marginally above baseline. The presence of turbidity will result in finite attenuance in this region that increases toward lower wavelengths.

2. From the above absorbance spectrum, the ratio A_{max}/A_{min} is measured, where A_{min} is the absorbance at the trough in the region 240 to 250 nm. This ratio will be specific for a given protein and should be measured for a sample that has been carefully and reproducibly clarified. Due to the strong wavelength dependence of scattering, the ratio is very sensitive, decreasing sharply with turbidity, and can be used as a semiquantitative check on the clarity of further solutions of the protein.

3. The scan of a fluorescence emission spectrum should routinely include the region of the Rayleigh peak (see Fig. 7.7.1). This provides a built-in indicator of turbidity of the buffer or protein solutions. The height of the peak should not differ greatly from that obtained for the solvent from the equivalent buffer blank scan; it will increase markedly in height if there is dust or aggregate in the solution.

BASIC PROTOCOL 1

RECORDING A FLUORESCENCE EMISSION SPECTRUM

A fluorescence emission spectrum is the plot of fluorescence intensity as a function of wavelength. Fluorescence emission takes place from the wavelength of excitation (λ_{ex}) upwards. The range of the spectrum recorded is described below (step 5).

Materials

Calibrated fluorescence spectrometer, buffer solution, and cleaned cuvettes (see Strategic Planning)

Clarified protein solution of known concentration (see Strategic Planning for clarification methods and *UNIT 7.2* for concentration determination) with absorbance usually in the range of 0.05 to 0.1 at the wavelength to be used for excitation

Prepare spectrometer

1. Switch on the spectrometer and allow it to warm up for the time specified in the manufacturer's instructions (usually ~30 min). Regulate the thermostat control to the desired temperature (normally 25°C unless the stability of the protein dictates otherwise).

   The intensity of fluorescence is highly temperature-dependent (see, e.g., Fig. 7.7.2) and it is important that the temperature be accurately controlled and measured in the cuvette with a calibrated electric thermometer. It is useful for future reference to note the time taken for the sample to reach the operating value.

2. Set the excitation wavelength (λ_{ex}).

   Setting λ_{ex} to the λ_{max} of the absorbance spectrum (usually 280 nm) will excite both tyrosine and tryptophan residues. Alternatively, λ_{ex} may be set to 295 nm in order to excite only tryptophan (see annotation to step 3).

3. Set the excitation bandwidth.

   The term bandwidth is described and defined in UNIT 7.6, Basic Protocol step 2b. The excitation bandwidth (in nm) is determined by the excitation slit width (in mm). It will

PCU IASI CENTRAL UNIVERSITY LIBRARY

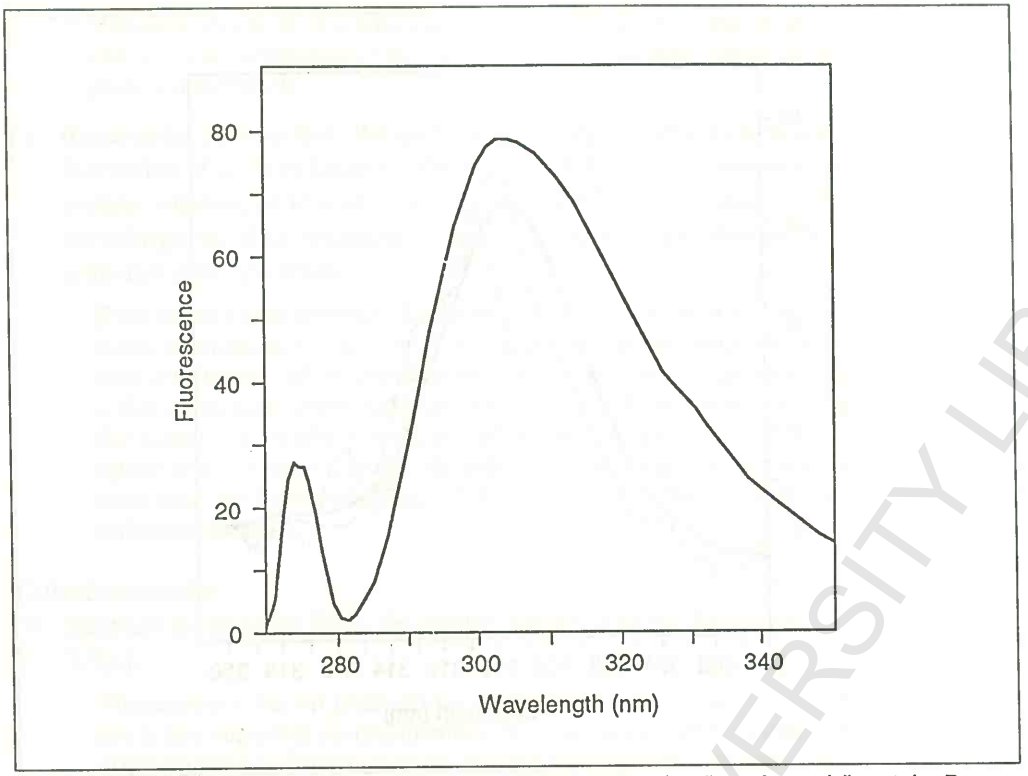

Figure 7.7.3 Fluorescence spectrum of ribonuclease (RNase), a "tyrosine only" protein. Parameters: Rnase A_{275} = 0.05; λ_{ex} = 275 nm; one scan, smoothed; other settings as for Figure 7.7.1. Baseline was measured with the same settings and subtracted. Measurements made using a Perkin-Elmer LS50B.

determine the intensity of the excitation and the amount of scattered light from the Rayleigh peak that will be "seen" in the emission spectrum. It is important in certain cases in determining which chromophore is excited. It is particularly important, for example, to limit the bandwidth when measuring the contribution of tyrosine in the presence of tryptophan. The emission maximum of tyrosine at 303 nm (see Fig. 7.7.3) is close to the required excitation wavelength of 295 nm. The envelope of the Rayleigh peak must not, in this case, significantly overlap the emission band of tyrosine. Settings of 2.5 to 5 nm for $\lambda_{ex} \approx 280$ nm and ≤ 2.5 nm for $\lambda_{ex} \approx 295$ nm are usual.

4. Set the emission bandwidth.

Since protein emission spectra are generally rather broad, larger emission bandwidths can usually be tolerated. Only where it is important to resolve tyrosine fluorescence from tryptophan fluorescence and the Rayleigh scattering peak is it necessary to minimize the bandwidth. In cases where only small amounts of material are available, it is necessary to strike a balance between resolution and light intensity in order to obtain the best possible signal-to-noise ratio. Settings of 2.5 to 10 nm are normal.

5. Set the range of emission wavelengths to be scanned for the emission spectrum.

The lower wavelength should be ~10 nm below the excitation wavelength in order to record the Rayleigh peak (see discussion of Clarification of Solutions in Strategic Planning). The higher end of the range should be chosen to include as much of the spectrum as possible, so as to allow integration of the peak if necessary. Values of 400 and 340 nm are suitable for proteins with and without tryptophan, respectively. Hence, for example, a typical emission wavelength range for a Trp-containing protein excited at 295 nm would be 285 to 400 nm.

BOSTON UNIVERSITY LIBRARY

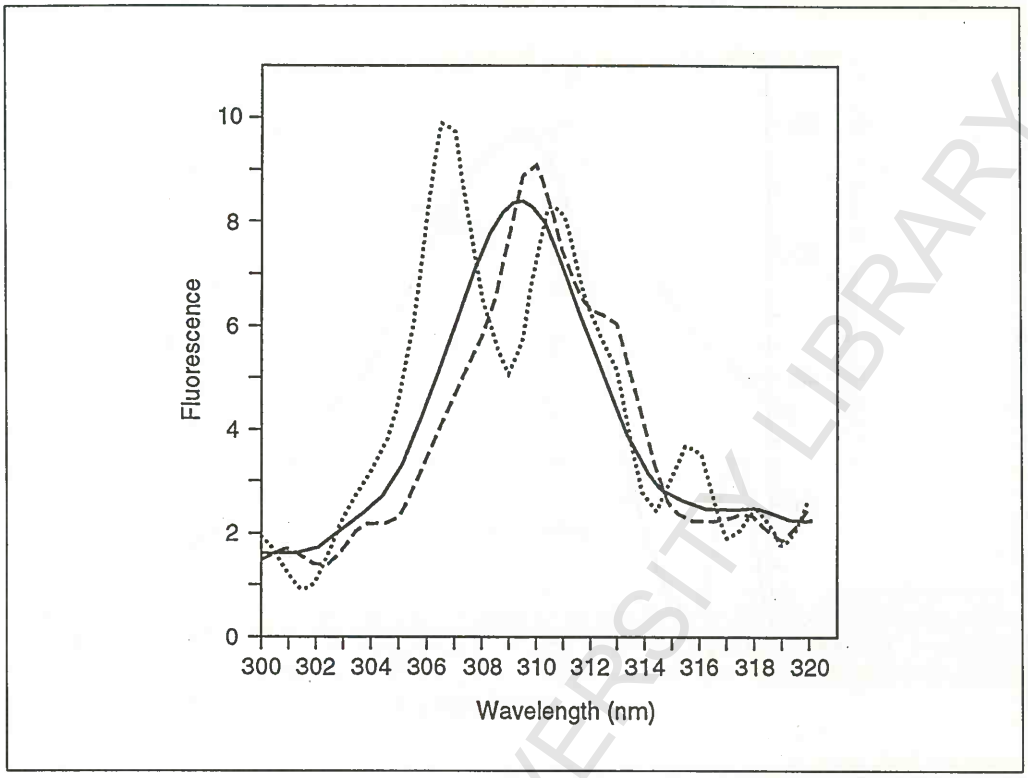

Figure 7.7.4 The Raman band measured under different scanning conditions. The appropriate section of the baseline in Figure 7.7.1 is shown for: a single scan at 1500 nm/min (dotted line); ten scans at 1500 nm/min (dashed line); and ten scans at 100 nm/min (solid line). The times required for scanning the complete baselines for these three measurements were 0.087 min, 0.87 min, and 13 min, respectively. Measurements made using a Perkin-Elmer LS50B.

6. Set the scan rate.

   The scanning rate for the emission wavelength has to be slow enough to allow the instrument to respond to changes in intensity with wavelength. Too fast a scan, even with a number of accumulations, results in an apparent spectrum that can differ markedly from the true spectrum (Fig. 7.7.4). When, as is usually the case with proteins, the emission band is rather broad (Fig. 7.7.1), a scan rate setting in the region of 100 nm/min will usually be appropriate.

Scan buffer blank and protein sample

7. Fill a cleaned cuvette with a filtered sample from the actual batch of buffer used to dissolve or dialyze the protein, then place the cuvette in the cell holder of the spectrometer in a reproducible orientation (see discussion of Cells in Strategic Planning). Scan this buffer blank using the same instrument settings as are appropriate for the sample, store the spectrum, and check for any unexpected fluorescence bands.

   If the settings appropriate for the protein sample cannot be estimated in advance, the sample may be run before the buffer blank, although special care will have to be taken to remove any protein adsorbed to the inner faces of the cuvette.

   Temperature equilibration is not usually important for the buffer, except in cases where it contains fluorescent components.

   Cell holders are susceptible to corrosion by salt solutions. Cells should therefore be filled outside the spectrometer.

   Apart from the Raman band, a buffer solution should give an almost flat baseline of low intensity (see Fig. 7.7.1). At the usual working concentrations of protein (A_{280} ≥0.05), buffer fluorescence constitutes only a minor contribution to the fluorescence spectrum of the protein and is accounted for by the appropriate baseline subtraction.

CU IASI CENTRAL UNIVERSITY LIBRARY

It is advisable to repeat baseline scans at intervals during a series of experiments to check on contamination of the outer faces of the cuvette, and of the inner faces due to protein adsorption.

8. Remove the cuvette from the spectrometer, empty with a protected Pasteur pipet (see discussion of Cells in Strategic Planning) and refill in the same way with the clarified protein solution of known concentration with an absorbance of 0.05 to 0.1 at the wavelength used for excitation. Allow to come to temperature in the cell holder, then scan and store spectrum.

   If the protein concentration has to be low, and/or the intensity of fluorescence is low, it may be necessary to accumulate a larger number of scans. Proteins differ widely in their sensitivity to photodegradation, but exposure to UV radiation may lead to damage to those molecules in the light path, with subsequent reduction in fluorescence intensity. Excitation slit widths should, therefore, be as narrow as is consistent with good signal-to-noise ratio. Stirring the solution in the cuvette will bring undamaged molecules into the light path (Fig. 7.7.8) and further reduce significant artifacts due to radiation damage.

Calculate results

9. Subtract the baseline from the sample spectrum using the instrument software (Fig. 7.7.1).

   Fluorescence has no units. Hence, if the fluorescence intensities of different samples are to be compared, careful attention must be paid to reproducible concentrations and instrumental conditions. Instrument response may vary with time, so must be controlled by the use of stable standards.

10. Correct the apparent fluorescence intensities for the inner filter effect.

    A protein solution will absorb a certain proportion of the radiation before it reaches the volume of solution whose fluorescence is viewed by the optics of the instrument (see Fig 7.7.5). For a solution of absorbance 0.1, the intensity at the center of the cell is about 10% less than that of the incident radiation, with a corresponding decrease in the observed fluorescence. Similarly, the fluorescence intensity may be reduced by absorption in the exit path. This is known as the inner filter effect. In practice, it means that the observed fluorescence intensity is directly proportional to protein concentration only at low concentrations, when absorbance is <0.1 at λ_{ex}. The apparent fluorescence intensity (F_{app}) can be corrected by the following approximation:

$$F_{corr} = F_{app} \text{ antilog}\{(A_{ex} + A_{em})/2\}$$

    where A_{ex} and A_{em} are the solution absorbances at the excitation and emission wavelengths, respectively.

    The effect is much more marked if a third component that absorbs in the wavelength range of the protein absorption or fluorescence is added to the solution (see Basic Protocol 2).

11. Determine the value of the fluorescence intensity at the wavelength of maximum intensity (I_{max} at λ_{max}), using, where available, the instrument software.

    It is possible to obtain corrected spectra, which take into account the variation of intensity of the light source as well as variation of the detector response with wavelength. The procedures for calculating these are not simple (see Lakowicz, 1983), and for the purposes of characterization described here the uncorrected spectra are normally used. Because of the above variations, however, it is important when comparing spectra to do so with spectra obtained using the same instrumental settings and, preferably, the same instrument.

    In order to compare complete spectra from different samples of a protein, they should be normalized by dividing the value of fluorescence intensity by the protein concentration (i.e., I_{em}/c).

BOLTON / CENTRAL UNIVERSITY LIBRARY

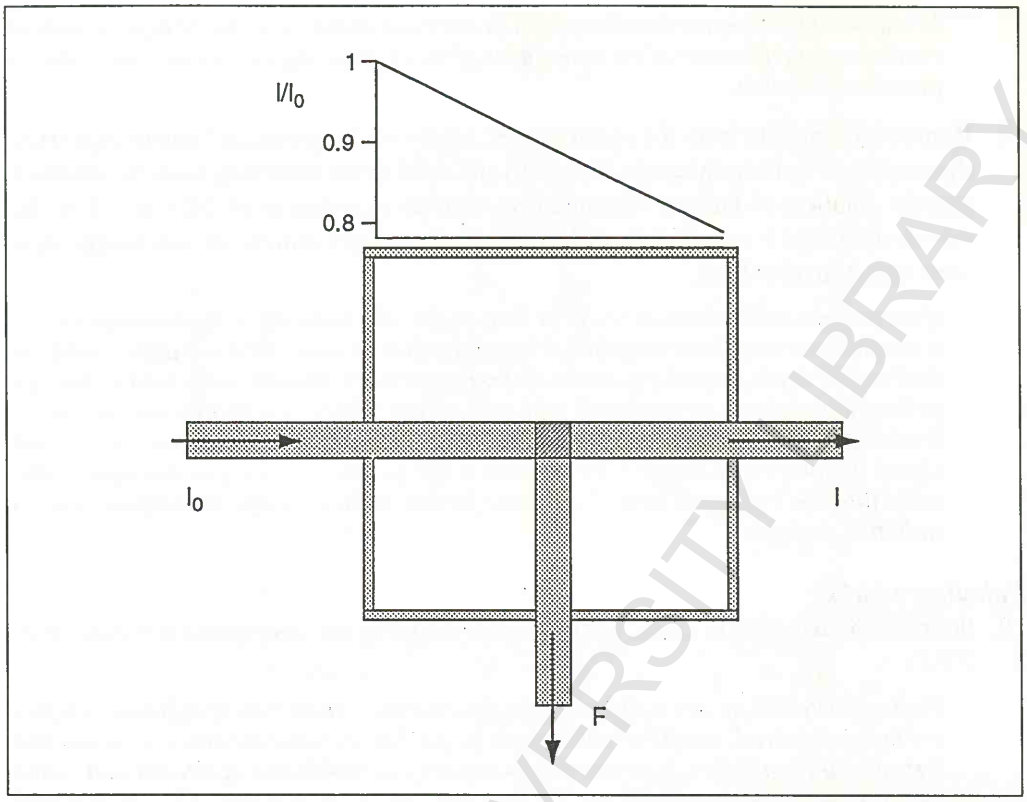

Figure 7.7.5 The inner filter effect. A cuvette (10 × 10–mm) is represented in plan view, with the collimated incident beam from the monochromator having intensity I_0. As a result of absorption by the protein solution, the intensity through the cuvette will decrease steadily, emerging with intensity I. The values are illustrated for a solution having absorbance at the excitation wavelength of 0.1. The optics of the fluorescence detector are focused so that only the fluorescence originating from the volume depicted by the heavily shaded square is "seen" by the photomultiplier. Thus the observed fluorescence intensity will be less than that expected from the fluorescence of the protein at infinite dilution. The fluorescence passes through the protein solution on its way to the detector and will be further decreased in intensity if the solution absorbs at the wavelengths of the emitted radiation.

BASIC PROTOCOL 2

DETERMINATION OF FLUORESCENCE QUENCHING

Fluorescence quenching provides a means of probing the accessibility of tryptophan residues to small molecules and thus gives information about their structural environment. The technique involves quantifying the decrease in protein fluorescence intensity in the presence of increasing concentrations of quencher, followed by analysis of the data to give details of the interaction of the quencher with the tryptophan residue.

Materials

Protein solution in buffer, A_{280} = 0.05 to 0.1

Quenchers: these are most conveniently made up as concentrated stock solutions; examples of frequently used quenchers include:

5 M NaI or 2.5 M KI solution containing 1 mM $Na_2S_2O_3$ to prevent I_3^- formation

5 M CsCl (optical grade, Aldrich)

8 M acrylamide (Electran grade from BDH; ε_{295} = 0.236 liter/mol/cm)

2.5 M succinimide (recrystallized from ethanol with activated charcoal treatment; ε_{295} = 0.03 liter/mol/cm)

Additional reagents and equipment for recording a fluorescence spectrum (see Basic Protocol 1)

FCU IASL / CENTRAL UNIVERSITY LIBRARY

1. Scan the fluorescence spectrum of a measured volume of the protein in the required buffer (see Basic Protocol 1).

2. Add a known small volume of a stock solution of quencher, mix thoroughly and again scan the spectrum.

   Alternatively, for economy of time, measure the intensity of fluorescence at just two wavelengths—315 and 350 nm—allowing a sufficient time of accumulation to achieve a reproducible average reading.

   The actual amount of quencher added is a matter of judgment, depending on the degree of quenching found. It is important to obtain at least ten measurements of fluorescence intensity spread evenly between zero and full quenching (see Fig. 7.7.6).

   Quenchers should be carefully purified. When iodide is used, it should be in the presence of 1 mM $Na_2S_2O_3$ to avoid the formation of I_3^-, which can react with tyrosine.

   The tryptophan residues in a given protein are likely to be in different environments and, therefore, to exhibit different values of λ_{max}. Measurement of the degrees of quenching at the red and blue ends of the emission spectrum will determine whether this is so and will also add further detail to the overall fingerprint of the protein (see discussion of Quenching in Support Protocol).

3. Correct each reading of the fluorescence intensity for dilution and for the absorbance of the quencher (see Basic Protocol 1).

   See also Eftink and Ghiron (1981).

4. Plot the resulting fluorescence intensities as a function of concentration of quencher according to the Stern-Volmer equation (see Fig. 7.7.6A):

   $$F_0/F = 1 + K_D[Q]$$

   where F_0 and F are the fluorescence intensities in the absence and presence, respectively, of a given concentration of quencher $[Q]$, and K_D is the Stern-Volmer quenching constant.

   K_D is determined by the bimolecular quenching constant (k_q) and by the fluorescence lifetime of the fluorophore (τ_0), in the absence of quencher ($K_D = k_q\tau_0$). The slope of a plot of F_0/F against $[Q]$ gives K_D directly, in units of liters/mol, with an intercept of unity. This plot is expected to be linear for a single fluorophore in a single environment. For a more complex system the plot will be non-linear (see Fig. 7.4.6A) and the data should be plotted according to a modified Stern-Volmer equation:

   $$F_0/\Delta F = 1/f_a K_D[Q] + 1/f_a$$

   where f_a is the fraction of the initial fluorescence accessible to the quencher,

   $$f_a = F_{0a}/(F_{0a} + F_{0b})$$

   and K_D is the Stern-Volmer quenching constant for that fraction of the fluorescence. A plot of $F_0/\Delta F$ against $1/[Q]$ gives an intercept of $1/f_a$ and a slope of $1/f_aK_D$ (see Fig. 7.7.6B).

CHILIE

BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

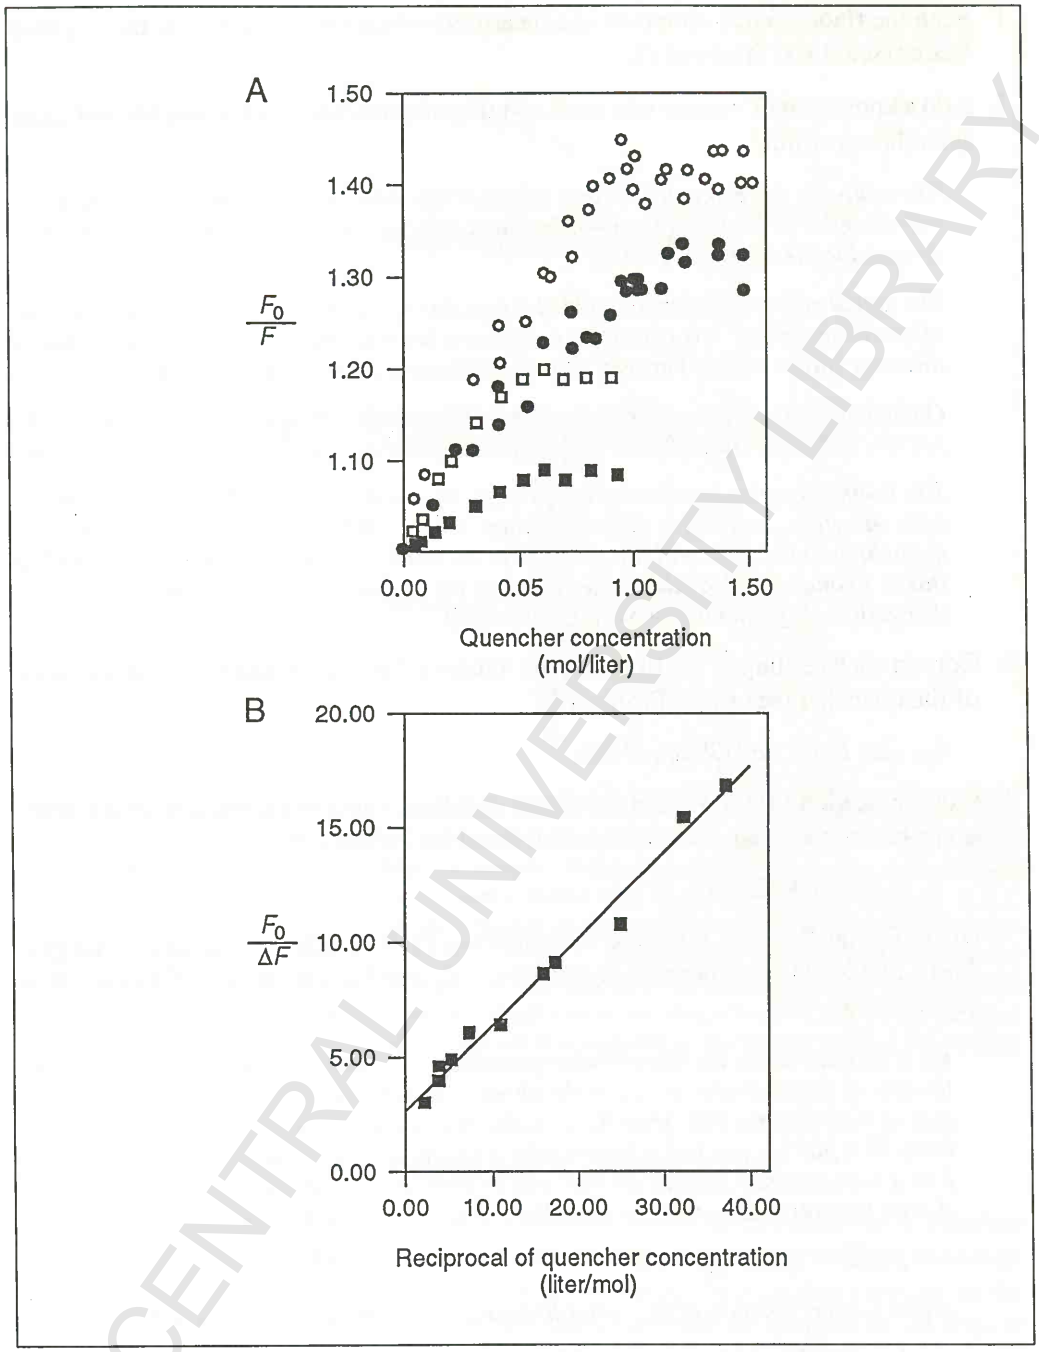

Figure 7.7.6 Quenching of fluorescence of 3-phosphoglycerate kinase (PGK). (**A**) Fluorescence emission intensities, expressed as a fraction of the unquenched fluorescence, are plotted according to the Stern-Volmer equation (see Basic Protocol 2, step 4) at 316 nm (filled symbols) and 350 nm (open symbols). Quenchers used were succinimide (circles; recrystallized from ethanol and treated with activated charcoal, 2.5 M stock solution) and potassium iodide (squares; 2.5 M stock solution with 1 mM $Na_2S_2O_3$). Fluorescence intensities were adjusted for dilution and for quencher absorbance using a molar extinction coefficient $\varepsilon_{295} = 0.03$ liter/mol/cm for succinimide. The greater level of quenching at 350 nm reflects the fact that the more exposed of the two tryptophan residues has a more red-shifted fluorescence maximum. (**B**) Modified Stern-Volmer plot for the quenching of PGK fluorescence by succinimide. The data in panel A for quenching at 350 nm is plotted according to the modified Stern-Volmer equation (see Basic Protocol 2, step 4 annotation). The intercept on the *y*-axis is 2.36 ± 0.2. The results in panels A and B are characteristic of a protein where part of the fluorescence is inaccessible to a given quencher, in this case, iodide and succinimide. Measurements made using a Perkin-Elmer MPF3-L. Reprinted from Varley (1991) with permission of Elsevier Science.

FCU IAS CENTRAL UNIVERSITY LIBRARY

BASIC THEORY AND INTERPRETATION OF FLUORESCENCE SPECTRA

When radiation is incident on a solution, most of it is scattered without change in wavelength. Thus, exciting radiation at 280 nm will be scattered and a fraction of it will be detected by the spectrofluorimeter as a peak at the same wavelength. The width of this **Rayleigh** scattering peak (Fig. 7.7.1) will depend on instrumental settings, mainly those of the excitation and emission slit widths, which determine the range of wavelengths observed. The **bandwidth** is the width, in nm, of the distribution of intensity measured at half the height of the maximum intensity.

A further low-intensity peak, known as the **Raman band**, is also observed in spectra (see Fig. 7.7.1). This is a low-intensity band of scattered radiation whose distance from the excitation band is a measure of the vibrational energy of the H–O bond in solvent water. At λ_{ex} = 280 nm, the Raman band for water occurs at 311 nm; in general, it occurs at $1/\{(1/\lambda_{ex}) - (3.6 \times 10^{-4})\}$, where λ_{ex} is the excitation wavelength in nm. The intensity and resolution of the Raman band provides a useful empirical check on the performance of the spectrofluorimeter. A decrease in the signal-to-noise ratio usually indicates a deterioration of the lamp.

Chromophores, such as the sidechains of tryptophan and tyrosine, will absorb some of the radiation in ~10^{-15} sec and become excited from the ground electronic state (S_0) to higher vibrational levels in a higher energy electronic state (S_1; see Fig. 7.7.7). The energy in the vibrational levels is rapidly (~10^{-12} sec) lost to the surroundings as thermal energy, so that the excited chromophore is very largely in its ground vibrational level. Return to the ground electronic state can result in the emission of radiation of lower energy and hence longer wavelength (Figs. 7.7.1 and 7.7.3), or the energy can be dissipated in a

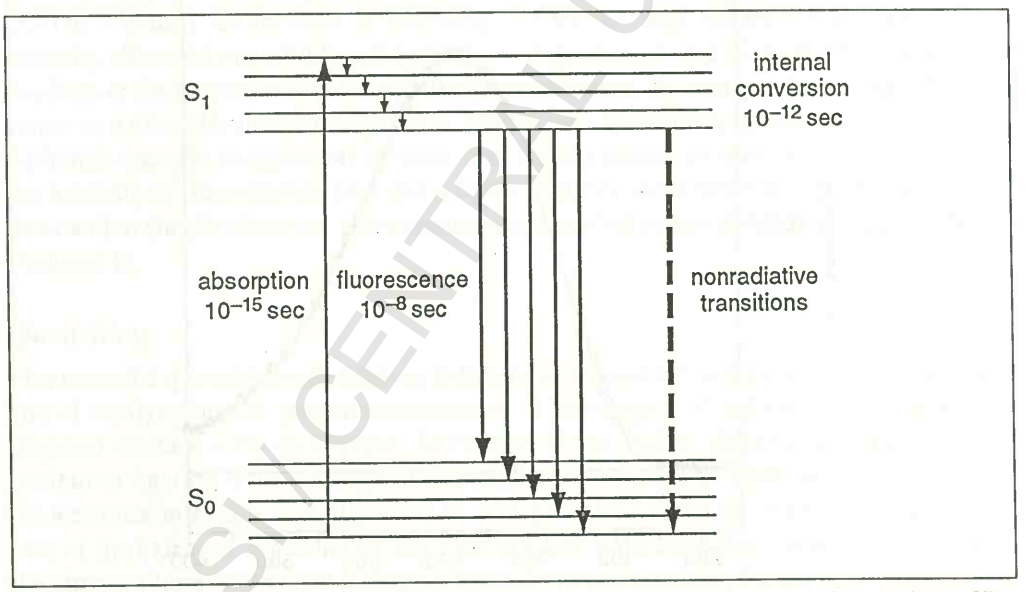

Figure 7.7.7 The processes of absorption and emission of radiation by a chromophore. The electronic structure of a chromophore is in the ground state (S_0) under normal conditions. Absorption of radiation, a rapid process, leads to excitation into an excited state (S_1). Within each electronic state are a number of vibrational states, represented by horizontal lines. Under normal thermal conditions, only the lower one or two vibrational levels are occupied. Thus, although excitation takes place into a range of levels in the excited electronic state, emission, in the form of fluorescence, takes place from the lowest vibrational level. The lengths of the vertical lines representing absorption and emission illustrate the relative energies of the radiation in each process and illustrate why fluorescence occurs almost always at longer wavelengths than absorption. The vertical broken line represents the dissipation of absorbed energy by means other than radiation.

PRINCE'S CENTRAL UNIVERSITY LIBRARY

number of ways that are nonradiative (Fig. 7.7.7), including quenching (see discussion of Quenching, below). The ratio of the rate constants for these two alternative processes defines the quantum yield or fluorescence efficiency, which is almost always less than unity.

The chromophores tyrosine and tryptophan absorb radiation in the 280 nm region, re-emitting a proportion of it as fluorescence. The quantum yields for tryptophan, tyrosine and phenylalanine are 0.2, 0.1, and 0.04, respectively. Coupled with their relative absorption coefficients (*UNIT 7.2*), it can be seen why most protein fluorescence spectra are dominated by tryptophan.

Quantitation of the fluorescent properties of a protein can provide a number of rather specific parameters that allow assessment of the correct folding, besides giving additional structural information.

Tyrosine Fluorescence Is Frequently Not Seen in the Presence of Tryptophan

The fluorescence intensity of free tyrosine is about one-fifth of that of tryptophan, but in proteins it is usually much weaker still. This is due to a combination of interactions—such as hydrogen bonding to peptide carbonyl groups, the presence of neighboring charged groups, and nonradiative energy transfer to tryptophan or disulfide bonds—all of which can result in tyrosine fluorescence being diminished or quenched. The degree of quenching varies from protein to protein and can be observed by paying careful attention to bandwidths (see Basic Protocol 1). In Figure 7.7.8, where the peak intensity at 335 nm of

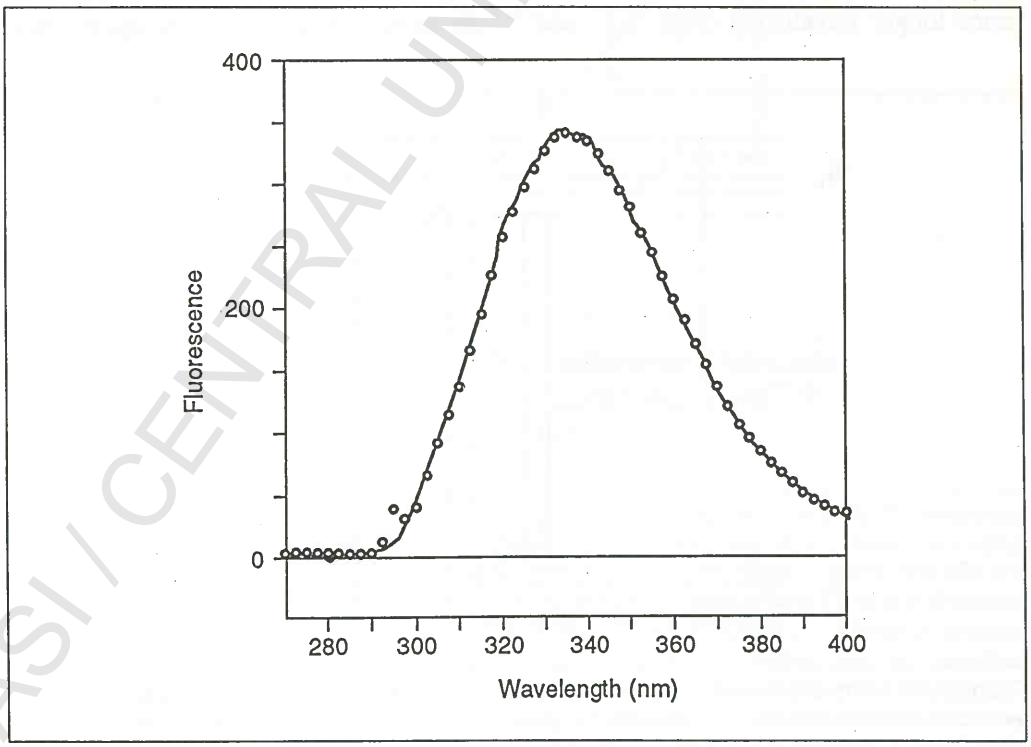

Figure 7.7.8 Quenching of the tyrosine fluorescence of chymotrypsinogen A. The solid line represents the emission spectrum excited at 280 nm. The circles represent the corresponding spectrum obtained with λ_{ex} = 295 nm. Because the latter spectrum is considerably less intense than the former (as a result of the differences in absorbance at 280 nm and 295 nm), the spectra were normalized using the ratio of their fluorescence intensities at 335 nm. Parameters: chymotrypsinogen A_{280} = 0.1; excitation and emission bandwidths, 2.5 nm; scan rate, 100 nm/min, two scans accumulated for λ_{ex} = 280 nm and four scans for λ_{ex} = 295 nm. Fluorescence was measured using a Perkin Elmer LS50B.

FCU IASI / CENTRAL UNIVERSITY LIBRARY

fluorescence excited at 295 nm (i.e., tyrosine is not excited) has been normalized to that excited at 280 nm (where both tryptophan and tyrosine are excited), it is evident that there is no separate contribution of tyrosine to the fluorescence excited at the latter wavelength. Essentially all the tyrosine fluorescence is quenched (see Lakowicz, 1983). The unfolded protein shows a separate shoulder resulting from unquenched tyrosine fluorescence.

λ_{max} and I_{max} Reflect the Detailed Environment of Aromatic Residues

The precise wavelength of emission is, in the case of tryptophan, dependent on the polarity of the immediate environment of the chromophore in the protein, and maximum values have been observed over a broad range between 308 nm (highly nonpolar) and 352 nm (fully exposed to solvent). In tumor necrosis factor (TNF), the maximum emission wavelength is 320 nm, compared to 350 nm for the fully unfolded protein (Fig. 7.7.9). The value of 336.5 nm for λ_{max} in acid solution indicates partial unfolding. By comparison, tryptophan residues in native chymotrypsinogen A, where λ_{max} = 332 nm (Fig. 7.7.10), are in a slightly less nonpolar environment than in TNF. The value of λ_{max} therefore provides both a characteristic parameter for a particular protein and structural information concerning the average degree of burial of the tryptophans. The wavelength of tyrosine fluorescence, on the other hand, does not vary with polarity of environment and occurs with a maximum at 303 nm. Phenylalanine does not absorb above 275 nm, so that its weak fluorescence is not normally observed.

The intensity of fluorescence is, for both tyrosine and tryptophan, dependent upon interactions with neighboring groups that may quench the fluorescence emission from the native conformation. Tryptophan and tyrosine fluorescence is quenched, relative to the emission intensity in water, in solutions of denaturant. Depending on the degree of quenching of these chromophores in the folded protein, therefore, denaturation can result in an increase or a decrease in intensity, as well as a shift in λ_{max} to longer wavelengths (350 to 355 nm). In the case of TNF (Fig. 7.7.9), the large reductions in fluorescence intensity observed on unfolding the protein in guanidine or acid show that the tryptophan residues in the native protein are relatively unquenched. By contrast, tryptophan fluorescence in native chymotrypsinogen A is seen to be considerably quenched (Fig. 7.7.10). Although specific assignments of these interactions cannot be derived from the spectra, the intensity of fluorescence provides a further empirical characteristic of a protein. Note that caution should observed when comparing recorded values of λ_{max} and I_{max} (see Basic Protocol 1).

Quenching

Fluorescence quenching provides an indicator of the solvent accessibility of tryptophans and of the dynamics of protein conformation. The presence of certain extrinsic groups in physical contact with an excited chromophore can lead to sharing or transfer of the excitation energy, with consequent reduction in the quantum yield and diminution of fluorescence intensity. The efficiency of this quenching depends on the electronic structure of the extrinsic molecule or ion. The fact that it depends also on its accessibility to the chromophore means that a study of quenching can provide a further and independent probe of tryptophan environment. Iodide ion (I^-) cesium ion (Cs^+), and succinimide are useful quenchers for determining accessibility (a fuller list of quenchers for proteins is provided by Eftink and Ghiron, 1981). The ionic character of I^- and Cs^+ and the relatively large size of succinimide mean that these quenchers cannot readily penetrate the nonpolar interior of the protein, so they can be used to differentiate between buried and solvent-accessible chromophores. Their accessibility to an aromatic residue in the surface of the protein will depend, in addition, on the stereochemistry, chemical nature, and, in particular, charge of the surrounding groups. Quenching can be readily quantitated using the

BOSTON BIOMEDICAL CENTRAL UNIVERSITY LIBRARY

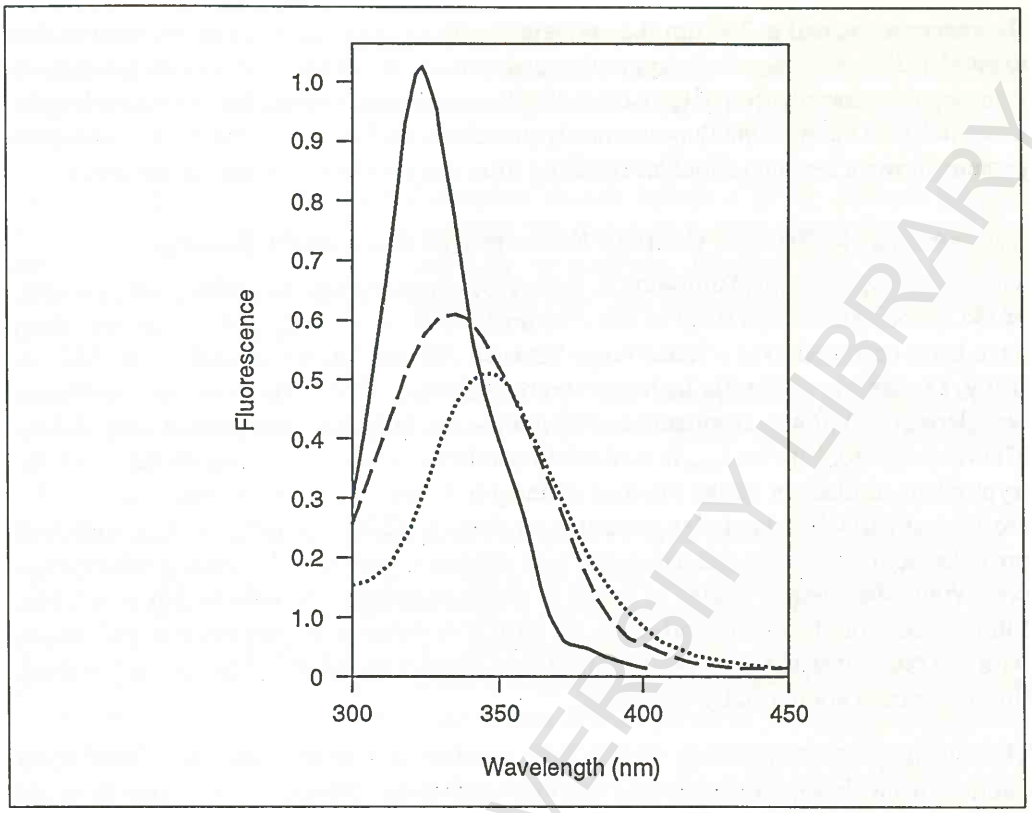

Figure 7.7.9 Quenching of fluorescence of tumor necrosis factor (TNF) upon denaturation. Fluorescence emission spectra are shown for native TNF (solid line), guanidine-unfolded TNF (dotted line), and acid-denatured TNF (dashed line). Parameters: TNF concentration, 30 µg/ml; λ_{ex} = 280 nm; bandwidths ranging from 16 to 24 nm. Measurements made using Perkin-Elmer MPF3 spectrofluorimeter. Figure 7.7.10 Dequenching of chymotrypsinogen A on unfolding. Native chymotrypsinogen A (N) was scanned as in Figure 7.7.8. Unfolded chymotrypsinogen A (U) was scanned in 6 M guanidinium chloride using the following parameters: A_{280} = 0.05; λ_{ex} = 280 nm; excitation and emission bandwidths, 2.5 nm; scan rate 100 nm/min; single scan, smoothed. The tryptophan fluorescence is seen to be considerably quenched in the folded protein. Measurements made using a Perkin-Elmer LS50B.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

Stern-Volmer equations to give the quenching constant (K_{SV}) and the fraction of the initial fluorescence that is accessible to the quencher (see Basic Protocol 1).

The quenching of fluorescence of phosphoglycerate kinase (PGK) is shown plotted according to the Stern-Volmer equation (see Fig. 7.7.6A). The quenching levels off above 0.9 M succinimide and 0.6 M iodide, respectively, indicating that part of the fluorescence is unquenched by these quenchers. The different degrees of quenching by iodide and succinimide is due to the nature of the neighboring groups affecting access to the tryptophan. The plot of some of the data according to the modified Stern-Volmer equation (Fig. 7.7.6B) shows the fluorescence quenched by succinimide to be 42% of the total. The different degrees of quenching at 316 and 350 nm are due to the two tryptophans having substantially different values of λ_{max}, and hence different degrees of accessibility to solvent. Thus, taking into account the crystal structure of PGK, one of the two tryptophans, W333, is seen to be buried and inaccessible to quencher while the other, W308, is quenched with a quenching constant of $K_{SV} = 0.39$ liters/mol.

Another quencher, acrylamide, can quench the fluorescence not only of exposed but also of buried tryptophan residues based on its ability to diffuse through the protein structure. The efficiency of quenching is, therefore, a reflection of the tightness of packing and the dynamics of the protein. Figure 7.7.11 shows the results of acrylamide quenching of the

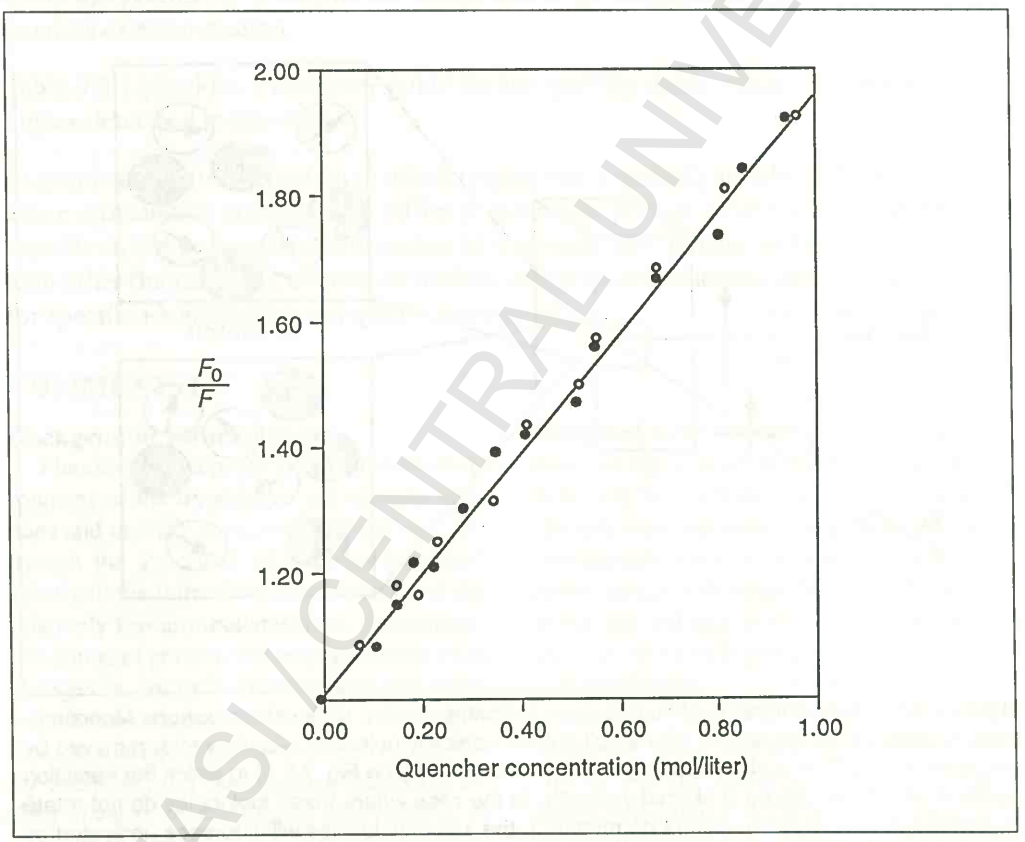

Figure 7.7.11 The quenching of buried tryptophan fluorescence in 3-phosphoglycerate kinase (PGK). In the presence of 1.12 M succinimide (shown to quench the exposed tryptophan fluorescence; see Fig. 7.7.6), fluorescence is further quenched by acrylamide, which is able to gain access to the buried tryptophan. Fluorescence was measured at 316 nm (filled circles) and at 350 nm (open circles) and plotted according to the Stern-Volmer equation (see Basic Protocol 2, step 4). Fluorescence intensities were corrected for dilution and for quencher absorbance using $\varepsilon_{295} = 0.236$ for acrylamide. The linear plot indicates the quenching of a single residue. Measurements made using a Perkin-Elmer MPF3-L. Reprinted from Varley (1991) with permission of Elsevier Science.

BOSPHORUS UNIVERSITY CENTRAL LIBRARY

buried W333 of PGK (in this experiment the more exposed W308 is quenched by succinimide). The linearity of the plot, combined with the coincidence of the quenching measured at 316 and 350 nm (in contrast to Fig. 7.7.6), shows that a single tryptophan only is being quenched by the acrylamide. A quenching constant $K_{SV} = 0.94$ liters/mol is obtained from the slope. In general, bimolecular rate constants for quenching, which reflect more directly the dynamics of the protein, can also be calculated if fluorescence lifetime measurements are available (see discussion of Stern-Volmer equation in Basic Protocol 2; see also Eftink and Ghiron, 1981).

Fluorescence Depolarization

If a polarizer is placed in the excitation beam, the radiation passing through the sample solution will be plane-polarized. This beam will now be absorbed only by those chromophores whose transition dipoles are in the same plane (see Fig. 7.7.12). If the chromophore does not rotate within 10^{-8} sec (see Fig. 7.7.7), the fluorescence will be emitted with the same degree of polarization and will pass through a second polarizer (or analyzer) oriented parallel to the first polarizer. If, on the other hand, the excited chromophores rotate before fluorescence takes place, emission will take place from a smaller number of molecules reoriented with transition dipoles parallel and perpendicular to the exciting radiation

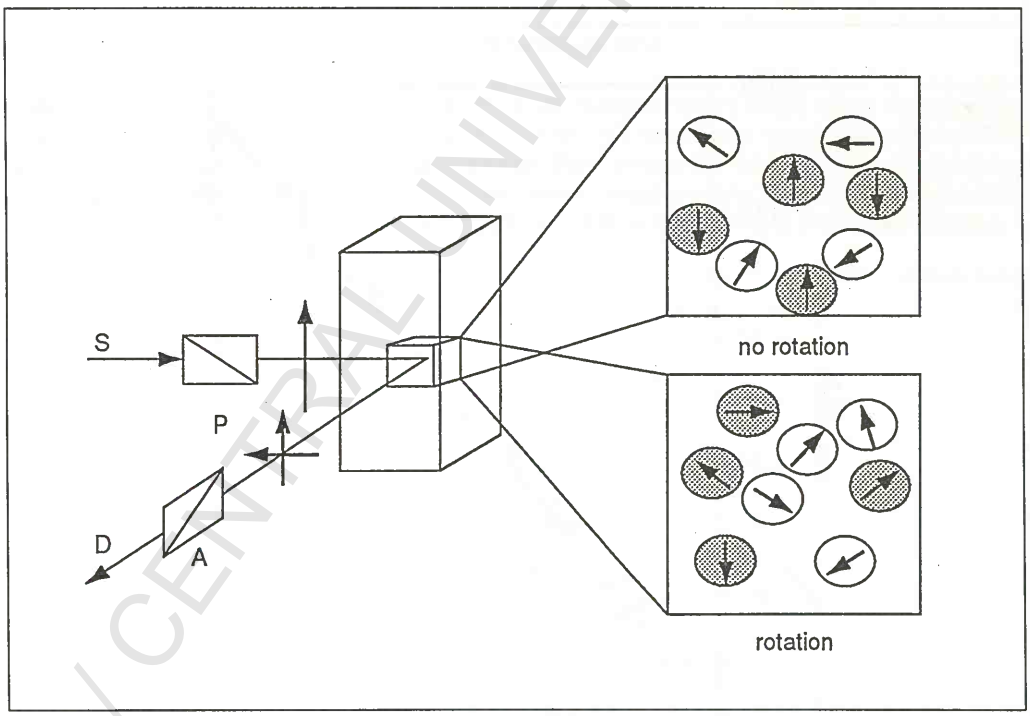

Figure 7.7.12 Depolarization of fluorescence indicates rotation of the chromophore. Monochromatic radiation from the source (S) has all but the vertically polarized electric vector removed by the polarizer (P). This is absorbed only by those molecules (see Fig. 7.7.5) in which the transition dipole of the chromophore is aligned vertically. In the case where these molecules do not rotate appreciably before they fluoresce ("no rotation"), the same molecules will fluoresce (indicated by shading) and their emitted radiation will be polarized parallel to the incident radiation. The intensity of radiation falling on the detector (D) will be zero when the analyzer (A) is oriented perpendicular to the polarizer. In the case where the molecules rotate significantly before fluorescence takes place, some of the excited chromophores will emit radiation with a horizontal polarization ("rotation") and some with a vertical polarization. Finite intensities will be measured with both parallel and perpendicular orientations of the analyzer. The fluorescence from the remainder of the excited molecules will not be detected. The heavy arrows on the left of the diagram illustrate the case where there is rotation.

FCU IAS / CENTRAL UNIVERSITY LIBRARY

(Fig. 7.7.12). The emitted radiation is now said to be depolarized. The polarization (P) can be quantitated as

$$P = (I_{par} - I_{perp})/(I_{par} + I_{perp})$$

where I_{par} and I_{perp}, respectively, are the intensities measured parallel and perpendicular to the original plane of polarization, usually vertical.

For chromophores that are part of small molecules, or that are located flexibly on large molecules, the depolarization is complete—i.e., $P = 0$. A protein of, say, $M_r = 25$ kDa however, has a rotational diffusion coefficient such that only limited rotation occurs before emission of fluorescence and only partial depolarization occurs, measured as $1 > P > 0$. The depolarization can therefore provide access to the rotational diffusion coefficient and hence the asymmetry and/or degree of expansion of the protein molecule, its state of association, and its major conformational changes. This holds provided that the chromophore is firmly bound within the protein and not able to rotate independently. Chromophores can be intrinsic tryptophan or extrinsic, covalently bound fluorophores—e.g., the dansyl (5-dimethylamino-1-naphthalenesulfonyl) group. More detailed information can be obtained from time-resolved measurements of depolarization, in which the kinetics of rotation, rather than the average degree of rotation, are measured. For further details, see Lakowicz (1983) and Campbell and Dwek (1984).

Although potentially powerful, the interpretation of fluorescence depolarization results requires extreme caution.

Table 7.7.1 provides a summary guide for interpreting results obtained using the techniques described in this unit.

In conclusion, given a protein in which tryptophan is partially or wholly buried, quantitative estimates of quenching by different quenchers provide a further fingerprint that is specific to the particular conformation of a recombinant protein and which, combined with other fluorescence, circular dichroism, and gel electrophoresis data, forms the basis for specific identification and quality assessment.

COMMENTARY

Background Information

Fluorescence depends on the atomic environment of the tryptophan and tyrosine residues and on their accessibility to solvent. Although the structural information is limited strictly to the immediate neighborhood of the relatively few aromatic residues, the cooperative nature of protein conformations means that changes in aromatic fluorescence frequently reflect more widespread changes in conformation. Similarly, measures of solvent accessibility obtained from fluorescence quenching reflect changes in the folding and packing of nonaromatic residues in a very sensitive way. Along with its sensitivity to small changes in conformation, fluorescence offers the additional advantage of requiring very small amounts of protein, in favorable cases down to tens of micrograms.

The method is less powerful in characterizing proteins lacking tryptophan, for reasons mentioned earlier (see Support Protocol), and does not apply at all to the rare proteins that lack both fluorophores. Near-UV circular dichroism measurements (*UNIT 7.6*) can still be of considerable value for proteins containing tyrosine and, in both cases, both far-UV circular dichroism and urea-gradient gel electrophoresis (*UNIT 7.4*) provide powerful contributions to characterization.

Extrinsic fluorescent probes can provide additional useful information about the integrity of protein conformation. 8-{2-[(iodoacetyl)ethyl]amino} naphthalene sulfonic acid (ANS) fluoresces only weakly in free solution but strongly when bound to a nonpolar surface. Originally used as a competitive probe to monitor fatty-acid binding to albumin, it has been widely used in studies of protein conformation—in partially denatured states at equilibrium as well as in transient intermediates that accumulate during protein folding (reviewed

BOSTON BIOMEDICAL RESEARCH INSTITUTE LIBRARY

by Christensen and Pain, 1994). Fully folded native proteins in general bind only limited amounts of ANS, although these are sufficient to characterize the surface hydrophobicity of a number of proteins (Cardamone and Puri, 1992). Fully unfolded proteins do not bind ANS. Partially folded or partially unfolded proteins will, however, bind ANS—indicating the presence of associated nonpolar groups that constitute a surface site, or the existence of relatively loosely packed hydrophobic cores into which ANS can intercalate. This and sim-

Table 7.7.1 Summary of the Interpretation of Fluorescence Spectra of Proteins[a,b]

1. All fluorescence of a protein is due to tryptophan, tyrosine, and phenylalanine, unless the protein contains another fluorescent component.
2. Maximum fluorescence of tryptophan occurs at lower wavelengths (<350 nm) and has greater intensity the lower the polarity of its environment.
   a. If λ_{max} is located at lower wavelengths when the protein is in a polar solvent—e.g., water—the tryptophan must be buried in a nonpolar environment.
   b. If λ_{max} is shifted to shorter wavelengths when the protein is transferred to a nonpolar medium, either the tryptophan is on the surface of the protein or the solvent induces a conformational change that causes it to be exposed to the solvent.
3. If a substance known to be a quencher quenches tyrosine and/or tryptophan fluorescence in a protein, these residues must be on the surface. If it fails to do so, there are several possible reasons:
   a. The residue may be buried in the interior of the protein.
   b. The residue may be in a crevice whose dimensions are too small for the quencher to enter.
   c. The residue may be in highly charged surroundings whose charge may repel a quencher with the same charge. In such a case, a quencher of the opposite charge or no charge would be expected to quench the fluorescence.
4. If a substance that does not affect the quantum yield of the free amino acid affects the fluorescence of a protein, it probably does so by inducing a conformational change in the protein.
5. If tryptophan or tyrosine are in a polar environment, their quantum yield decreases with increasing temperature, whereas in a nonpolar environment there is little change. Deviation from a monotonic decrease with increasing temperature signifies a change in polarity of the tryptophan environment, the sign of the change indicating the direction of change in polarity. Either indicates a conformational change in the protein.
6. Tryptophan fluorescence is quenched by protonated acidic groups, either in the neighboring environment or covalently attached as an α-carboxyl group. If the fluorescence changes with a particular pK, then a residue with that pK must be close to the tryptophan. Such an interpretation only holds if evidence is provided that no pH-induced conformational change taking place.
7. If the binding of a substance is accompanied by quenching of tryptophan fluorescence, either there is a resulting conformational change or tryptophan is in or very near the binding site. Furthermore, because a decrease in polarity causes a shift to shorter wavelengths, a decrease in λ_{max} on binding indicates that water is excluded in the complex.
8. If the absorbance spectrum of a small molecule overlaps the emission spectrum of tryptophan and if the distance between them is small, quenching will be observed. If binding of such a molecule to a protein quenches tryptophan fluorescence, tryptophan must be in or near (<2 nm away from) the binding site.

[a]Adapted from Freifelder (1982). Reproduced with permission of W.H. Freeman, New York.

[b]In making these interpretations, two important facts must be borne in mind. First, fluorescence is so sensitive to environmental factors that alternative interpretations must always be considered. Second, if a protein contains more than one tryptophan, each may have a different quantum yield. For this reason the absolute magnitude of changes cannot be used to determine the fraction in a given environment.

CU IAS/CENTRAL UNIVERSITY LIBRARY

ilar probes are mainly used as empirical indicators of conformational change, as the detailed mechanisms of interaction are not well defined. Fluorescence energy transfer, which can be observed when the absorbance spectrum of a fluorescent probe such as the dansyl group overlaps the emission spectrum of tryptophan, provides a means of estimating distances between groups, and hence of conformation and conformational change. An example where this approach is used alongside ANS fluorescence to follow protein folding is reported by Agashe et al. (1995).

In the present context, fluorescence is an important tool for the rapid comparison of a sample of recombinant wild-type or mutant protein with a standard sample of the recombinant or the authentic protein, as part of the process of characterizing and authenticating a recombinant protein. Coupled with measurements of the depolarization of fluorescence, the method can provide information on the dynamics of a protein and on the change in dynamics in response to, for example, binding of ligands.

Critical Parameters

Recording a spectrum is basically very simple, but the critical element is to avoid the production of artifacts. For this reason, it has to be emphasized that scrupulous attention to the cleanliness of cells and of the cell compartment of the spectrofluorimeter is essential, as is attention to the clarification of solutions and buffers (see Strategic Planning).

It is important also to make intelligent choices in the selection of instrumental parameters to optimize resolution and signal-to-noise ratio (see Basic Protocol 1).

Troubleshooting

One of the main causes of artifacts in the spectroscopy of proteins is the frequent tendency of proteins to aggregate, either during the folding step in recovery from inclusion bodies or as a result of the delicate balance of solubility of many proteins. For this reason, it is important to pay strict attention to monitoring aggregation (see discussion of Clarification of Solutions in Strategic Planning).

Light Scattering

Light scattering methods can provide information about the native molecular weight, oligomeric composition, and gross conformation of a protein in solution. These methods are particularly well suited for studying large oligomeric systems or glycoproteins and can be used to characterize much larger structures involving protein such as viruses and even bacterial spores (Harding, 1997). Light scattering techniques are not so well suited for characterization of smaller protein systems (where the molecular weight, M, is <30,000 Da); in these cases other methods such as analytical ultracentrifugation (*UNIT 7.5*) and solution X-ray scattering are more suitable. All light scattering measurements on solutions of proteins and protein assemblies are based on the principle of analyzing the intensity of light scattered by the solution (Fig. 7.8.1), either in terms of the time-averaged intensity ("classical" or "static" light scattering) or intensity fluctuations with time ("dynamic" or "quasielastic" light scattering) at a given angle or series of angles.

There are three types of "static" light scattering experiment:

1. Turbidimetry, which is simple but gives only crude molecular-weight estimates for large assemblies;
2. Low-angle light scattering, which is also simple and gives molecular-weight and molecular-weight-distribution information;
3. Multiangle light scattering, which gives more reliable molecular-weight and molecular-weight-distribution information and, for proteins of molecular weight at least ~50,000 Da, solution conformation information.

There are also three types of "dynamic" light scattering measurements:

1. Fixed-angle (90°-angle) measurements, which are simple and give an estimate for the translational diffusion coefficient and an idea of sample polydispersity for approximately globular macromolecules;
2. Variable-angle measurements, which are less simple, give more reliable estimates for translational diffusion coefficient and sample polydispersity, and can in some circumstances yield an estimate for rotational diffusion coefficients;

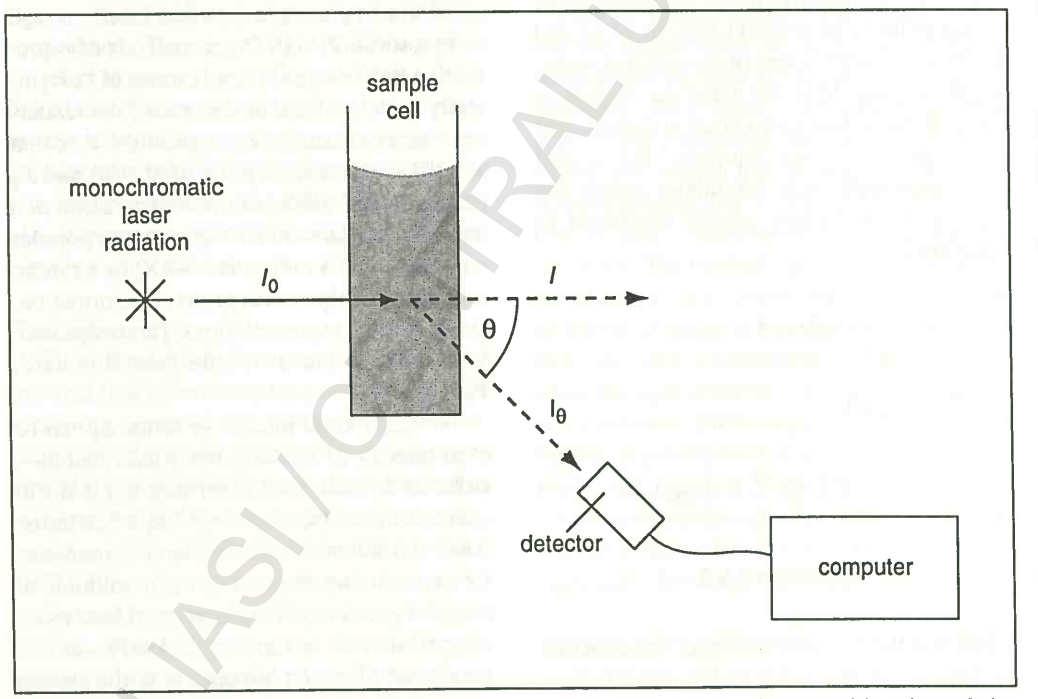

Figure 7.8.1 Light scattering studies on biomolecular solutions involve consideration of the relationship between the time-averaged scattered light intensity, $I(\theta)$, with the incident intensity, I_0, and angle of detection, θ ("static light scattering") or of the rapid fluctuations of the scattered intensity, $I(\theta)$, with time, τ ("dynamic light scattering"). Turbidimetry involves static light scattering measurements on the relation between I_0 and transmitted light intensity, I (at zero angle) alone.

STATIC LIGHT SCATTERING ANALYSIS OF PROTEIN SOLUTIONS

Basic Theory

The basic equation for the angular dependence of light scattered from a solution of proteins or protein assemblies is the Debye-Zimm relation (Zimm, 1948), shown in Equation 7.8.1,

$$\frac{Kc}{R_\theta} = \frac{1}{MP(\theta)}(1 + 2A_2c + \ldots)$$

Equation 7.8.1

In this equation, A_2 (ml mol/g^2) is the thermodynamic (2nd virial) nonideality coefficient. R_θ is the Rayleigh excess ratio (the ratio of the intensity, I_θ, of excess light scattered compared to pure solvent) at an angle θ to that of the incident light intensity, I_0 (a correction term is necessary if unpolarized light is used but not necessary if lasers are used). K is an experimental constant dependent on the square of the solvent refractive index, the square of the refractive index increment (*dn/dc* in ml/g), and the inverse fourth power of the incident wavelength, λ (cm). M is the molecular weight in Da, c is the solute concentration (g/ml), and $P(\theta)$ is the form factor. Equation 7.8.1 is valid if the proteins/protein assemblies satisfy the Rayleigh-Gans-Debye criteria illustrated in Equation 7.8.2:

$$\left|\frac{n}{n_0} - 1\right| << 1$$

and

$$\left(\frac{4\pi n_0}{\lambda_0}\right) d \left|\frac{n}{n_0} - 1\right| << 1$$

Equation 7.8.2

where n is the refractive index of the solution, n_0 is the refractive index of the solvent, λ_0 is the incident wavelength (in vacuo), and d is the maximum dimension of the particle. The form factor $P(\theta)$ can also be given to a good approximation by Equation 7.8.3,

$$\frac{1}{P(\theta)} \approx \left[\frac{1 + 16\pi R_\theta^2}{3\lambda^2} \sin^2\left(\frac{\theta}{2}\right)\right]\left(\frac{1}{M} + 2A_2c\right)$$

Equation 7.8.3

R_g is extensively referred to as the "radius of gyration" of the macromolecule and c is the solute concentration (g/ml). If the solute is heterogeneous, M (g/mol = Da) will be a weight average, M_W, and R_g a z-average. Equation 7.8.1 is generally a good representation for particles whose maximum dimension is between $\lambda/20$ and λ. Since λ is typically ~600 nm, this covers all proteins and protein assemblies up to the sizes of filamentous viruses. For larger particles, much more complex representations are necessary.

For particles of dimension $<\lambda/20$ ($M <$ 50,000 Da) the angular term in Equation 7.8.1 is small. No angular-dependence measurements are necessary to obtain M (although R_g cannot be obtained; if this is needed then X-ray or neutron solution scattering measurements need to be employed instead). For particles of dimension $>\lambda/20$, a double extrapolation to zero angle and zero concentration is necessary. This is usually performed on a grid-like plot referred to as a "Zimm plot" or via measurement at a single angle assumed small enough so that $\sin^2(\theta/2) \sim 0$. Other methods of representing the data have been in terms of "disymmetry": $z(\theta)$ (defined as the ratio of the scattering intensity at an angle θ, typically 45°, to that at 180° − θ) versus θ plots. Both $z(\theta)$ and R_g provide useful guides to the conformation of a macromolecule, with $z(\theta)$ being more popular with linear DNA molecules and R_g being more suited for descriptions of protein conformation. Other useful representations for nonprotein systems are also available (see Burchard, 1992).

For fairly rigid protein systems, R_g can be used directly to model gross conformation—either as an additional parameter to the diffusion coefficient (see Dynamic Light Scattering Analysis) and other hydrodynamic parameters for representing the structure in solution of complex protein systems in terms of bead modeling (Garcia de la Torre et al., 1997)—or as a parameter, after combination with the second virial coefficient A_2 and a parameter from solution viscometry known as the intrinsic viscosity, for representing the triaxial structure of a protein (Harding et al., 1997).

The principal useful parameters to be derived from static light scattering measurements

BCU IASI / CENTRAL UNIVERSITY LIBRARY

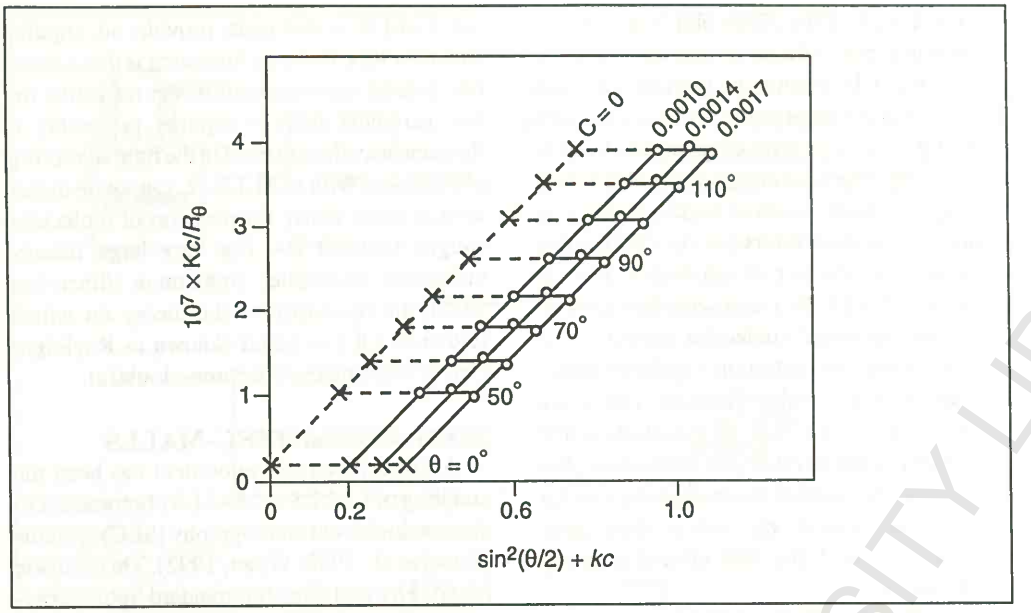

Figure 7.8.2 Zimm biaxial plot for a (diptheria) toxin-antibody aggregate. The arbitrary scaling constant, *k*, equals 200 ml/g. The molecular weight (M_w) as calculated from the (reciprocal) common intercept of the $c = 0$ and $\theta =$ lines is equal to ~78×10^6 Da. Data from Johnson and Ottewill (1954) and Johnson (1993).

are thus M, R_g, and to a lesser extent A_2. M can be obtained to a reasonable accuracy (usually to within 5%). The extraction of R_g is more difficult, requiring considerable care in the form of the angular extrapolation, and becomes even more difficult as the lower limit of $\lambda/20$ is approached. The use of light scattering photometers incorporating a flow cell that can be linked directly on-line to size-exclusion chromatography columns is becoming increasingly popular, particularly for the characterization of polydisperse systems (the hallmark, for example, of many glycoproteins), and as an on-line sample clarification system.

Turbidimetry

Turbidimetry involves the measurement of the total loss of intensity by a solution through scattering, summed over the entire angular intensity envelope and compared with the intensity of the incident radiation. It can be used to measure the molecular weights of protein assemblies of $M > 10^5$ Da (Bahls and Bloomfield, 1977). It is a type of measurement that can be performed on a good-quality spectrophotometer (i.e., one whose detector does not accept appreciable amounts of scattered light). Measurements have to be made at wavelengths away from the influence of absorption maxima.

Low-Angle Light Scattering (LALLS)

As θ approaches 0, Equation 7.8.1 becomes Equation 7.8.4:

$$\frac{Kc}{R_\theta} = \frac{1}{M} + 2A_2c$$

Equation 7.8.4

Low-angle light scattering photometers permit the measurement of Kc/R_θ at one fixed, small scattering angle θ (usually <8°) at which Equation 7.8.4 is taken to be valid (see Jumel et al., 1992). Although the angle used is assumed low enough that no angular correction of the scattering data is required, an extrapolation to zero concentration of Kc/R_θ may be necessary. The method can thus provide values for M and A_2 of a system, but not for R_g since no record is made of the angular dependence of Kc/R_θ. At low concentration, and especially when the light scattering detector is on-line to size-exclusion chromatography columns, the further approximation that $2A_2c \sim 0$ can be made, and hence M is simply $\sim R_\theta/Kc$. Since lasers are now routinely used as the light source, this technique takes the popular acronym of "LALLS" (low-angle laser light scattering).

Multiangle Light Scattering (MALLS)

Multiangle light scattering measurements are based on the full Debye-Zimm equation (Equation 7.8.1). Performing measurements at multiple angles permits extrapolation of the ratio Kc/R_θ to zero $\sin^2(\theta/2)$, which, together with an extrapolation to zero concentration,

POLISH ACADEMY OF SCIENCES CENTRAL UNIVERSITY LIBRARY

forms the basis of the Zimm plot (Fig. 7.8.2), a method that can yield M, A_2 and R_g.

Values for A_2 returned are typically between 10^{-5} ml mol/g^2 (for globular proteins) and 10^{-3} ml mol/g^2 (for large glycoconjugates). A warning is in order here—a common misconception is to ignore these values as small numbers. In actuality, it is the product $2 \times A_2 \times M \times c$ that manifests the influence of nonideality. The expression $1/(1 + 2A_2Mc)$ represents the factor by which an "apparent" molecular weight measured at a finite concentration c underestimates the true or "ideal" value (Tanford, 1961). An opposing effect to that of thermodynamic nonideality is that of reversible interaction phenomena (as represented for example by a molar dissociation constant, K_d), and in some cases ("pseudoideality") the two effects approximately cancel.

As with LALLS, lasers are now routinely used as the light source, and hence the acronym "MALLS" (multiangle laser light scattering) has now been adopted. Besides the potential for extracting R_g, a more important advantage of MALLS over LALLS is that the angular extrapolation permits identification and avoidance of any spurious results at the lowest angles. Plots of Kc/R_θ are only linear over a limited range of angles. For globular proteins of $M <$ 50,000 Da (corresponding to a maximum dimension ~$\lambda/20$), the angular dependence of K_c/R_θ will be negligible, permitting a more accurate determination of M but of course excluding the possibility of measuring R_g. As with LALLS, at low concentration, the further approximation that $2A_2c \sim 0$ can be made; hence Equation 7.8.1 reduces to

$$\frac{Kc}{R_\theta} = \frac{1}{MP(\theta)}$$

Equation 7.8.5

and where there is no angular dependence, this reduces further to $M \sim R_\theta/Kc$, as noted above.

Limitations of Static Light Scattering Methods

The principal limitation for all these "static" light scattering measurements is the need for sample clarification to avoid dust and supramolecular aggregates (see Clarification of Solutions and Scattering Cells). This is especially serious if solutions of proteins of M <50,000 Da are being studied, and also if LALLS is used, since large-particle contamination effects become disproportionally larger at low angles and the LALLS instruments provide no angular check for this. Another limitation is that a separate precise measurement of the refractive index increment dn/dc is required, preferably at the same wavelength used in the light scattering photometer. With MALLS, R_g cannot be measured as noted above for particles of molecular weight <50,000 Da. For very large macromolecular assemblies (maximum dimension >$\lambda/2$), the reliability of the theory on which Equation 7.8.1 is based (known as Rayleigh-Gans-Debye theory) becomes doubtful.

SEC-LALLS and SEC-MALLS

A revolutionary development has been the coupling of LALLS or MALLS photometers to size-exclusion chromatography (SEC) systems (Jumel et al., 1992; Wyatt, 1992). This is made possible by replacing the standard light scattering cuvette with a flow cell that can be coupled downstream from an HPLC pump and size-exclusion chromatography column(s), and upstream from a (UV-absorption or refractive index) concentration detector (Fig. 7.8.3). This has the double advantage of providing an online clarification system to remove supramolecular contamination and allowing fractionation of polydisperse materials prior to light scattering analysis. However, care must still be taken, particularly against the spurious shedding of column material. The coupled SEC systems are referred to as "SEC-LALLS" or "SEC-MALLS."

Samples for Analysis in Static Light Scattering

Solutions should be dialyzed against an appropriate buffer of defined pH and ionic strength, I. Normally an ionic strength of at least 50 mM is needed to suppress the contribution of molecular charge on the protein to the nonideality coefficient (A_2 in Equation 7.8.1) although, of course, the I chosen will obviously depend on its effect on the protein.

The concentration of protein required depends on: (1) its molecular weight, since the scattering signal is approximately proportional to the product of concentration and molecular weight; (2) the output of the laser; and (3) the clarity of the solutions, since substantial material may be lost on filtering or from the column in SEC-LALLS or SEC-MALLS. For scrupulously clean solutions, a 5-mW laser for a loading concentration of ~3-mg/ml is sufficient for proteins of molecular weight ~40,000 Da. For smaller proteins, a proportionally higher con-

BCU IAS CENTRAL UNIVERSITY LIBRARY

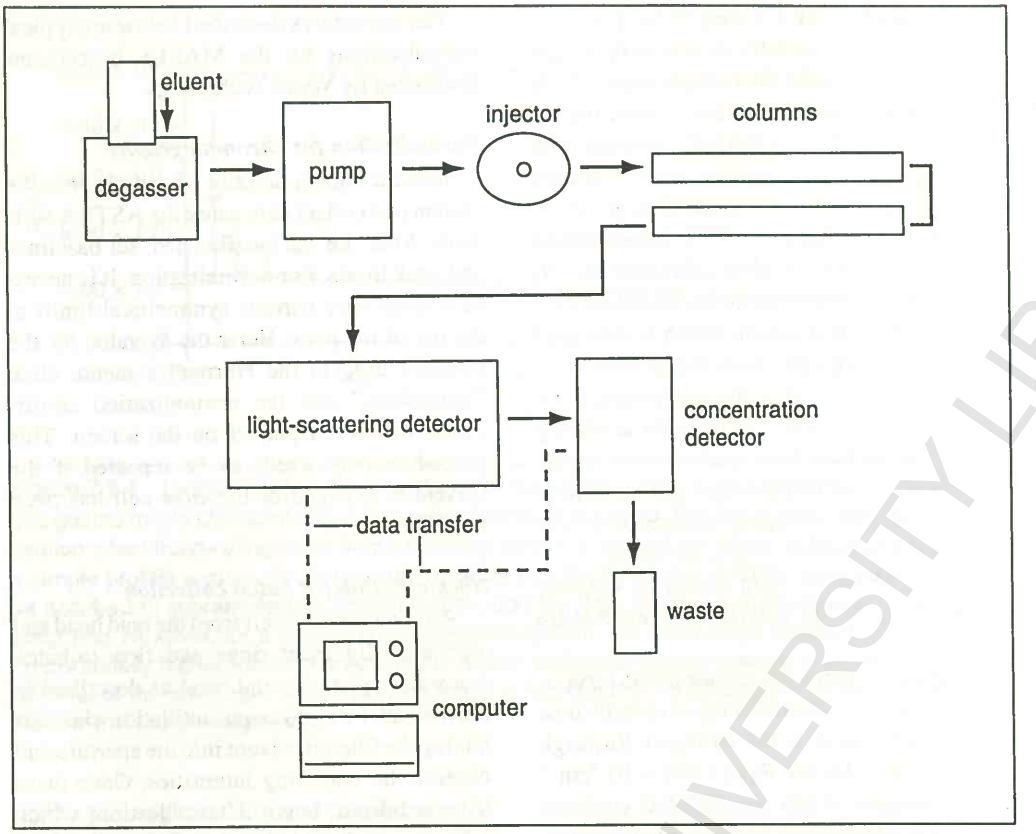

Figure 7.8.3 Experimental setup for SEC-MALLS (see Wyatt, 1992).

centration and/or higher laser power is required.

With regard to volume requirements, if a flow cell arrangement is used (linked, e.g., to an SEC system), loading volumes can be as low as 0.1 ml. For use with scintillation vials (which are nowadays used instead of fluorimeter-type cuvettes), ≥3 ml of solution is required. Square cuvettes, of course, prevent measurements in the angular part of the scattering envelope near the corners of the cuvette; if cylindrical cuvettes are employed, then small diameters (<2 cm) are to be avoided because of extraneous scattering or reflections from the glass walls, although large-diameter cuvettes can be expensive in terms of quantity of solution required. Flow cells are now preferred, and a typical experimental set up would have MALLS coupled to an SEC, but with a separate injection port (via a filter or guard column) if the SEC separation is not needed.

Clarification of Solutions and Scattering Cells

For molecular weights <200,000 Da, the most serious experimental problem has been that of clarification. All traces of dust and supramolecular aggregates have to be removed since experiments on incompletely purified material are "not useful" (Johnson, 1993), and clarification can lead to a significant loss of material. Contaminating particles can be removed by ultracentrifugation and ultrafiltration.

If scintillation vials are used, these too must be scrupulously clean. They should be cleaned and rinsed in double-distilled water, then dried and covered with aluminum foil to prevent any dust from entering the vials. It is also extremely important that there are no scratches or fingerprints or other marks on the outside of the vial. Sample preparation for batch work should, if possible, be carried out in a flow cabinet to prevent any dust from entering the solutions.

If a flow-cell device is used for clarification (Sanders and Cannell, 1980), this too will frequently need to be removed and cleaned using detergent, acetic acid, and a final necessary rinse with ultrafiltered water. An acetone reflux may also be occasionally necessary. When attached to an SEC column, prior to solution injection and after all the solution has been eluted, the solvent eluant must be monitored for any shedding from the column material. When the solution is injected, this needs to be done via a Millipore filter of appropriate size.

BOSTON UNIVERSITY LIBRARY

Calibration (LALLS and MALLS)

The quantities directly measured by a light scattering photometer are voltages and not light scattering intensities. For this reason, the instrument has to be "calibrated"—usually with a strong Rayleigh scatterer with a known Rayleigh ratio such as toluene (Stacey, 1956; Johnson and McKenzie, 1977). Measurement of the scattered and incident light intensities (I_θ and I_0, respectively) then facilitates calculation of the calibration constant, which is then used to calculate Rayleigh ratios for sample solutions from the output of the instrument. Calibration does *not* mean that the light scattering measurements have to be made relative to protein standards as in calibrated gel chromatographic methods. A typical calibration procedure would include the following steps.

1. Switch on the light scattering detector and laser at least 1 hr before measurements are made.
2. Make sure that the sample cell is scrupulously clean and the calibrating solvent (in most cases toluene as it is the strongest Rayleigh scatterer with a known R_θ of 1.406×10^{-5}cm^{-1} at a wavelength of 633 nm) is HPLC grade.
3. Inject the solvent into the cell via a membrane filter (preferably ≤0.2 μm pore size).
4. Measure the scattered light intensity and calculate the instrument calibration constant by means of the dedicated software (e.g., ASTRA, Wyatt Technology), using the known Rayleigh ratio of the solvent.

Normalization (MALLS)

For simultaneous multiangle detection in MALLS photometers of the type now commonly available, the detectors have to be "normalized" to allow for the different scattering volumes as a function of angle and the differing responses of the detectors. This is normally achieved using a solution of molecules that scatter light isotropically (i.e., with equal intensity in all directions)—as is the case when the diameter of the sample molecule is less than ~λ/20 of the incident wavelength. The best molecules of this kind for use in a chromatography system are either a polystyrene standard in toluene or tetrahydrofuran (THF) with molecular weight of ~30,000 Da or a pullulan or dextran standard of 20,000 to 30,000 Da in aqueous solution; the R_g of these molecules is ~5 nm. In the batch mode—i.e., with the sample in a vial–10 mg/ml solutions of 4000-Da polystyrene in toluene or THF, or 5000 Da pullulan in water work well; these standards have R_g's of ~2 nm.

The procedures described below are typical normalizations for the MALLS instruments distributed by Wyatt Technology.

Normalization for chromatography

Inject a known amount of sample into the system and collect data using the ASTRA software. After the run has finished, set baselines and peak limits. For normalization, it is necessary to set very narrow, symmetrical limits at the top of the peak. Enter the R_g value for the standard used in the Normalize menu, click "normalize," and the normalization coefficients will be displayed on the screen. This procedure only needs to be repeated if the solvent is changed or the flow cell has been cleaned.

Normalization for batch collection

Remove the flow cell from the read head and assemble alignment rings and flow-to-batch conversion plate in read head as described in the manual. First, place a scintillation vial containing the filtered solvent into the aperture and observe the scattering intensities. Once these have stabilized, begin data collection, which will stop after a preset volume. Save the data. Next, insert the vial containing the sample for normalization measurement and again wait for signals to stabilize. Append the file containing the values for the solvent. After collection has stopped, measure the scattering for the solvent again. Set a baseline and peak limits that cover most of the plateau corresponding to the normalization standard. Go to the Normalization menu and enter the concentration and R_g of the normalization standard. Click "normalize" and the normalization coefficients will appear on the screen.

Evaluation of Molecular Weight (LALLS)

After measurement of R_θ, the molecular weight, M, can be calculated from this value, the concentration, the experimental constant K, and a subsequent extrapolation to $c = 0$ (Equation 7.8.4) if the nonideality term A_2c is significant. The concentration, c (from, e.g., UV absorbance or refractometry) should be known as accurately as possible.

Evaluation of Molecular Weight and Radius of Gyration (MALLS).

If the nonideality term A_2c (and of course any higher-order terms) is insignificant (i.e., if the measurements can be performed at low enough concentration), then only an extrapola-

BCU IASTER CENTRAL UNIVERSITY LIBRARY

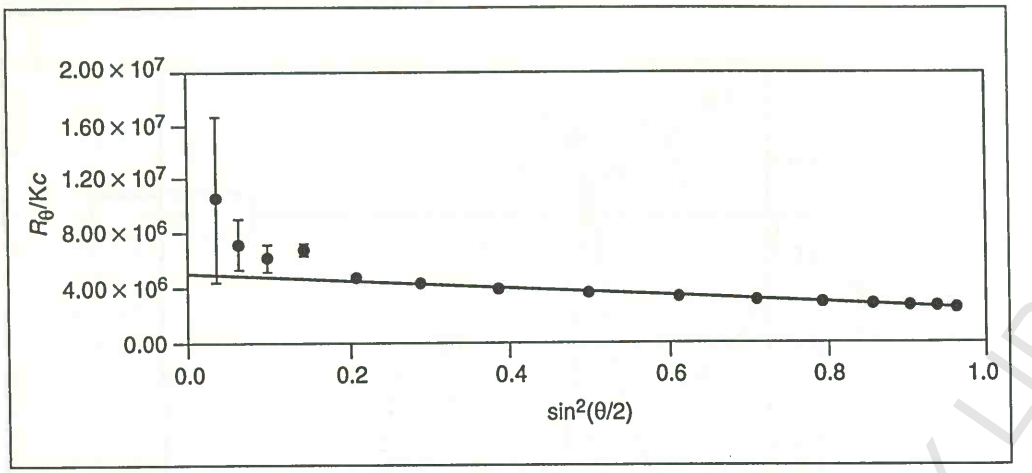

Figure 7.8.4 Debye plot (angles from 21.7° to 58.3°) for a heavily glycosylated protein system (pig gastric mucin glycoprotein). A first-order (linear) fit is shown. This figure illustrates the need for caution when interpreting static light-scattering data: the upward curvature at the lower angles for a simple protein system (or downward curvature in a Kc/R_θ versus $\sin^2(\theta/2)$ plot) would normally be ascribed to supramolecular contamination, and the data points would be ignored or given low weighting. However, for a genuinely polydisperse system, the lower-angle measurements contain proportionally higher information about the higher-molecular-weight species in a distribution, and removal of the low-angle data and/or choice of a first-order fit could bias the distribution towards the low-molecular-weight end.

tion to zero angle and not zero concentration is necessary (see Equation 7.8.5). Sometimes the inverse form of Equation 7.8.4 is used, known as a "Debye plot" of R_θ/Kc versus $\sin^2(\theta/2)$ (Wyatt, 1992). Although this invokes a further approximation, the ordinate axis does correspond to an apparent molecular-weight axis (Fig. 7.8.4). It must be noted that Figure 7.8.4 is a rather extreme example for a highly glycosylated and polydisperse system. Figure 7.8.4 also shows that care must be taken in choosing the appropriate fit, and that there is a proportionally larger effect at low angles of supramolecular contaminants. The order of the fit chosen (usually linear or quadratic) has a more dramatic effect on the (limiting) slope of such plots and hence on the value for R_g returned. This feature needs to be borne in mind when conclusions on macromolecular conformation based on the relationship between M and R_g are being drawn, particularly using the SEC-MALLS devices considered below.

If the nonideality term is significant, and an assumed value for A_2 cannot be taken as zero (which can in fact be predicted from the triaxial shape of the protein; Harding et al., 1997)—and charge effects are not significant, then an additional extrapolation to zero concentration is necessary. Both angular and concentration extrapolations are usually done on the same plot, known as a Zimm plot (Fig. 7.8.2), which can yield M from the reciprocal of the common intercept, and estimates for A_2 (from the $\theta = 0$, c extrapolation line) or R_g [from the $c = 0$, $\sin^2(\theta/2)$ extrapolation line]. However it cannot be overstressed that the R_g returned can be very sensitive to the order of extrapolation used. An arbitrary (positive or negative) constant k is used on the abscissa to scale the data points better.

Evaluation of Molecular Weight Distribution (SEC-LALLS) and (SEC-MALLS)

Absolute molecular weight distributions (Fig. 7.8.5) of mixed protein systems or glycosylated protein systems such as mucins, glycoproteins, or glycosaminoglycans may be obtained with either of the above techniques.The sample is injected via the injection valve and separated by the column system. Effluent from the column(s) is monitored by light scattering and concentration detectors. Once the peak area from the chromatogram has been chosen, the concentration and R_θ at each data point within this area are known from light scattering and concentration detectors, respectively, and the molecular weight (M) at each of these points is calculated using Equation 7.8.4 (for SEC/LALLS) or Equation 7.8.5 (for SEC/MALLS). Molecular weight averages for the whole of the peak area may then be calculated. In addition, a so-called "calibration plot" of molecular weight versus elution vol-

BOSTON BIOMEDICAL RESEARCH INSTITUTE LIBRARY

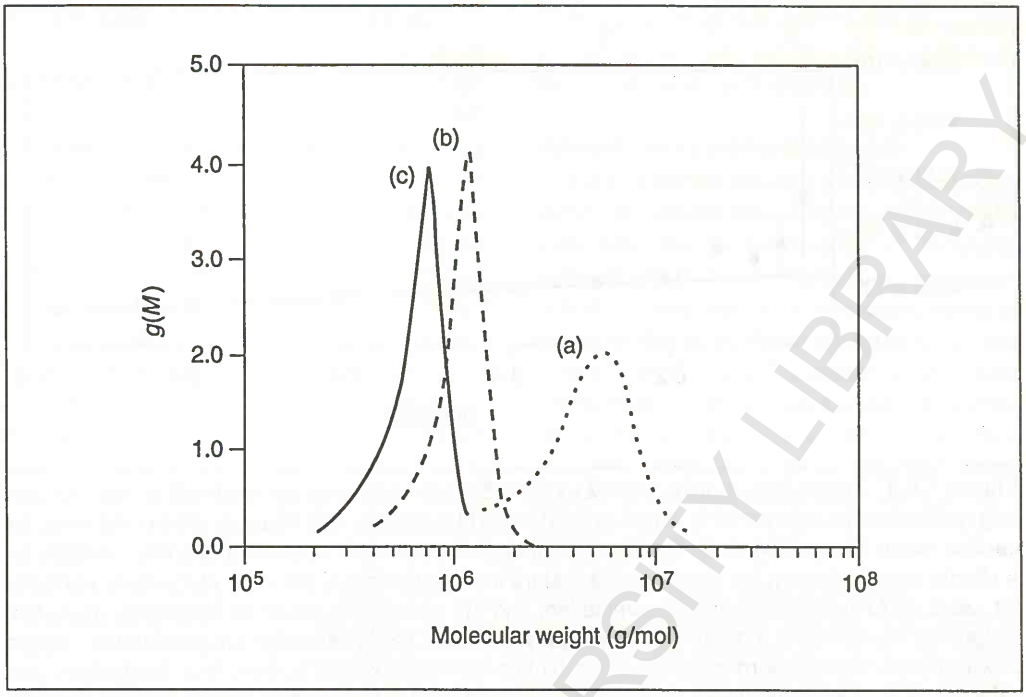

Figure 7.8.5 SEC-MALLS molecular-weight distribution for colonic mucin glycoprotein (peak a) and its thiol-reduced (peak b) and papain digested (peak c) forms (from Jumel et al., 1997). The quantity g(M) is in arbitrary units.

ume can be constructed, thus enabling the elution volume versus concentration plot to be converted to a molecular weight distribution. Such molecular weight distributions thus found will be absolute in the sense that, unlike with conventional SEC, calibration standards of known *M* are not required. This is particularly useful not only for protein mixtures but for heavily glycosylated systems because of their polydispersity and the difficulty in obtaining standards of the appropriate (often uncertain) conformation.

For a more detailed account of the theory the reader is referred to Yau et al. (1979).

DYNAMIC LIGHT SCATTERING ANALYSIS OF PROTEIN SOLUTIONS

Basic Theory

Whereas static light scattering is concerned with the time-averaged scattering intensity properties, dynamic light scattering is concerned with time fluctuations in intensity caused by motions of macromolecules and macromolecular assemblies. Whereas lasers are highly desirable for static light scattering because of their high intensity, collimation, and monochromaticity—with dynamic light scattering they are mandatory because of the requirement for spatial and time ("temporal") coherence—light has to be emitted from the source as a continuous wave rather than as short bursts.

The physics underlying dynamic light scattering is rather complicated (Brown, 1993), although the basic principle and experimental setup is relatively simple (Fig. 7.8.1 and Fig. 7.8.6). Laser light is directed onto a thermostatted protein solution, and the intensity is recorded at either a single angle or multiple angles using a photomultiplier/photodetector. The moving biomolecules will "Doppler broaden" the otherwise monochromatic incident radiation. The scattered intensity recorded as the number of photons received by a detector (photomultiplier) will fluctuate because of "beating interference" of scattered waves of different but similar wavelength. The situation is analogous to the fluctuations in intensity of a radio channel caused by interference from another radio channel of very close wavelength. This "broadening" of the otherwise monochromatic incident radiation is why the technique is often referred to as "quasielastic light scattering" or QLS. The detector sends the intensity signal to a special computer called an autocorrelator, which compares or correlates the intensity at different times (hence the other name often used—photon correlation spectroscopy or PCS).

BCU IAS / PERTANIAN UNIVERSITY LIBRARY

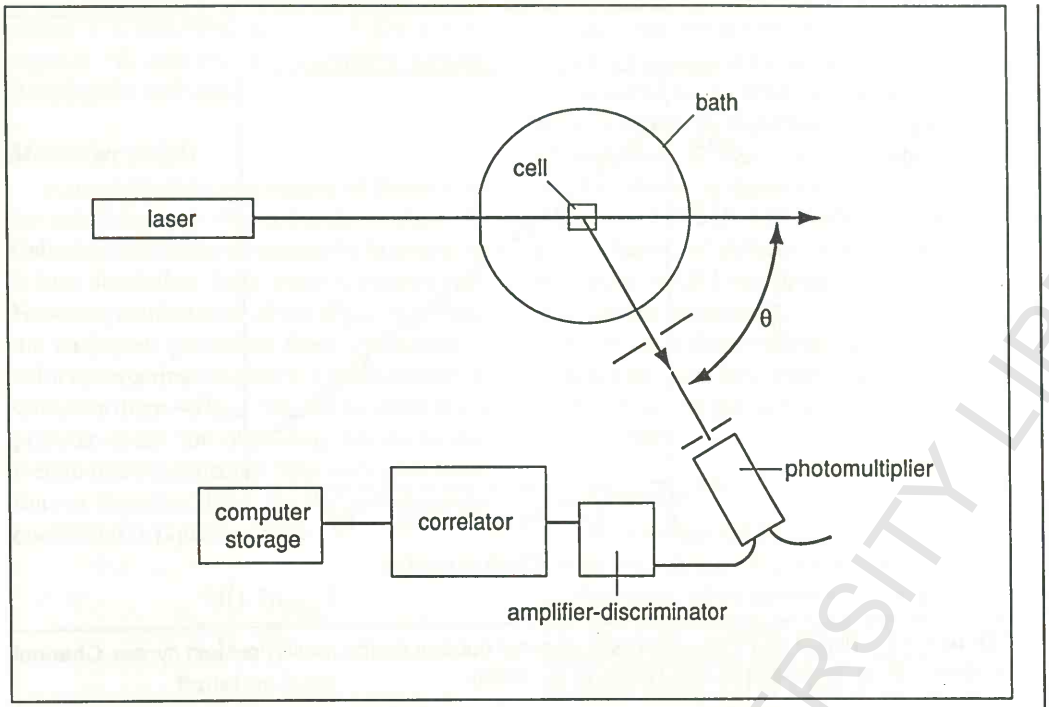

Figure 7.8.6 Schematic dynamic light scattering setup for multiangle measurement (see Johnson, 1993).

How rapidly the intensity fluctuates over short time periods or "delay times," τ (in nsec to msec depending on how mobile the scattering biomolecules/assemblies are), is represented by how a parameter known as the normalized intensity autocorrelation function—$g^{(2)}(\tau)$—decays as a function of τ. The superscript "(2)" is used to indicate that it is an intensity as opposed to an electric field or "(1)" autocorrelation function, and many data sets of $g^{(2)}(\tau)$ as a function of τ are accumulated and averaged. The amount of averaging necessary depends on the incident laser intensity and the size and concentration of the scattering biomolecule (at a given concentration, larger molecules scatter more). For globular proteins, sufficient data can usually be acquired over the time scale of one to several minutes. The calculation of the correlation function from the intensity fluctuations is performed after the signal has passed through an amplifier-discriminator via the autocorrelator. Calculation of the diffusion coefficient from the decay of $g^{(2)}(\tau)$ with τ is performed on a computer. Some of the most modern instrumentation (particularly fixed-angle photometers) have all of the units depicted in Figure 7.8.6 built into one instrument.

Analysis of how the normalized intensity autocorrelation function $g^{(2)}(\tau)$ decays as a function of τ can be used to evaluate the translational diffusion coefficient, D. For dilute systems of spherical or near-spherical (i.e., globular) biomolecules and assemblies, the variation of $g^{(2)}(\tau)$ with τ can be represented by the simple logarithmic equation

$$\ln\left[g^{(2)}(\tau-1)\right]=-2Dg^{(2)}\tau$$

Equation 7.8.6

where q is known as the Bragg wave vector whose magnitude is defined by $q = \{4\pi n/\lambda\}\sin(\theta/2)$—$n$ being the refractive index of the medium, θ being the scattering angle, and λ being the wavelength of the incident light. Thus D can be found from a plot of $\ln[g^{(2)}(\tau) - 1]$ versus τ, and Figure 7.8.7 shows an example for the motility protein dynein.

D can then be converted to standard conditions (i.e., the viscosity and temperature of water at 20.0°C) to give $D_{20,w}$ as noted above, and then extrapolated to zero concentration to give $D^0_{20,w}$. An additional extrapolation is necessary if the biomolecule is not globular: this is because at finite angles θ there will be an extra term on the right-hand side of Equation 7.8.6 deriving from rotational diffusional phenomena. This term approaches 0 as θ approaches 0; therefore true D can be measured according to Equation 7.8.6 so long as measurements of the apparent D are made at a

CHILIE

BOURAT CENTRAL UNIVERSITY LIBRARY

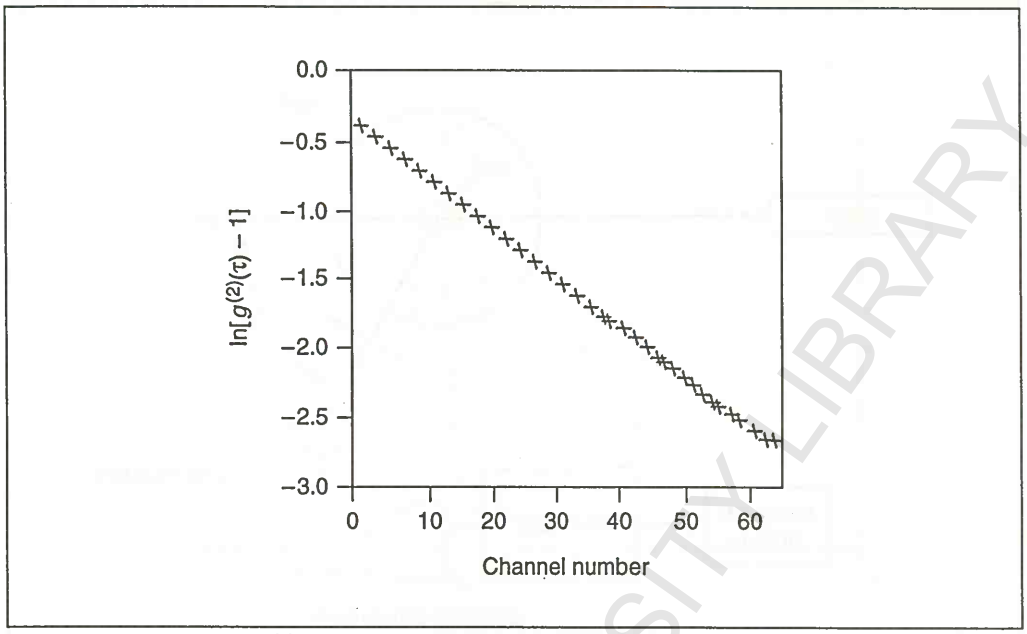

Figure 7.8.7 Plot of $\ln[g^{(2)}(\tau) - 1]$ versus channel number for the motility protein dynein. Channel number = delay time/sample time (Wells et al., 1990).

number of angles and at an additional extrapolation to zero angle (or Bragg vector q) is performed. The extrapolations to zero concentration and zero angle (or q) can be performed simultaneously on a biaxial extrapolation plot known as a dynamic Zimm plot (Burchard, 1992). If an angular extrapolation is not necessary, a scattering angle of 90° is usually chosen, and fixed-angle instruments are usually set at this angle (see Claes et al., 1992). At lower angles the problems due to supramolecular contamination are accentuated.

If a system is heterogeneous it is possible, at least in principle, to obtain a distribution of diffusion coefficients after various assumptions and mathematical manipulations of the autocorrelation data. The various methods of manipulation have been reviewed by Johnsen and Brown (1992) and several commercially available computer routines are available for performing these. A more simple way of representing heterogeneity is the polydispersity factor (PF) which is obtained by comparing linear with quadratic or quadratic with cubic-order fits of the normalized autocorrelation function decay data (Pusey, 1974).

Translational Diffusion Coefficient

The translational diffusion coefficient, $D_{20,w}$ or $D^0_{20,w}$, obtained by dynamic light scattering or boundary spreading in the ultracentrifuge, can be used to provide a number of useful characteristics about a biomolecular system.

Equivalent hydrodynamic radius (r_H)

The simplest deduction one can make from $D^0_{20,w}$ is the size of the biomolecule as represented by the equivalent hydrodynamic radius (also known as the Stokes radius)—r_H. What this means is, although the biomolecular system may not be a sphere at all, its diffusive behavior can be represented by an equivalent spherical particle of radius r_H. The value of r_H can be easily obtained from $D^0_{20,w}$ via the Stokes-Einstein relation:

$$r_H = \frac{k_B T}{6\pi\eta_{20,w} D^0_{20,w}}$$

Equation 7.8.7

where k_B, the Boltzmann constant, is equal to 1.379×10^{-16} erg/°K, T = 293.15°K and $\eta_{20,w}$ (the viscosity of water at 20.0°C) is equal to 0.01 poise. If D values are not corrected to standard conditions then the appropriate values for T and η have to be used.

Frictional coefficient (f)

The frictional coefficient provides a handle on molecular weight and shape as discussed below. Like r_H it can also be calculated simply from $D^0_{20,w}$ according to Equation 7.8.8.

$$f = \frac{RT}{N_A D^0_{20,w}}$$

Equation 7.8.8

BCU IAS CENTRAL UNIVERSITY LIBRARY

where T = 293.15°K and R = 8.314×10^{-7} erg/mol °K and N_A is Avogadro's number (6.022137×10^{23} mol).

Molecular weight

A more absolute description of biomolecular size than r_H is the molecular weight, *M*. Calculation of *M* from dynamic light scattering is less direct than from static measurements. However, combination of the $D^0_{20,w}$ value with the analogous parameter from sedimentation velocity experiments (*UNIT 7.5*) in the analytical ultracentrifuge—$s^0_{20,w}$ (in sec)—provides a popular route for obtaining the molecular weight of a biomolecule. The analogous equation to Equation 7.8.8 for the sedimentation coefficient is Equation 7.8.9.

$$f = \frac{M\left(1-\bar{v}\rho_{20,w}\right)}{N_A s^0_{20,w}}$$

Equation 7.8.9

Elimination of *f* between Equation 7.8.8 and Equation 7.8.9 yields the Svedberg (1927) equation (Equation 7.8.10):

$$M = \left(\frac{s^0_{20,w}}{D^0_{20,w}}\right)\left(\frac{RT}{1-\bar{v}\rho_{20,w}}\right)$$

Equation 7.8.10

where again T = 293.15°K. The variable $\bar{v}$ is the partial specific volume of the biomolecule (which can be measured from densimetry or from the composition of the biomolecule) and $\rho_{20,w}$ is the density of water at 20.0°C (0.9982 g/ml). It is possible in principle to measure both $D^0_{20,w}$ and $s^0_{20,w}$ simultaneously from analysis of the boundary shape in sedimentation velocity analytical ultracentrifugation, although in practical terms this needs data of very high quality and the absence of any effects of sample heterogeneity. Equation 7.8.10 also of course provides a route for measurement of $D^0_{20,w}$ if $s^0_{20,w}$ and *M* are known.

A simpler method for *M* measurement is possible if the conformation of the biomolecule is assumed and use is made of a power law relation, known as a Mark-Houwink relation (Equation 7.8.11):

$$D = KM^{-\varepsilon}$$

Equation 7.8.11

where $\varepsilon = 0.333$, 0.85, or 0.5 to 0.6 for sphere-, rod-, and coil-shaped molecules, respectively. From a calibration plot of log *D* versus log *M* for biomolecules of known *D* and *M* (Claes et al., 1992), *M* of an unknown can be found from its measured *D*. A conformation has of course to be assumed; the Equation 7.8.11 method for *M* evaluation is thus not as reliable as the method shown in Equation 7.8.10. Equation 7.8.11 can be taken even further in converting a distribution of diffusion coefficients into a molecular-weight distribution, although such distribution information is not as reliable (because of the approximations made) as that obtained with static light scattering methods coupled directly on-line to a gel-filtration column (Wyatt, 1992).

Conformation

The translational frictional coefficient (*f*) can be used directly to provide information on conformation. More convenient, however, is to use the corresponding dimensionless ratio called the frictional ratio (f/f_0), where f_0 is the frictional coefficient of a spherical particle of the same anhydrous mass and density as the biomolecule. The quantity f/f_0 can be calculated from $D^\circ_{20,w}$ by the relation in Equation 7.8.12.

$$f/f_0 = \left(\frac{k_B T}{6\pi\eta_{20,w}}\right)\left(\frac{4\pi N_A}{3\bar{v}M}\right)^{\frac{1}{3}}\left(\frac{1}{D^0_{20,w}}\right)$$

Equation 7.8.12

The frictional ratio depends intrinsically on the conformation, flexibility, and degree of solvent association (water plus other salt ions and any other solvent molecules) of the biomolecule. This degree of water association is termed the "hydration" of the biomolecule, δ, and is defined as the mass (in g) of associated solvent per g of anhydrous biomolecule. This associated solvent includes both chemically bound solvent and solvent physically entrained in the interstices of the molecule. The value of δ is typically between 0.2 and 0.5 g/g for proteins, although it is a notoriously difficult parameter to pin down with any accuracy.

The function defining the shape and flexibility of the biomolecule is the Perrin translational frictional function, *P*, illustrated by Equation 7.8.13:

$$P = (f/f_0)\left\{1+\frac{\delta}{\bar{v}\rho_0}\right\}^{-\frac{1}{3}}$$

Equation 7.8.13

ACU ... RAL UNIVERSITY LIBRARY

where ρ_0 is the density (g/ml) of the bound solvent. For a molecule that is fairly rigid on a time-averaged basis, the gross conformation can be specified using P in terms of the axial ratio of the equivalent hydrodynamic ellipsoid or in terms of sophisticated arrangements of spheres called hydrodynamic bead models. Computer programs are available for both types of modeling strategy (Harding et al., 1997; Garcia de la Torre et al., 1997)—although particularly with the latter, the diffusion coefficient should be used in conjunction with other hydrodynamic measurements to minimize uniqueness problems of the determined solution conformation.

Limitations of Dynamic Light Scattering Methods

As with static light scattering, the main limitations here relate to sample clarification. The technique is most suited to larger proteins and protein assemblies (M >100,000 Da) where problems due to contamination are less, and, as with static light scattering, the problems become disproportionally higher at the lower scattering angles. If the protein systems are approximately globular, then to a good approximation these low angles can be avoided and measurements at a single higher angle (usually 90°) can suffice. For nonspheroidal systems, angular extrapolations are necessary to eliminate rotational diffusion contributions. The user should also be wary of interpreting data from fixed-angle photometers, which do not permit such angular measurements.

The other limitations concern direct molecular-weight evaluation via Equation 7.8.11 and interpretation of the autocorrelation data in terms of polydispersity or size distribution. The user should be aware that such distributions are obtained purely by mathematical manipulation of the autocorrelation data, instead of involving a physical separation of different sizes (as with SEC-LALLS or SEC-MALLS), and the user is advised to be extremely cautious when interpreting such information produced by computer packages.

Samples for Analysis in Dynamic Light Scattering

Aqueous solvents should be of sufficient ionic strength to suppress charge effects. The loading concentrations required—which, as with static light scattering, should be measured *after* clarification—will depend principally on the size of the scatterer and the output from the laser. For example, if a 25-mW He-Ne laser is used, a loading concentration of at least ~1 mg/ml (and a volume of 2 to 3 ml) is required for a large protein assembly whose molecular weight (M) is ~5 × 10^6 Da. For proteins of molecular weight down to a lower limit of ~10,000 Da, more powerful lasers (~100 mW) and/or higher concentrations and/or longer experimental duration times are generally necessary to obtain meaningful results.

Temperature Control

D is very sensitive to temperature, mainly because of the dependence of diffusion on the viscosity of the solvent. Temperature needs to be controlled or, at the very least, monitored accurately during the measurement, and a water bath is highly desirable.

Clarification of Solutions and Scattering Cells

As with static light scattering, the scattering signal in dynamic light scattering is very sensitive to the presence of trace amounts of dust or supramolecular aggregation products; solutions and scattering vessels (called scattering cells or cuvettes) need to be scrupulously clean and free of particulates. Appropriate filtration, centrifugation of solutions, and washing of vessels with solvent is necessary. Special in-house cell-filling devices can be used along the lines described by Sanders and Cannell (1980); these can also be used for static light scattering.

Choice of Scattering Cuvette/Cell

The same criteria apply as with static light scattering (see Samples for Analysis in Static Light Scattering). The cell design depends on whether the photometer is a fixed-angle or multi-angle design.

Procedure for Making Scattering Measurements Using a Fixed-Angle Instrument with a Flow Cell

The following steps describe the injection procedure for a fixed (90°) angle photometer with a 20-mW infrared (780 nm) semiconductor laser (Claes et al., 1992).

1. The user should be satisfied that the protein/protein assembly is approximately globular. If not, then a multiangle instrument should be used (see Procedure for Making Scattering Measurements Using a Multiangle Instrument with a Conventional Cell).

2. Switch on the instrument and allow the laser to warm up 5 to 10 min.

BCU IAS CENTRAL UNIVERSITY LIBRARY

3. Inject pure ultrafiltered water or buffered solvent via a 0.1-μm filter to get the clean water count rate.

4. If the count rate is below the manufacturer's threshold, check the instrument alignment or increase the protein concentration.

5. Inject the protein solution in the same way as the water or buffer, using the appropriate filter, and check that the count rate meets the criteria specified by the manufacturer.

6. The choice of sample time and experimental duration time is normally done automatically.

7. Use the instrument's software to obtain the diffusion coefficient, and, where appropriate, the in-built calibration to directly obtain the approximate molecular weight.

8. Rinse and dry the flow cell of the photometer.

Procedure for Making Scattering Measurements Using a Multiangle Instrument with a Conventional Cell

1. Choose the appropriate cuvette or cell, using the same criteria (square versus cylindrical) as discussed above for static light scattering (see Samples for Analysis in Static Light Scattering).

2. Ensure that the cell is clear and free from dust and perform a check with pure ultrafiltered water, which should give only a negligibly small number of photon counts. Visually check for any "sparkling" in the laser beam passing through the water.

3. Remove the water from the cuvette, dry with ultrafiltered air, and inject the sample solution using the appropriate filter.

4. Set the goniometer for a scattering angle of 90°.

5. The choice of sample time and experimental duration time is normally done automatically.

6. Use the instrument's software to obtain the apparent diffusion coefficient, D_{app}. Inspect the autocorrelation decay plots (see Fig. 7.8.7). Nonlinearity can be due to sample polydispersity, particle asymmetry (effect of rotational diffusion phenomena), or particle settling (usually only observed for cellular systems, not for macromolecules). If it is not reasonable to assume an approximately globular system, then measure D_{app} at a series of angles and extrapolate to zero angle, but be aware of enhanced supramolecular contamination problems at the lower angles.

7. Remove the solution, rinse the cell with ultrafiltered pure water (after, if necessary, prior rinsing with detergent and mild acetic acid), dry with ultrafiltered air, and dry the cuvette.

Electrophoretic Light Scattering

Electrophoretic light scattering (ELS) uses dynamic light scattering to measure the velocity of migration, V, of a protein or other macromolecular system under the influence of an electric field, E (Langley, 1992; McNeil-Watson and Parker, 1992) The velocity V is related to the Doppler broadening, $\Delta\nu$, of the frequency of the incident laser radiation due to the velocity of the macromolecule. $\Delta\nu$ is related to V by Equation 7.8.14.

$$\Delta\nu = \left(\frac{2nV}{\lambda_0}\right)\sin\left(\frac{\theta}{2}\right)$$

Equation 7.8.14

The mobility, $U = V/E$, can thus be defined and hence the zeta potential, ζ:

$$U = \varepsilon\zeta/\eta$$

Equation 7.8.15

This procedure is however used more for the investigation of the stability of colloids rather than protein structure and so will not be discussed further here.

Measuring Protein Thermostability by Differential Scanning Calorimetry

Every chemical reaction is accompanied by heat effects that, at constant pressure, are described by the enthalpy of the process. Protein folding/unfolding, being an isomerization reaction between different macroscopic states, is no exception (Sturtevant, 1972; Privalov and Khechinashvili, 1974; Krishinan and Brandts, 1978). Temperature-induced changes in the enthalpy of the macroscopic states of a protein are of particular significance. Temperature and enthalpy are coupled extensive and intensive thermodynamic parameters. Thus, the functional relationship between enthalpy and temperature, $f = H(T)$, includes all thermodynamic information about the macroscopic states in the system. This information can be extracted using the formalism of equilibrium thermodynamics.

The $H(T)$ function of a system can be determined experimentally from calorimetric measurements of its heat capacity at constant pressure $C_p(T)$, over a broad temperature range:

$$C_p(T) = \left(\frac{\partial H}{\partial T}\right)_p \text{ and thus } H(T) = \int_{T_0}^{T} C_p(T)dT + H(T_0)$$

Equation 7.9.1

The heat capacity function, $C_p(T)$, of a system can be directly measured by differential scanning calorimetry (DSC), making DSC the method of choice to study the conformational stability of biological macromolecules and proteins in particular.

This unit presents step-by-step protocols for DSC, including sample preparation and interpretation of the results in the simplest cases (see Basic Protocol) as well as calibration of the apparatus (see Support Protocols 1, 2, and 3) and maintenance of DSC cells (see Support Protocol 4). Various general experimental considerations, including possible pitfalls and errors, are discussed in the Commentary (see Critical Parameters; see Troubleshooting).

STRATEGIC PLANNING

To study biological macromolecules using DSC instrumentation, a number of requirements must be satisfied: the measurements must be performed (1) in a physiological milieu, i.e., aqueous solution; (2) on protein samples that are dilute—i.e., at concentrations as low as 1 mg/ml (0.1%)—to minimize intramolecular interactions; and (3) in a small volume, since isolating and purifying protein samples is costly (in most cases only a few milligrams of protein are available, which at 1 mg/ml is only a few milliliters). Under such conditions the partial heat capacity of a protein in aqueous solution is on the order of 0.03% to 0.5%, and this is measured on the background of >99.5% heat capacity of solvent. Such measurements require extreme sensitivity, reproducibility, and signal stability from the DSC instrumentation. This implies that particular care should be taken with the experimental procedures for sample preparation and routine DSC operation. Currently two companies manufacture DSC instruments capable of working with solutions of biological macromolecules (Calorimetric Science and Microcal; see *SUPPLIERS APPENDIX*). These instruments are fully automated for control and for data collection, handling, and analysis using PC computers. The general principles of DSC instrument operation are outlined by Privalov et al. (1995) and Plotnikov et al. (1997).

BOSTON UNIVERSITY MEDICAL CENTRAL LIBRARY

In performing a DSC experiment, it is important to keep in mind that DSC operates in differential mode. This means that the heat capacity of the protein in aqueous solution is measured relative to the heat capacity of the surrounding buffer. In an ideal situation, when the heat capacities and volumes of both sample and reference cells are precisely the same, a single protein/buffer scan will suffice. However, in reality, sample and reference cells are not identical and this difference has to be taken into consideration. Experimentally this requires the use of an internal instrument standard—the buffer/buffer scan, or baseline of the instrument. Before starting the protein scan it is very important to establish the stability of the baseline, i.e., its relative position and shape. Most contemporary calorimeters have very high baseline stability and reproducibility. Before starting to prepare the protein it is always a good idea to take several overnight buffer/buffer baselines and compare these to make sure that they are reproducible in accordance with previous observations. If this criterion is satisfied, one may start preparing the protein sample (see Critical Parameters for crucial steps in sample preparation).

When setting the DSC control program, one of the most important parameters is the heating rate. Several considerations have to be taken into account. First, the higher the scan rate, the higher the sensitivity of the instrument. The increase in sensitivity is linear with respect to the heating rate: i.e., sensitivity at a heating rate of 2°/min is twice as high as at 1°/min. One needs to keep in mind that the increase in sensitivity does not mean an increase in the signal-to-noise ratio. Second, if the expected transition is very sharp—i.e., occurs within a few degrees—a high heating rate will affect the shape of the heat absorption profile and lead to an error in the determination of all thermodynamic parameters for this transition. This error will be particularly large for the transition temperature. Third, the higher the heating rate, the less time the system has to equilibrate. So for slow unfolding/refolding processes it is advisable to use low heating rates. In practice, for small globular proteins exhibiting reversible temperature-induced unfolding, the maximal heating rate (on most DSC instruments) of 2°/min is acceptable. For large proteins lower heating rates (0.5° to 1°/min) are more appropriate. In the case of fibrillar proteins, which usually exhibit very narrow transitions, a heating rate of 0.1° to 0.25°/min is most suitable.

BASIC PROTOCOL

DIFFERENTIAL SCANNING CALORIMETRY

Before beginning calorimetry, an instrument baseline is established by a buffer/buffer scan. If there are changes in the shape and/or relative position of the buffer/buffer scan, the cells are probably dirty (see Support Protocol 4 for cleaning procedure).

Materials

Protein solution, dialyzed (*UNIT 4.4 & APPENDIX 3.B*) and in dialysis bag (see Critical Parameters)
Equilibration buffer (buffer solution used for the last dialysis; see Critical Parameters for discussion of buffer selection)
Pasteur pipet or automatic pipettor
Spectrophotometer and quartz cuvettes of appropriate optical path length (depending on the expected protein concentration)
2-ml all-glass syringe (e.g., Becton Dickinson 2-cc Yale syringe)
Precut needle supplied with the DSC instrument
Differential scanning calorimeter (DSC), calibrated (see Support Protocols 1, 2, and 3)

PAU IASI CENTRAL UNIVERSITY LIBRARY

1. Turn on the spectrophotometer.

   This step is required only if a spectrophotometric method of determining protein concentration is used. See Critical Parameters for discussion of appropriate methods for determining protein concentration, which is crucial to obtaining accurate DSC data.

2. Transfer the protein solution from the dialysis bag into a 1.5-ml microcentrifuge tube using a clean Pasteur pipet or an automatic pipettor, and centrifuge 15 to 20 min at ~12,000 to 13,000 × *g*, 4°C.

   This step removes insoluble material.

3. While the protein is centrifuging, fill two quartz spectrophotometer cuvettes with equilibration buffer and take a buffer/buffer spectrum.

   This step establishes the buffer-buffer baseline of the spectrophotometer, which is particularly important with buffers containing absorbing components (e.g., dithiothreitol).

4. Empty both calorimetric cells, and rinse an all-glass syringe and attached needle (precut needle supplied with the DSC instrument) at least five to seven times with equilibration buffer.

5. Rinse one calorimetric cell (the reference cell) as follows: fill up the syringe, pump out all air bubbles, and insert the needle into the cell, letting the plunger slide down under its own weight (needles are precut to a specific length so that the tip of the needle will be barely above the bottom of the cell). Once the buffer appears in the overflow reservoir, start abruptly pumping buffer in and out of the cell, for a total of at least eleven to thirteen syringe volumes. Then fill the cell with more buffer.

   The abrupt pumping will force trapped air bubbles out of the cell.

   Calorimetric cells can be refilled using disposable plastic syringes as well (e.g., in the case of Ca^{2+}-binding proteins, where it is desirable to avoid glass syringes since they will "leak" calcium). In this case the operator should slowly inject solution into the cell until the solution appears in the overflow reservoir, and then briskly pump the solution in and out of the cell. During the last step, the solvent level should never get below the level of the overflow reservoir.

6. Repeat rinsing procedure with the second calorimetric cell (sample cell) and leave it empty. Remove all buffer leftovers from the overflow reservoir.

7. Stop the centrifuge. Using the syringe, transfer the supernatant of the protein solution into a spectrophotometric cuvette and record the protein spectrum.

   It is advisable not to try and remove all of the supernatant, but to leave last 50 to 70 µl in the microcentrifuge tube.

8. Transfer the protein solution from the spectrophotometric cuvette into the sample calorimetric cell.

   Follow the same technique as for filling the reference cell (see step 5).

9. Apply pressure, maintaining at least 1.5 atm (~22 psi) in the cell.

   All calorimetric experiments should be performed under excess pressure (see Critical Parameters).

10. Select scan parameters and start the DSC control program.

    See Strategic Planning for discussion of control parameters; see Anticipated Results for information on data analysis procedures.

BOUVIER / CENTRAL UNIVERSITY LIBRARY

CALIBRATION OF THE DSC INSTRUMENT

DSC instruments are precalibrated by their manufacturers for temperature scale and heat capacity. It is unlikely that the characteristics of an instrument will change, but it is nonetheless advisable to check them once or twice a year. Two other calibrations should be done in the lab: electrical calibration (y axis of the instrument readout) using the system built into the instrument (see Support Protocol 1), and temperature calibration (x axis) using either hydrocarbon capsules obtained from the manufacturer (see Support Protocol 2) or lipid suspensions that can be prepared in the laboratory (see Support Protocol 3).

SUPPORT PROTOCOL 1

Electrical Calibration

All DSC instruments have a built-in capability to perform heat capacity calibration using an electrical pulse. Electrical calibration is performed using a special built-in circuit with a precisely measured resistance. A precise electrical current applied to this circuit generates a defined amount of power, δW, supplied to one of the cells. Exactly the same amount of power will be supplied to the other cell by the cell heaters in order to compensate for the inequality of temperature between the sample and reference cells. The power generated by the heaters of the instrument is related to the apparent heat capacity, δC_p; the y-axis value generated by the instrument is $\delta C_p = \delta W/(dT/dt)$, where dT/dt is the heating rate. Follow the manufacturer's suggested procedures for electrical calibration.

SUPPORT PROTOCOL 2

Temperature Calibration Using Hydrocarbon Capsules

Temperature calibration is performed by melting pure hydrocarbons of known melting temperatures. The instrument manufacturers supply capsules containing hydrocarbons that can be inserted into a DSC cell filled with water (follow the manufacturer's suggested procedure). Alternatively, aqueous suspensions of certain lipids with known melting temperatures can be used (see Support Protocol 3).

SUPPORT PROTOCOL 3

Temperature Calibration Using Lipid Suspensions

The following procedure for preparing lipid suspensions was suggested by Mabrey and Sturtevant (1976).

Additional Materials (also see Basic Protocol)

Lipid: dipalmitoylphosphatidylcholine (DPPC) or distearoylphosphatidylcholine (DSPC)
10 mM sodium phosphate buffer, pH 7.0 (*APPENDIX 2E*)

Vortex mixer
Water bath, 60°C

1. Add the lipid (DPPC or DSPC) to 10 mM sodium phosphate buffer, pH 7.0, to a 0.5 to 1.0 mg/ml final lipid concentration.
2. Heat the suspension at 60°C for several minutes, then vortex vigorously.
3. Fill the reference calorimetric cell with 10 mM sodium phosphate buffer; fill the sample cell with the lipid suspension.
4. Set the heating rate of the calorimeter at 0.1° to 0.25°C/min.

If it is possible to set the response time of the instrument, use the fastest available.

P.G.U. IASI / CENTRAL UNIVERSITY LIBRARY

5. Start the scan.

The DPPC suspension has two transitions, a low-temperature, broad transition at 35.3°C and a high-temperature, sharp transition at 41.4°C. For the DSPC suspension the low-temperature transition is at 51.5°C and the high-temperature transition is at 54.9°C.

MAINTENANCE AND CLEANING OF DSC CELLS

SUPPORT PROTOCOL 4

DSC cells that become clogged by protein aggregates must be cleaned carefully in order to provide a reproducible baseline and thus accurate results. Proper use of calorimeters (i.e., avoidance of aggregating systems) minimizes the need for this sometimes very tedious procedure. Depending on the composition of the calorimetric cells (gold, platinum, titanium, tungsten), the chemical resistance of the material and the degree of contamination, a number of different procedures can be recommended.

Additional Materials (also see Basic Protocol)

1 M HCl *or* 1 M NaOH
Distilled water
Concentrated formic acid
95% (190-proof) ethanol
2% (w/v) SDS, or other detergent
Concentrated nitric acid

1. Rinse calorimetric sample cell with one syringe volume of 1 M HCl or 1 M NaOH. Rinse the cells well with water (~20 to 30 syringes-full; see Basic Protocol, step 5). Fill both cells and record a water-water scan. If the baseline does not return to its original position, proceed with step 2.

   The choice between acid and base depends on the properties of the protein aggregates formed. This can be checked by titrating the aggregated protein sample removed from the calorimeter with acid or base (half and half).

   IMPORTANT NOTE: *Do not use NaOH with cells made out of tungsten or titanium, as they will corrode.*

2. Fill the sample cell with formic acid and let it sit for ~10 to 15 min at room temperature. Rinse the cells well with water (~20 to 30 syringes-full), fill both cells, and record a water-water scan. If the baseline does not return to its original position, proceed with step 3.

3. Fill both cells with formic acid and scan several times up to 70°C. Rinse the cells well with water (~20 to 30 syringes-full), fill both cells, and record a water-water scan. If the baseline does not return to its original position, proceed with step 4.

4. Fill both cells with 95% ethanol and scan several times to 70°C. Rinse the cells well (~20 to 30 syringes-full of water), fill both cells, and record a water-water scan. If the baseline does not return to its original position, proceed with step 5.

5. Fill both cells with detergent and scan several times to the maximal temperature allowed by the instrument. Rinse very well (it is quite difficult to rid cells of detergent, but ~40 to 50 syringes-full of water per cell usually suffice). Fill both cells and record a water-water scan. If the baseline does not return to its original position, proceed with step 6.

6. Fill both cells with nitric acid and scan to 70°C several times. Rinse well (~20 to 30 syringes-full), fill both cells with water, and record a water-water scan.

   Particular care should be taken to prevent exposing the pan or pressure sensor (in some designs) to the nitric acid fumes, which will cause rusting. Put wet cotton wool or a Kimwipe on top of the cell outlets and pressure-sensor hole.

BOSTON BIOMEDICAL RESEARCH INSTITUTE CENTRAL UNIVERSITY LIBRARY

If none of these treatments helps, a possible alternative reason for changes in the shape and position of the baseline is changes in the intrinsic thermal properties of the cells that can occur over time. Contact the instrument manufacturer for advice.

COMMENTARY

Background Information

The major advantage of using DSC to study protein stability compared to other methods for monitoring temperature-induced unfolding of proteins is that it provides direct information about the modes of unfolding. This technique is unique for establishing whether the unfolding process is a two-state or a multi-state process. It also provides direct measurement of the energetics of the unfolding transition. Another important parameter directly measured by DSC is the heat capacity change upon unfolding, which can be used to compute the temperature dependencies of enthalpy, entropy, and Gibbs energy functions. Until recently, the major drawback to DSC was the requirement for relatively large amounts of a protein sample. Contemporary DSC instruments have overcome this and allow measurements at spectroscopic concentrations (0.1 mg/ml).

Critical Parameters

Protein purity

The purity of the sample should be maintained very scrupulously. Traditional electrophoresis (native, *UNIT 10.1*, and SDS-PAGE, *UNIT 10.3*) as well as emerging, more sensitive methods (MALDI-TOF or ion-spray mass spectroscopies, *UNIT 16.2*) should be used to check sample purity. Impurities can affect both the shape of the calorimetric profiles and the estimation of the thermodynamic parameters of unfolding through errors in determination of the sample concentration (see below).

Buffer solutions

Careful attention should be paid to the buffer composition. Two factors are particularly important.

1. Since calorimetric experiments are performed over a broad temperature range, the pH of the buffer should have a low temperature dependence. For this reason the very popular "physiological" buffer Tris is not the best choice. Glycine, sodium or potassium acetate, sodium or potassium phosphate, sodium cacodylate, and sodium citrate are all suitable buffers. See Izatt and Christensen (1976) for tabulated data on the physicochemical properties of various buffers.

2. Protein unfolding is usually accompanied by changes in the ionization state of certain moieties within the protein (i.e., amino acid functional groups). The heat of ionization can be very large (e.g., 30 to 44 kJ/mol for histidine, depending on pH) and can obscure the "true" conformational enthalpy of unfolding. In some cases this problem can be avoided by selecting buffers with heats of ionization close to the heats of ionization of the protein groups. In this case the heat of proton release/absorption for the protein will be compensated by the heat of proton absorption/release for the buffer. This can be achieved in the acidic pH ranges of 2.0 to 3.2 (with the glycine/HCl buffer system) and 3.5 to 5.0 (with the sodium acetate/acetic acid buffer system). In this overall pH range (2.0 to 5.0), the carboxyl groups of aspartic and glutamic acid are titrated, and their heat of ionization will be counterbalanced by the heat of ionization of the carboxyl groups of the buffer. In neutral and alkaline pH ranges, such compensation is not possible and corrections for the effects of functional group ionization should be made during data analysis (see Anticipated Results).

Equilibration of the protein solution with the solvent

Equilibration of the protein with buffer is a vital part of sample preparation for calorimetric experiments. One should keep in mind that what the DSC instrument measures is the difference in heat capacity between buffer and protein solutions. This means that any small variations in buffer composition will result in an incorrect absolute value and an incorrect slope of the heat capacity profile. Direct dissolution of a protein sample in the corresponding buffer gives an equimolar concentration of the low-molecular-weight component (the buffer). In the case of ionic compounds, this will lead to nonidentical buffer compositions, since the ionic solute—i.e., protein—will directly interact with the buffer components, thereby decreasing its bulk concentration.

The best way to achieve equilibrium between buffer and protein solution is dialysis. The protein sample should be dialyzed against at least two changes of buffer (see *UNIT 4.4*). The appropriate dialysis time will vary depending

PCU IASI CENTRAL UNIVERSITY LIBRARY

on the molecular weight cutoff (MWCO) of the dialysis membrane: the lower the MWCO, the longer the dialysis should be. For membranes with MWCO of 3500, 6 hr per change are enough. Higher-MWCO membranes equilibrate somewhat faster. It is advisable to filter the buffer solutions prior to dialysis using a 0.45-μm filter to eliminate all insoluble material.

Clarification of the solution

After dialysis, all insoluble particles should be carefully removed from the protein solution. This can be achieved either by passing the protein solution through a 0.22- to 0.45-μm filter or by microcentrifuging the solution for 15 to 20 min at ~12,000 × *g*. Centrifugation is preferable for several reasons: (1) quite often there is nonspecific adsorption of protein to the filtration membrane; (2) the filtration membrane can contain compounds that will be washed off into the protein solution, thus changing the buffer composition of the protein solution compared to the equilibration buffer; and (3) filtration membranes are costly.

Concentration of the protein solution

Knowledge of the exact protein concentration *after* dialysis against the corresponding buffer is another important prerequisite to DSC. Among all available methods for determining protein concentration, the spectrophotometric method seems to be most accurate and rapid. This method requires (1) a standard double-beam UV/visible spectrophotometer with resolution of at least 0.002 absorption units, and (2) knowledge of the extinction coefficient of the protein at a given wavelength. The extinction coefficient can be determined experimentally by determination of the nitrogen content (Jaenicke, 1974) or by quantitative amino acid analysis (*UNIT 3.2*). Alternatively, if the protein of interest contains at least one tyrosine or tryptophan residue or disulfide bond, the extinction coefficient can be calculated from the number of aromatic residues and disulfide bonds using an empirical equation (Gill and von Hippel, 1989):

$$\varepsilon_{280\ nm}^{0.1\%,1\ cm} = \frac{5690N_{Trp} + 1280N_{Tyr} + 120N_{SS}}{MW}$$

Equation 7.9.2

where N_{Trp}, N_{Tyr}, and N_{SS} are the number of tryptophans, tyrosines, and disulfide bonds, respectively, and MW is the molecular weight of the protein in daltons. A more elaborate procedure, described by Pace et al. (1995), improves the accuracy of this calculation.

For proteins that do not contain any aromatic residues, the method of Scopes (1974), which also uses spectrophotometry, gives fast and accurate results (see *UNIT 3.1*).

Light scattering in spectrophotometric measurements of protein concentration can be a significant problem. This can be taken into account using a procedure suggested by Winder and Gent (1971).

Pressure in the calorimetry cell

All calorimetric experiments are performed under excess pressure. There are two main reasons for this. (1) The solubility of gases in aqueous solution is temperature dependent—thus, the lower the temperature, the higher the solubility. Excess pressure prevents air bubble formation in the cell at elevated temperatures. In some cases this can also be achieved by degassing protein solutions by exposing them to vacuum. However, degassing inevitably leads to a change in the solvent composition due to evaporation, which will in turn introduce a distortion in the calorimetric profile. (2) Excess pressure keeps sample evaporation from the calorimetric cell to a minimum. It is important to obtain heat capacity measurements for as broad temperature range as possible; for some proteins, the unfolding transition is not complete until the temperature is above the boiling point of water. Excess pressure will elevate the boiling temperature, and allow measurements at temperatures above the boiling point of water (100°C) in these cases. It is recommended that the pressure in the cell be kept to at least 1.5 atm (~22 psi) in all experiments.

Troubleshooting

The most frequent problem in DSC experiments is irreversibility of the unfolding transition. This applies particularly to large proteins that tend to aggregate after unfolding. The sensitivity of contemporary DSC instruments provides reliable heat capacity profiles at concentrations as low as 0.1 mg/ml for proteins 6 to 17 kDa in size, and the concentration can be even lower for larger proteins. Low protein concentration decreases the probability of aggregation. However, even at low protein concentrations, finding the proper solvent conditions to prevent aggregation is not a simple task. A rule of thumb is that at a pH value close to the isoelectric point of the protein, aggregation

PCU INSTITUTIONAL UNIVERSITY LIBRARY

after unfolding is highly probable. High concentrations of neutral salts also promote aggregation. In many cases, aggregation can be avoided by keeping the ionic strength of the solvent very low (10 to 50 mM) and by using pH values a couple of units away from (usually below) the isoelectric point.

Anticipated Results

Calculation of the partial heat capacity profile

The first step in calculating the partial heat capacity profile is subtraction of the scan rate–normalized baseline (buffer/buffer scan) from the scan rate–normalized protein scan (protein/buffer) to obtain $\Delta C_p^{app}(T)$, the heat capacity difference between sample and reference cells at temperature T. Knowledge of $\Delta C_p^{app}(T)$ allows calculation of the partial heat capacity of the protein at temperature T, $C_{p,pr}^{exp}(T)$, as:

$$C_{p,pr}^{exp}(T) = C_p,buf(T)\cdot\frac{\overline{V}_{pr}(T)}{\overline{V}_{buf}(T)} - \frac{\Delta C_p^{app}(T)}{m_{pr}(T)}$$

Equation 7.9.3

where $C_{p,buf}(T)$ is the heat capacity of buffer at temperature T, $\overline{V}_{pr}(T)$ is the partial volume of the protein at temperature T, $\overline{V}_{buf}(T)$ is the partial volume of buffer at temperature T, and $m_{pr}(T)$ is the mass of the protein in the calorimetric cell at temperature T. The mass of the protein in the cell is calculated as $m_{pr}(T) = v_{cell}(T)\cdot W_{pr}(T)$, where $v_{cell}(T)$ is the volume of the cell at temperature T and $w_{pr}(T)$ is the concentration of the protein at temperature T.

In practice, however, for aqueous buffers

$$\frac{C_{p,buf}}{V_{buf}} \cong \frac{C_{p,H_2O}}{V_{H_2O}}$$

Equation 7.9.4

and $m_{pr}(T) \cong$ constant, because

$$\frac{\partial v_{cell}(T)}{\partial T} \cong \frac{\partial w_{pr}(T)}{\partial T}$$

Equation 7.9.5

so that Equation 7.9.3 is simplified to:

$$C_{p,pr}^{exp}(T) = \frac{C_{p,H_2O}}{\overline{V}_{H_2O}}\cdot\overline{V}_{pr} - \frac{\Delta C_p^{app}(T)}{m_{pr}}$$

Equation 7.9.6

where only one term, $\Delta C_p^{app}(T)$, is temperature dependent. In any case, both equations require knowledge of the partial volume of the protein, $\overline{V}_{pr}$. This parameter can be calculated from the amino acid composition of the protein using an additivity scheme described by Makhatadze et al. (1990). Calculations can also be performed via the World Wide Web at the URL *http://www.ttu.edu/~chem/makhatadze/Vpartial.html.*

Interpretation of DSC profiles

Two important pieces of information should be established prior to the analysis of the calorimetric profiles. These will help to decide whether the formalism of equilibrium thermodynamics is applicable to the protein being studied.

1. Reversibility of the unfolding transition should be examined under several conditions by rescanning the sample. Reversibility depends on the upper temperature of heating. The unfolding transition can be considered reversible if rescanning after the sample has been heated to the temperature just past the completion of the transition leads to the recovery of at least 85% to 90% of the initial endotherm. If no endotherm is observed after rescanning, the unfolding reaction is irreversible. Thermodynamic analysis for irreversible transitions is possible only in special cases (Sanchez-Ruiz, 1992).

2. The equilibrium conditions of reversible unfolding should be examined to find the optimal scan rate that permits establishment of equilibrium between native and unfolded states at all temperatures—i.e., the scan rate should not be faster than the folding/unfolding rates. This can be accomplished by comparing the heat capacity profiles obtained on the same exact sample at two different heating rates, usually 2°/min and 0.5°/min. If the difference in the transition temperature exceeds 0.5° to 0.7°C, additional experiments should be performed at a lower heating rate (i.e., 0.1°/min) and compared to the 0.5°/min experiment. If there is still a difference in the transition temperature, all experiments at a given solvent composition should be performed at several different heating rates and the transition temperatures should be extrapolated to a zero heating rate (for more details see Yu et al., 1994).

NOTE: Sensitivity of DSC is reversibly proportional to the heating rate, so these experiments should be performed at protein concentrations high enough to obtain the transition temperature with a relatively high accuracy.

ASU IASI CENTRAL UNIVERSITY LIBRARY

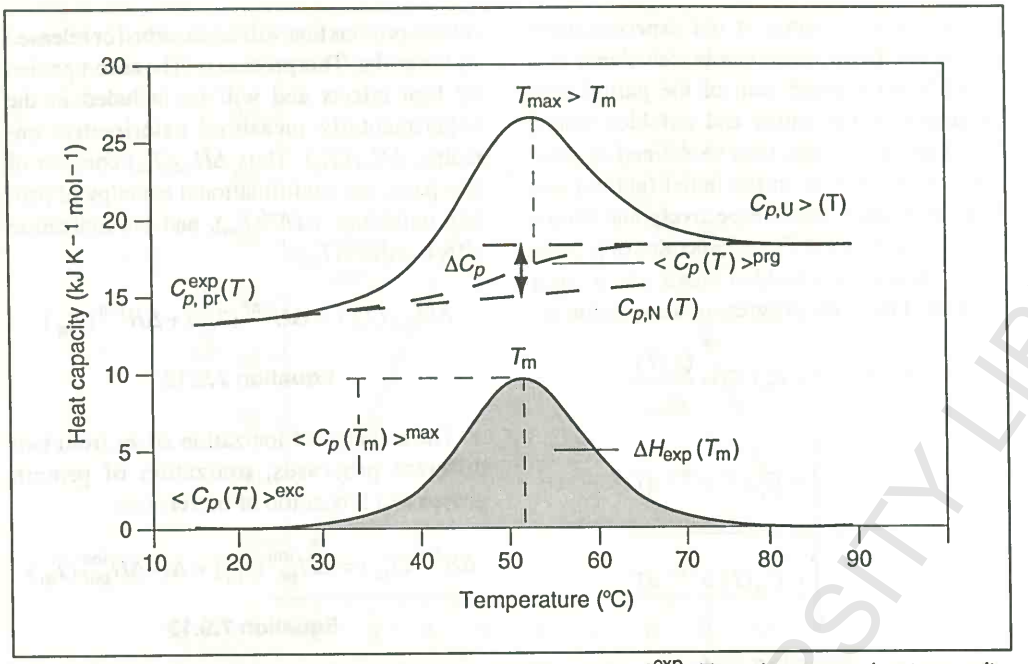

Figure 7.9.1 The relation of the partial molar heat capacity, $C_{p,pr}^{exp}(T)$, to the excess heat capacity, $<C_p(T)>^{exc}$, progress heat capacity, $C_p^{prg}(T)$, and partial heat capacities of the native, $C_{p,N}(T)$, and unfolded, $C_{p,U}(T)$, states.

By visual inspection of the calorimetric profiles one can establish whether the unfolding transition represents a single endotherm (as shown in Fig. 7.9.1) or is more complex. These two cases are analyzed differently.

If the DSC profile is a single endotherm

Heat capacity functions for the native and unfolded states. The partial specific heat capacity of the native state, $C_{p,N}$, ranges from 1.25 to 1.80 J/(K·g) at 25°C depending on the protein (Makhatadze, 1998). $C_{p,N}$ has a linear dependence on temperature with a slope from 0.005 to 0.008 J/(K^{-2} g), also depending on the protein (Makhatadze, 1998). The partial specific heat capacity of the unfolded state, $C_{p,U}$, in the temperature range from 5° to 100°C is always higher than the heat capacity of the native state. At 25°C, $C_{p,U}$ values for different proteins range from 1.85 to 2.2 J/(K·g), whereas at 100°C these values are higher, from 2.1 to 2.4 J/(K·g) (Makhatadze, 1998). The partial heat capacity of the unfolded state has a nonlinear dependence on temperature (e.g., Wintrode et al., 1994). It increases gradually (with a slope comparable to that for the native state) and approaches a constant value at 60° to 75°C. At temperatures above 60° to 75°C, $C_{p,U}$ does not depend on temperature. As a result of the different temperature dependencies of the heat capacities of the native and unfolded states, the heat capacity change upon protein unfolding, $\Delta C_p = C_{p,U} - C_{p,N}$, appears to be a temperature-dependent function.

Excess heat capacity profile. The so-called excess heat capacity function $<C_p(T)>^{exc}$ is the heat capacity caused exclusively by the heat absorbed due to the unfolding reaction. $<C_p(T)>^{exc}$ thus is expressed as a difference between the experimental, $C_p^{exp}(T)$, and progress, $C_p^{prg}(T)$, heat capacity functions of a protein:

$$< C_p(T) >^{exc} = C_p^{exp}(T) - C_p^{prg}(T)$$

Equation 7.9.7

where the progress heat capacity is defined by the intrinsic (partial) heat capacity of the protein in the entire temperature range:

$$C_p^{prg}(T) = F_N(T) \cdot C_{p,N}(T) + F_U(T) \cdot C_{p,U}(T)$$

Equation 7.9.8

where $C_{p,N}(T)$ and $C_{p,N}(T)$ are the temperature dependencies of the partial heat capacities of the native and unfolded states, respectively. Because of the difference in the partial heat capacities of the native and unfolded states, in the temperature range where transition occurs,

B.C.U. „M. Eminescu" IAŞI
CHIMIE

BUCHAREST UNIVERSITY LIBRARY

progress heat capacity is not experimentally accessible. However, it can be calculated as a population-weighted sum of the partial heat capacities of the native and unfolded states. $F_N(T)$ and $F_U(T)$ can thus be defined as fractions of the protein in the initial (native) and final (unfolded) states, respectively, and consequently $F_N(T) + F_U(T) = 1$. Fractions of protein in the native or unfolded states are in turn calculated from the progress of the reaction as:

$$F_U(T) = 1 - F_N(T) = \frac{Q_i(T)}{Q_{tot}} = \frac{\int_0^T < C_p(T) >^{exc} dT}{\int_0^\infty < C_p(T) >^{exc} dT}$$

Equation 7.9.9

where Q_{tot} is the total heat absorbed upon unfolding and $Q_i(T)$ is the heat absorbed at temperature T.

Transition temperature, T_m. The transition temperature, T_m, is defined as the temperature at which the areas under the excess heat capacity profile on both sides of T_m are equal, i.e.:

$$\int_0^{T_m} < C_p(T) >^{exc} dT = \int_{T_m}^\infty < C_p(T) >^{exc} dT$$

Figure 7.9.10

T_m always differs from the temperature of maximum partial heat capacity, T_{max}, due to the difference in the heat capacities between the native and unfolded states, $\Delta C_p = C_{p,U} - C_{p,N}$. $T_{max} - T_m$ decreases with an increase in the relative ratio of the area under the excess heat capacity profile to ΔC_p.

Calorimetric enthalpy, ΔH_{exp} (T_m). Calorimetric enthalpy is defined as the area under the excess heat capacity function, i.e.,

$$\Delta H_{exp}(T_m) = Q_{tot} = \int_0^\infty < C_p(T) >^{exc} dT$$

Equation 7.9.11

and is referred to as the enthalpy at the transition temperature.

Enthalpy of the conformational transition, $\Delta H^{cnf}(T_m)$. When a protein unfolds, internal groups buried in the native state can bind or release protons that will be absorbed or released by the buffer. This process will be accompanied by heat effects and will be included in the experimentally measured calorimetric enthalpy, $\Delta H_{cal}(T_m)$. Thus $\Delta H_{cal}(T_m)$ consists of two parts, the conformational enthalpy of protein unfolding, $\Delta H^{cnf}(T_m)$, and the ionization effects, $\Delta H^{ion}(T_m)$:

$$\Delta H_{exp}(T_m) = \Delta H^{cnf}(T_m) + \Delta H^{ion}(T_m)$$

Equation 7.9.12

The enthalpy of ionization arises from two different processes, ionization of protein groups and ionization of buffer; i.e.:

$$\Delta H^{ion}(T_m) = \Delta H^{ion}_{pr}(T_m) + \Delta\nu \cdot \Delta H^{ion}_{buf}(T_m)$$

Equation 7.9.13

where $H^{ion}_{pr}(T_m)$ is the enthalpy of ionization of protein, $H^{ion}_{buf}(T_m)$ is the enthalpy of ionization of buffer, and ν is the change in the protonation state of the protein (see below). When the enthalpies of ionization of protein groups and of the buffer are close, the calorimetric and conformational enthalpies are also close to each other, i.e, $\Delta H_{cal}(T_m) \cong \Delta H^{cnf}(T_m)$. Such a situation occurs in glycine or acetate buffer systems with an acidic pH. In the acidic pH range, the most probable titratable groups of the protein are the carboxylic acids (aspartic and glutamic acid). Their heats of ionization are very close to the heats of ionization for carboxylic groups of glycine or acetic acid. However, at neutral or alkaline pH, titratable groups (histidine, lysine, arginine, tyrosine, and cysteine) have heats of ionization very different from those of the buffer systems used (e.g., phosphate and cacodylate). In these cases, differences between calorimetric and conformational enthalpies can be significant (see, for example, Yu et al., 1994).

Changes in the protonation state of the protein upon unfolding, $\Delta\nu$. Under certain solvent conditions protein unfolding is accompanied by a change in the protonation state of the protein, $\Delta\nu$. This difference in the number of protons bound to the unfolded, ν_U, and native, ν_N, states can be determined from the dependence of the transition temperature on the pH values of the solution dT_m/dpH as:

$$\Delta\nu = \nu_U - \nu_N = \frac{\Delta H_{exp}(T_m)}{2.303 \cdot R \cdot T_m^2} \cdot \frac{dT_m}{dpH}$$

Equation 7.9.14

KSU IASRI CENTRAL UNIVERSITY LIBRARY

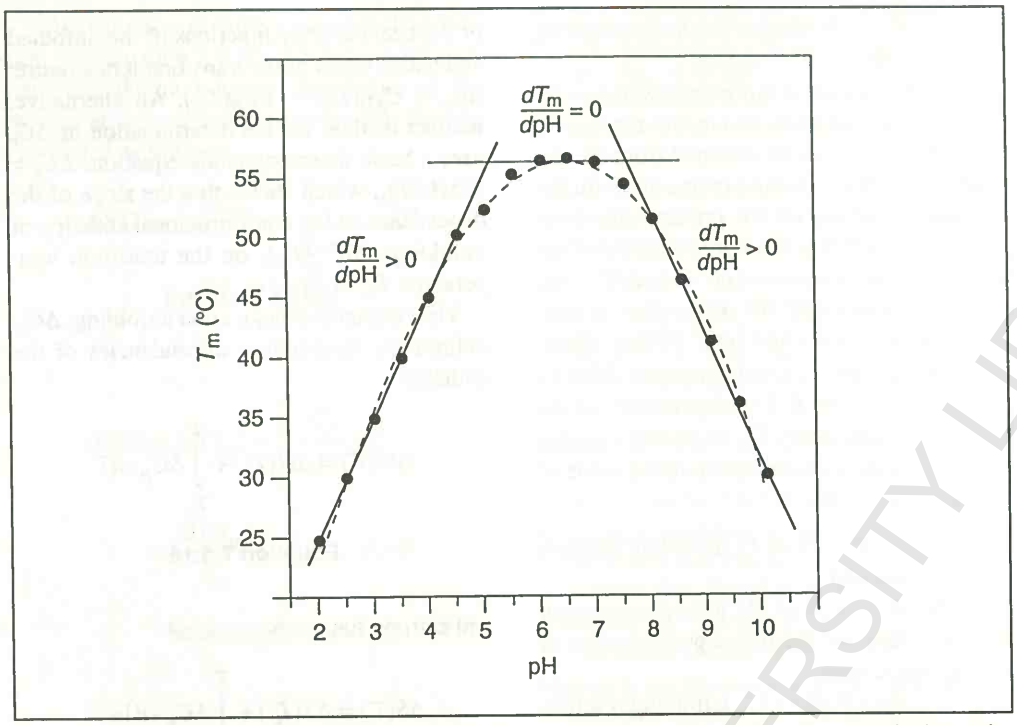

Figure 7.9.2 Dependence of the transition temperature on solution pH for a hypothetical protein.

Typically, the curve representing the dependence of the transition temperature on the pH of the solution has a bell shape (Fig. 7.9.2). On the left shoulder, $dT_m/d\text{pH} > 0$ and thus $\Delta\nu < 0$—i.e., the protein releases protons upon unfolding. On the right shoulder of T_m dependence on pH, $dT_m/d\text{pH} < 0$ and thus the protein absorbs protons upon unfolding ($\Delta\nu > 0$). At the maximum of the T_m(pH) function, $dT_m/d\text{pH} = 0$ and thus the protonation states of the native and unfolded states of a protein are identical ($\Delta\nu = 0$).

Van't Hoff enthalpy, $\Delta H_{vH}(T_m)$, and modes of unfolding transition. The so-called van't Hoff enthalpy for a two-state unfolding process is determined by the temperature dependence of the equilibrium constant, K_{eq}:

$$\Delta H_{vH}(T_m) = -R \cdot \frac{d \ln K_{eq}}{d(1/T)} = R \cdot T^2 \cdot \frac{d \ln K_{eq}}{dT}$$

Equation 7.9.15

where K_{eq} is defined as

$$K_{eq}(T) = \frac{F_N(T)}{F_N(T) + F_U(T)}$$

Equation 7.9.16

From this definition, it follows that van't Hoff enthalpy can be estimated from Equation 7.9.8 or Equation 7.9.9. However, for the calorimetric curves ΔH_{vH} (T_m) can be estimated as:

$$\Delta H_{vH}(T_m) = \frac{4 \cdot R \cdot T_m^2 \cdot < C_p(T_m) >^{max}}{\Delta H_{exp}(T_m)}$$

Equation 7.9.17

where $<C_p(T_m)>^{max}$ is the maximum value of the excess heat capacity function.

A direct estimate of two enthalpies—experimental calorimetric enthalpy, ΔH_{exp} (T_m), and van't Hoff enthalpy, $\Delta H_{vH}(T_m)$—from a single DSC experiment provides a unique way to determine the modes of protein unfolding (Biltonen and Freire, 1978; Privalov and Potekhin, 1986; Kidokoro and Wada, 1987; Marky and Breslauer, 1987; Ghosaini et al., 1988). When the ratio $\beta = \Delta H_{vH}(T_m)/\Delta H_{cal}(T_m)$ equals 1 (in practice, ~0.95 to 1.05), this indicates that the observed transition is two-state, proceeding from the native to the unfolded state without a significant population of intermediates: i.e., the unfolding reaction can be represented by N ↔ U. Deviations from unity indicate that the transition is more complicated. There are two possible explanations of β deviating from unity for

BCU IASRI CENTRAL UNIVERSITY LIBRARY

the reversible unfolding of the protein showing a single-isotherm DSC profile.

1. *The reaction is not monomolecular.* Information on whether or not the reaction is monomolecular can be obtained from the dependence of the transition temperature for the reversible reaction on the protein concentration. The possibility of oligomerization of the protein in the native or/and unfolded states should be examined by performing experiments under exactly the same solvent conditions using protein concentrations that differ by at least a factor of 5. The dependence of the transition temperature, T_m, on protein concentration, w, will be an indication of the mode of unfolding reaction:

a. $\partial T_m/\partial w = 0$: N $\leftrightarrow$ U, unfolding reaction is monomolecular;

b. $\partial T_m/\partial w > 0$: N $\leftrightarrow n$U, unfolding reaction is of nth order and the native protein exists in an oligomeric state;

c. $\partial T_m/\partial w < 0$: N $\leftrightarrow$ U_n, unfolding reaction is of nth order and the unfolded protein exists in an oligomeric state.

Situations (a) and (b) are very common and the thermodynamic formalism for their analysis is well developed. Situation (c) is rare for reversible reactions, but does occur for irreversible reactions when irreversibility is caused by aggregation (usually nonspecific) in the unfolded state.

2. *Intermediate states.* An alternative explanation for β being >1 is the existence of intermediate states during equilibrium reversible unfolding: i.e., N $\leftrightarrow$ $I_1 \leftrightarrow I_2$, ... $I_n \leftrightarrow$ U.

Consider the most common example of such an unfolding reaction, which is the unfolding of a two-domain protein. Both domains have similar intrinsic stability, $\Delta G_1(T) \approx \Delta G_2(T)$, and their interactions with one another are described by Gibbs free energy $\Delta G_{12}(T)$. The ratio of calorimetric to van't Hoff enthalpy, β, will depend on the strength of the interdomain interactions. If $\Delta G_{12}(T) = 0$, i.e., there is no interaction between domains, each domain will unfold independently of the other, and $\beta = 2$. If there is a strong interaction between domains, i.e., neither domain can exist in a folded state if the other domain is unfolded, unfolding will be very cooperative and $\beta = 1$.

Heat capacity change upon unfolding, ΔC_p, and thermodynamic functions for protein unfolding: enthalpy, $\Delta H(T)$, entropy, $\Delta S(T)$, and Gibbs free energy, $\Delta G(T)$. One way of estimating the heat capacity change upon protein unfolding is directly from the difference of the heat capacity functions of the unfolded and native states at the transition temperature: $\Delta C_p = C_{p,U}(T_m) - C_{p,N}(T_m)$. An alternative, indirect method for the determination of ΔC_p uses a basic thermodynamic equation, $\Delta C_p = (\partial \Delta H/\partial T)_p$, which shows that the slope of the dependence of the conformational enthalpy of unfolding, $\Delta H^{cnf}(T_m)$, on the transition temperature, T_m, is equal to ΔC_p.

Heat capacity change upon unfolding, ΔC_p, defines the temperature dependencies of the enthalpy

$$\Delta H(T) = \Delta H(T_0) + \int_{T_0}^{T} \Delta C_p \cdot dT$$

Equation 7.9.18

and entropy functions,

$$\Delta S(T) = \Delta S(T_0) + \int_{T_0}^{T} \Delta C_p \cdot d\ln T$$

Equation 7.9.19

and thus the Gibbs free energy function:

$$\Delta G(T) = -R \cdot T \cdot \ln K_{eq} = \Delta H(T) - T \cdot \Delta S(T)$$

Equation 7.9.20

The integration constants $\Delta H(T_o)$ and $\Delta H(T_o)$ in Equation 7.9.19 and Equation 7.9.20 have to be determined experimentally. The integration constant the enthalpy function can be set as $\Delta H(T_o) = \Delta H_{exp}(T_m)$. The integration constant for the entropy function (Equation 7.9.19) for a two-state transition is determined as follows. If the transition is two-state—i.e., $\Delta H_{exp}(T_m) \approx \Delta H_{vH}(T_m)$—then at the transition temperature (T_m) the population of native and unfolded states is equal. This means that at T_m the equilibrium constant of the reaction $K_{eq} = F_N/F_U$ is equal to 1, and thus the Gibbs free energy difference between the native and unfolded states at T_m is equal to zero and $\Delta G(T_m) = \Delta H(T_m) - T_m \cdot \Delta S(T_m) = 0$. Thus the entropy change upon protein unfolding at the transition temperature, $\Delta S(T_m)$, is equal to:

$$\Delta S(T_m) = \frac{\Delta H(T_m)}{T_m}$$

Equation 7.9.21

PCU IASS (CENTRAL UNIVERSITY LIBRARY)

This equation provides a constant of integration for Equation 7.9.20, $\Delta S(T_m) = \Delta S(T_o)$. A complete thermodynamic description of the system at *any* other temperature can then be calculated as follows:

$$\Delta H(T) = \Delta H(T_m) + \int_{T_m}^{T} \Delta C_p \cdot dT$$

Equation 7.9.22

$$\Delta S(T) = \Delta S(T_m) + \int_{T_m}^{T} \frac{\Delta C_p}{T} \cdot dT$$

$$= \frac{\Delta H(T_m)}{T_m} + \int_{T_m}^{T} \Delta C_p \cdot d\ln T$$

Equation 7.9.23

$$\Delta G(T) = \Delta H(T_m) - T \cdot \frac{\Delta H(T_m)}{T_m}$$

$$+ \int_{T_m}^{T} \Delta C_p \cdot dT - T \cdot \int_{T_m}^{T} \Delta C_p \cdot d\ln T$$

Equation 7.9.24

where the heat capacity change upon protein unfolding, ΔC_p, is a function of temperature itself. In practice, however, if no extrapolations over a wide temperature range are necessary, as a first approximation a temperature-independent ΔC_p is a reasonable assumption.

Time Considerations

Sample preparation (of which dialysis is the most time-consuming step) usually requires 12 to 16 hr. Consult *UNIT 4.4* for possible ways of reducing dialysis time. Baseline data is usually collected in overnight experiments; a calorimetric experiment with a protein sample requires several hours, depending on the heating rate. However, optimization of experimental conditions (reversibility and equilibrium) when first working with an unfamiliar sample may take several days. Time requirements for data analysis vary in individual cases.

CHAPTER 8
Conventional Chromatographic Separations

INTRODUCTION

It can be argued with conviction that the purification of proteins has been a key step in many of the advances in our understanding of biological structure and function. The careful dissection of enzyme mechanisms would have been impossible without isolated catalytic species. Before the advent of gene sequencing, determination of protein structure absolutely required clean protein samples. Precise determination of the biological effects of cytokines and growth factors necessitates the preparation of pure polypeptides. Impressive advances from X-ray structure determination must begin with homogeneous, concentrated protein samples. The utility of site-specific mutagenesis, which is crucial to asking precise questions about structure-function relationships, is limited if the recombinant protein cannot be separated from contaminating cellular proteins. Finally, the revolution created by the availability of restriction enzymes is founded upon the preparation of pure samples of the reagents.

This chapter presents a rational, systematic approach to the discovery and optimization of protein separations by chromatographic methods. The first unit provides a description of how to plan an overall strategy to attempt the isolation of a new protein (*UNIT 8.1*). Important initial considerations include the desired quality level of the final product and the properties of the source as well as the anticipated properties of the target protein. The choice of a strategic approach is described, beginning with consideration of the needs of the final sample with respect to concentration, buffer composition, and pH. The competing factors of selectivity, efficiency, and capacity are discussed with reference to how each method can influence the choice of the next step.

The second unit provides a series of steps to identify conditions for optimizing a separation strategy (*UNIT 8.2*). Alternative methods for sample processing and elution are described, thus providing numerous choices for the fractionation of a variety of proteins. In addition, critical parameters for the long-term care of a chromatography system are detailed. The relationship of the ion-exchange method to other procedures is also discussed.

A single procedure, no matter how carefully performed, is unlikely to totally resolve a mixture of proteins. Accordingly, use of additional procedures that provide separation based on different physical properties are essential to complete the isolation procedure. Protein fractionation by gel-filtration chromatography can provide a separation based on molecular size (*UNIT 8.3*). Gel filtration can also be used to remove salts from a protein at various stages of isolation; this may be valuable before ion-exchange chromatography, for example. When performed using standard proteins for calibration, gel filtration can also provide information about the size of a new protein.

Another orthogonal separation method that has proven to be very valuable, particularly for protein isolation, is hydrophobic interaction chromatography (*UNIT 8.4*). In this method the protein interacts with a matrix through surface-exposed hydrophobic groups. Guidelines for beginning and optimizing a separation based on hydrophobic interaction chromatography are provided.

Chromatofocusing (*UNIT 8.5*) is a technique that separates proteins on the basis of their isoelectric points. High resolution is achieved, making the procedure perfect for intermediate polishing steps. Selection of proper media and buffers is essential to the technique, as described in the unit.

Binding of the charged groups of proteins (positive as well as negative) to the calcium phosphate matrix of hydroxylapatite provides another unique separation mechanism to resolve protein mixtures (*UNIT 8.6*). The unit also includes recommendations for alternative methods to derive the optimal advantages of this strategy.

Each unit defines chromatographic parameters and describes methodology to provide quantitative evaluation of column efficiency. In addition, each unit presents summaries of the properties of chromatographic media available from commercial sources, which have undergone significant improvements over the past twenty years. The advantages of some features such as pore size and bead diameter are discussed in the context of the competing needs of resolution, capacity, and speed.

Although all the procedures are presented so that separations can be done manually, the advantages of automation for some steps are described. As separation technology is rapidly changing, future updates will expand the methodology described in this chapter.

Overview of Conventional Chromatography

The key to success in purification of any protein is developing the right separation strategy. This involves selecting and correctly applying a combination of separation techniques, chosen on the basis of information about the target protein and contaminants. There is no single separation technique and no single purification scheme that will allow successful purification of all types of proteins. However, there is a single approach to developing a successful purification strategy.

Three basic steps must be completed before beginning to develop a purification strategy. First, the amount and purity of the target protein (the protein to be purified) required for its intended use must be determined. Second, all available physical and chemical information concerning potential source materials, the nature of the target protein itself, and major contaminants must be gathered. Third, the best source material from which to purify the target protein must be determined. These three steps are mutually interdependent—what is learned in one will have an impact on the others. The more that is known before beginning development of a purification strategy, the more successful that strategy will be.

YIELD AND PURITY OF TARGET PROTEIN

How much protein must be purified? How pure must the protein be? These two questions establish the criteria for selecting specific chromatographic techniques and for judging the efficacy of any individual purification step or overall purification procedure. The answers to these simple questions depend upon the nature of the source material from which the target protein will be purified, the intended use for the purified protein, and the methods available to assess the purity of the target protein.

Amount of Protein Required

The amount of protein required from a purification process depends primarily on the intended use for the target protein. However, the amount of protein that will be used during the purification process to develop methods and assess purity must also be considered. It is necessary only to estimate whether analytical (≤1 mg), preparative (≤1 g), pilot (≤ 1 Kg), or process (>1 Kg) amounts of target protein will be needed. This is often referred to as the scale of operation. When the source material is very expensive, unstable, or difficult to obtain, it is necessary to develop and optimize the purification strategy on a small scale first, then scale up. Conversely, if multiple samples are to be processed, as for analytical applications, it may be desirable to develop the purification process at a larger scale, then scale down. The amount of target protein to be purified may also be determined by limited availability of source material.

Source Material

Once the scale of operation has been determined, the amount of source material needed to begin the procedure must be clearly defined. This obviously depends on the concentration of target protein in the source material, which can vary greatly. Certain proteins and peptides are present in natural sources only in very minute quantities. Purification of even a microgram of pure material may require many kilograms of tissue, or many liters of fermentation broth if microorganisms are the source. On the other hand, some recombinant proteins are expressed at such high levels in a host that the protein may be present in milligram per milliliter or higher concentrations. Source materials containing very low or very high concentrations of target protein each present unique problems that must be addressed in selecting a purification strategy.

Yield of Purification Procedure

The next major consideration in deciding how much protein to purify is what yield is necessary at each step of the purification procedure to ensure that there will be enough pure target protein at the end, taking into account the availability of source material. If a 75% yield of target protein is obtained at each of four steps in a purification procedure, less than one-third of the desired protein will remain at the end of the procedure (Fig. 8.1.1). It is obviously advantageous to use as few steps as possible in a purification process while maintaining as high a yield as possible at each step.

The yield from any purification step may be reported as total protein, percentage of total activity, or change in specific activity. The yield information from progressive purification steps is used to construct a purification table (e.g., see Table 8.1.1).

In Table 8.1.1, the yield is reported as percent of total activity remaining from the crude

RUTGERS / CAMDEN UNIVERSITY LIBRARY

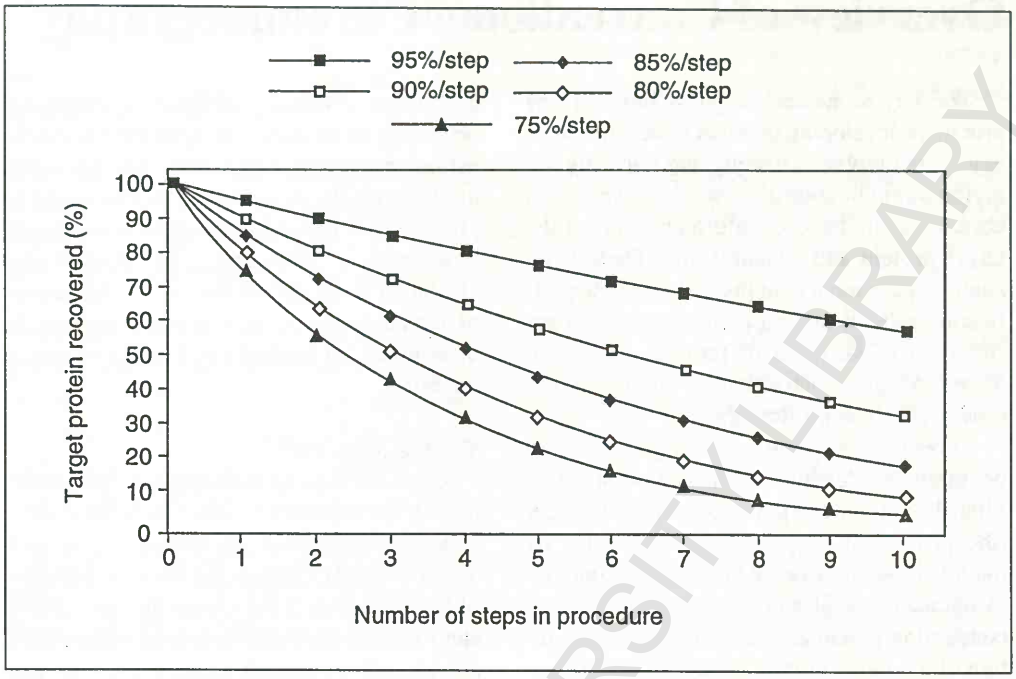

Figure 8.1.1 Theoretical yields from multistep protein purifications. Each curve represents a multistep process with a given percentage yield per step. The percentage of the original quantity of target protein remaining at the end of purification is plotted against the number of purification steps.

homogenate; the step yield is the percent activity relative to the previous step; and the purification factor reflects the change in specific activity relative to the crude homogenate. It is not unusual to have yields >100% based on activity (e.g., the yield after anion-exchange chromatography in Table 8.1.1). This is most often due to the removal of inhibitors or contaminants that interfere with the activity assay.

Assessment of Protein Purity

Assessing protein purity is often the most time-consuming and labor-intensive step in the purification process. It is generally desirable to limit the number of steps in a purification process simply to reduce the number of assays that must be performed to assess purity at each step. Protein purity is judged from a structural and/or functional perspective, depending on the nature of the target protein and its intended use. If the intention is to examine the function of the target molecule, the activity of the target protein must be maintained during the purification process. A functional assessment of the purity of the target protein will thus be required at each step. If the intention is to examine the structure of the target molecule, structure must be maintained, but function may or may not have to be preserved. A structural assessment of purity will, however, be required in this case. If structural/functional relationships involving the target molecule are to be examined, assessment of both structural and functional purity will be required.

Methods for assessing protein purity must quantitate the amount of target protein relative to the amount of contaminant(s) in the sample. This requires two separate analytical methods: one for the target protein and one for the total protein including contaminants. For example, with enzymatic proteins, assessment of functional purity typically relies on kinetic assays in which the amount of substrate consumed or product produced per unit time is proportional to the amount of enzyme present. The total activity of the sample is calculated and compared to the total amount of protein to give the specific activity of the sample. Methods for determining total protein are discussed in Chapter 3. An increase in specific activity at a purification step reflects a loss of contaminant proteins.

Functional purity of structural proteins, denatured proteins (i.e., proteins that have lost their function during the purification procedure), and proteins for which a functional assay does not exist must usually be assessed by measuring structural attribute(s)—e.g., molecular weight, pI, presence of a metal ion or cofactor, or presence of an antibody binding

PCU IASRI CENTRAL UNIVERSITY LIBRARY

[c]Increase in specific activity.

site. As in the case of functional purity, an increase in the amount of target protein relative to total protein reflects an increase in purity.

STEPS IN A PURIFICATION STRATEGY

A purification strategy for any protein at any scale of operation can be broadly divided into three sequential stages—capture, intermediate purification, and polishing. Each stage represents a set of specific problems that may be encountered during a purification process. The nature of the sample and the scale of operation will dictate what equipment and methodology are appropriate to solve the problem.

Capture Stage

The capture stage is the initial purification of the target protein from the source material. The goal of capture is to concentrate the target protein while removing as much of the major contaminant(s) as possible; to this end, an adsorptive chromatographic technique should be employed. Ion-exchange chromatography (*UNIT 8.2*) and hydrophobic-interaction chromatography (HIC; *UNIT 8.4*) are generally the best chromatographic techniques for capture at any scale of operation. Certain affinity techniques are also effective, including lectin affinity chromatography (*UNIT 9.1*), dye affinity chromatography (*UNIT 9.2*), immunoaffinity chromatography, and metal-chelate affinity chromatography (MCAC). Affinity chromatography is very useful for capture on a small scale (e.g., <1 g). Larger-scale capture using affinity-based methods is generally avoided because of the cost of the chromatographic media and reagents (especially for immunoaffinity chromatography).

At the capture stage the sample is very crude. It may be turbid from the presence of cellular debris or viscous from the presence of DNA, and will typically represent the largest volume to be processed during the purification procedure. Water is often the major contaminant, especially in samples from cell-culture fluids or fermentation broth. The sample may also contain pigments, particulates, and lipophilic materials that can easily clog chromatography columns or bind nonspecifically to certain media. Once such contaminants are introduced into a chromatography system, they can be very difficult to remove. The sample may also contain proteinases or other agents that can potentially destroy or denature the target protein.

Ion-exchange or HIC media suitable for capture must allow high throughput of dilute, turbid, or viscous samples. This is achieved by using bead diameters of 40 to 300 µm. Columns packed with such relatively large beads can usually be operated at lower pressures and higher flow rates, and are less prone to fouling or clogging from particulates in the sample. Higher flow rates reduce the time required to handle large volumes, which in turn reduces the potential for product loss from degradation or denaturation.

When the volume of crude sample is very large (or larger than can be reasonably handled with available pumps or columns), batch techniques (*UNIT 8.2*) can be used at the capture stage. In batch adsorption of the target protein by ion exchange, HIC, or affinity chromatography, the chromatography medium is mixed directly with the sample in a suitable vessel. When the target protein is adsorbed, the medium is separated from the sample by filtration, centrifu-

POLK CENTRAL UNIVERSITY LIBRARY

gation, or settling and decantation. The target protein is then eluted from the medium and collected. For both column and batch techniques, elution of the target protein at the capture stage is often achieved using simple step gradients, but continuous gradients may be used to achieve higher resolution with column techniques. Specific medium requirements and methodologies for use at the capture stage are presented in *UNIT 8.2* for ion-exchange chromatography and in *UNIT 8.4* for HIC.

Intermediate Purification Stage

The next stage in the purification process is intermediate purification. Once the solution containing the target protein has been clarified and concentrated, only small amounts of other types of biomolecules (e.g., lipids and nucleic acids) should be present. The target protein and remaining protein contaminants have a functional or structural attribute in common, whose nature depends on the technique that was used at the capture stage. If ion exchange was used, the contaminants and target protein will be similar in charge characteristics; if HIC was used, similar in hydrophobicity; if affinity methods were used, similar in a ligand- or antibody-binding site, and if ultrafiltration or gel filtration was used, similar in size.

Because the contaminants have a physicochemical similarity to the target protein, it is best to exploit a different attribute of the target protein or contaminant during the intermediate purification stage than was used during the capture stage. Use of the same chromatographic technique for both capture and intermediate purification is not recommended. The combination of ion exchange and HIC is very effective in most purification strategies. Proteins are eluted from HIC media at low ionic strength, which is ideal for direct application of the sample to an ion-exchange column, where binding occurs at low ionic strength. Conversely, proteins are eluted from ion-exchange media with increasing ionic strength, which is ideal for subsequent direct application of the sample to a HIC column, where binding occurs at high ionic strength. Cation and anion exchange in combination can also be very effective. The reduced sample volume in the intermediate purification stage also allows use of negative adsorption chromatography, which is designed to bind contaminants to the column, allowing the target protein to pass through.

Chromatography techniques used in intermediate purification should resolve the target protein from contaminants on the basis of small differences in a single physicochemical attribute. High resolution and high yield are the primary goals of intermediate purification. To achieve these goals, a chromatography medium of smaller bead size than that used at the capture stage should be selected. The advantage of smaller bead diameters is increased resolution resulting from decreased peak width. However, smaller bead diameters typically require higher operating pressures. To further enhance resolution during intermediate purification, elution of the target protein is often done using a linear gradient. Specific medium requirements and methodologies for use at the intermediate purification stage are presented in *UNIT 8.2* for ion-exchange chromatography and in *UNIT 8.4* for HIC.

Polishing Stage

Polishing is the final stage in the purification process. The goal of polishing is to remove structural and functional variants of the target protein, as well as any trace contaminants. After polishing, the target protein should be in a suitable form for its intended use. The contaminants and structural variants that must be removed during polishing share very similar physicochemical attributes with the target protein. Chromatographic techniques employed in the polishing stage should exploit a different physicochemical attribute of the target protein than those used for capture and intermediate purification. The similarity of contaminants to target protein heightens the need for high-resolution techniques during this stage. Chromatofocusing, gel filtration (*UNIT 8.3*), reversed-phase chromatography (RPC; Corran, 1989), and affinity-based techniques (Chapter 9) are all useful in this stage. RPC is very effective for resolving structural variants of a target protein, but generally leads to loss of activity of the target protein because of the organic solvents employed. Adsorptive techniques such as chromatofocusing and affinity chromatography often require special eluants to recover the target protein, which may have to be removed before the purified target protein can be used. Gel filtration does not generally require any special eluants, and is often the best technique for polishing.

Optimizing Purification

Throughout the three stages of the purification process, the concentration of target protein is increasing with respect to the concentration of contaminants. In addition, the contaminants to be removed at each stage are increasingly

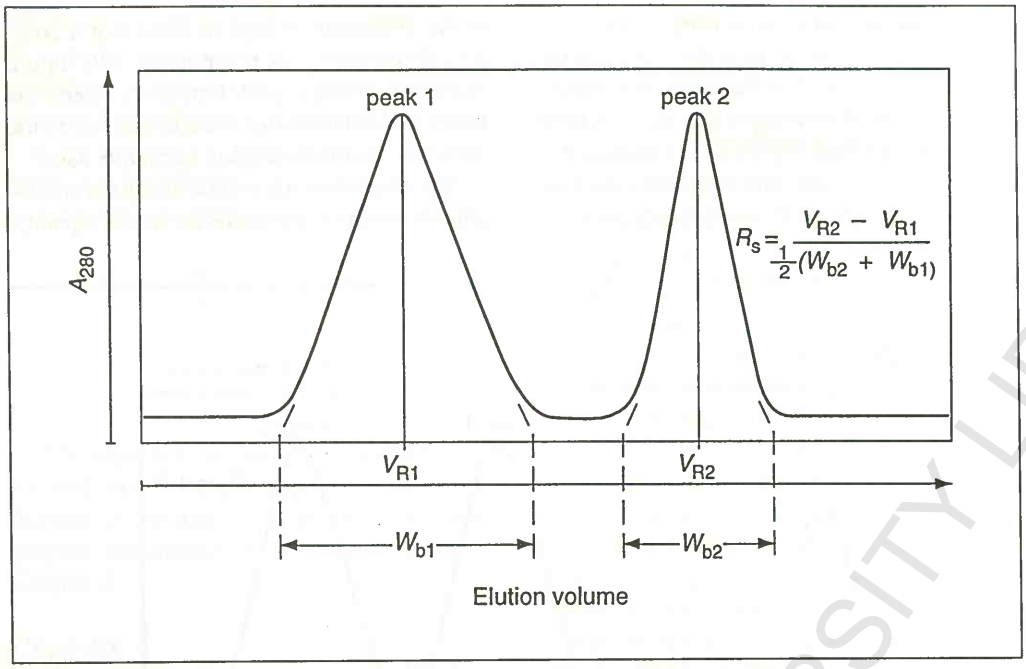

Figure 8.1.2 Hypothetical chromatogram illustrating calculation of elution volumes and peak widths for two peaks. Total elution volume is plotted against absorbance at 280 nm. V_{R1} and V_{R2} are the elution volumes (at the peak maxima) of peaks 1 and 2, respectively; W_{b1} and W_{b2} are the peak widths (at base) of peaks 1 and 2, respectively. Peak widths at base represent the segment of the baseline intercepted by the tangents drawn to the inflection points of the peak. Resolution (R_s) is defined as the distance between the elution volumes at peak maxima divided by the average of the peak widths, according to Equation 8.1.1 (see discussion of Resolution).

similar to the target protein. This increases the need for higher resolution and better yields at each progressive step. It is desirable to examine the efficacy of several techniques at each stage of the procedure before deciding on a specific one to use. Once a specific chromatographic technique has been chosen, the methodology for that step should be optimized: first to achieve maximum resolution, then maximum capacity and yield, and finally maximum speed. This approach will result in a fast, efficient, economical, and robust purification strategy.

PARAMETERS AFFECTING CHROMATOGRAPHIC RESOLUTION

Resolution

Resolution is a measure of the relative separation achieved between two chromatographically distinct materials, and maximum resolution is the primary goal of any purification step. This discussion covers the main theoretical parameters that affect ability to resolve components of a protein sample into chromatographically distinct forms, thereby providing a basis on which to judge chromatographic results. The main parameters affecting resolution are selectivity, efficiency, and capacity. More detailed discussions are found in Giddings and Keller (1965) and Janson and Ryden (1989).

The result of any chromatographic separation is often expressed as the resolution between the zones or peaks containing the chromatographically distinct sample components. The resolution (R_s) of two peaks obtained in a chromatography step may be determined from the chromatogram shown in Figure 8.1.2 according to Equation 8.1.1, where V_{R2} is the elution volume of peak 2, V_{R1} is the elution volume of peak 1, W_{b1} is the width of peak 1, and W_{b2} is the width of peak 2. In cases where a constant eluant flow is maintained and fractions are collected at regular time intervals, V_{R1}, V_{R2}, W_{b2}, and W_{b1} may be expressed in units of time rather than volume. It is necessary that the same units (time or volume) be used to express all terms in the equation to give a dimensionless value to R_s.

$$R_s = \frac{V_{R2} - V_{R1}}{\frac{1}{2}(W_{b2} + W_{b1})}$$

Equation 8.1.1

POLITECNICA UNIVERSITY LIBRARY

Resolution values can be used to determine if further optimization of a chromatographic procedure is required, as they provide a numerical indication of whether two peaks have been completely resolved. Figure 8.1.3 compares two separation results: one with completely resolved peaks and the other with incompletely resolved peaks. It should be kept in mind that a completely resolved peak is not necessarily a pure substance. A single peak frequently represents multiple substances that are not resolved by the particular chromatographic technique used.

The resolution achievable in any chromatographic system is proportional to the capacity,

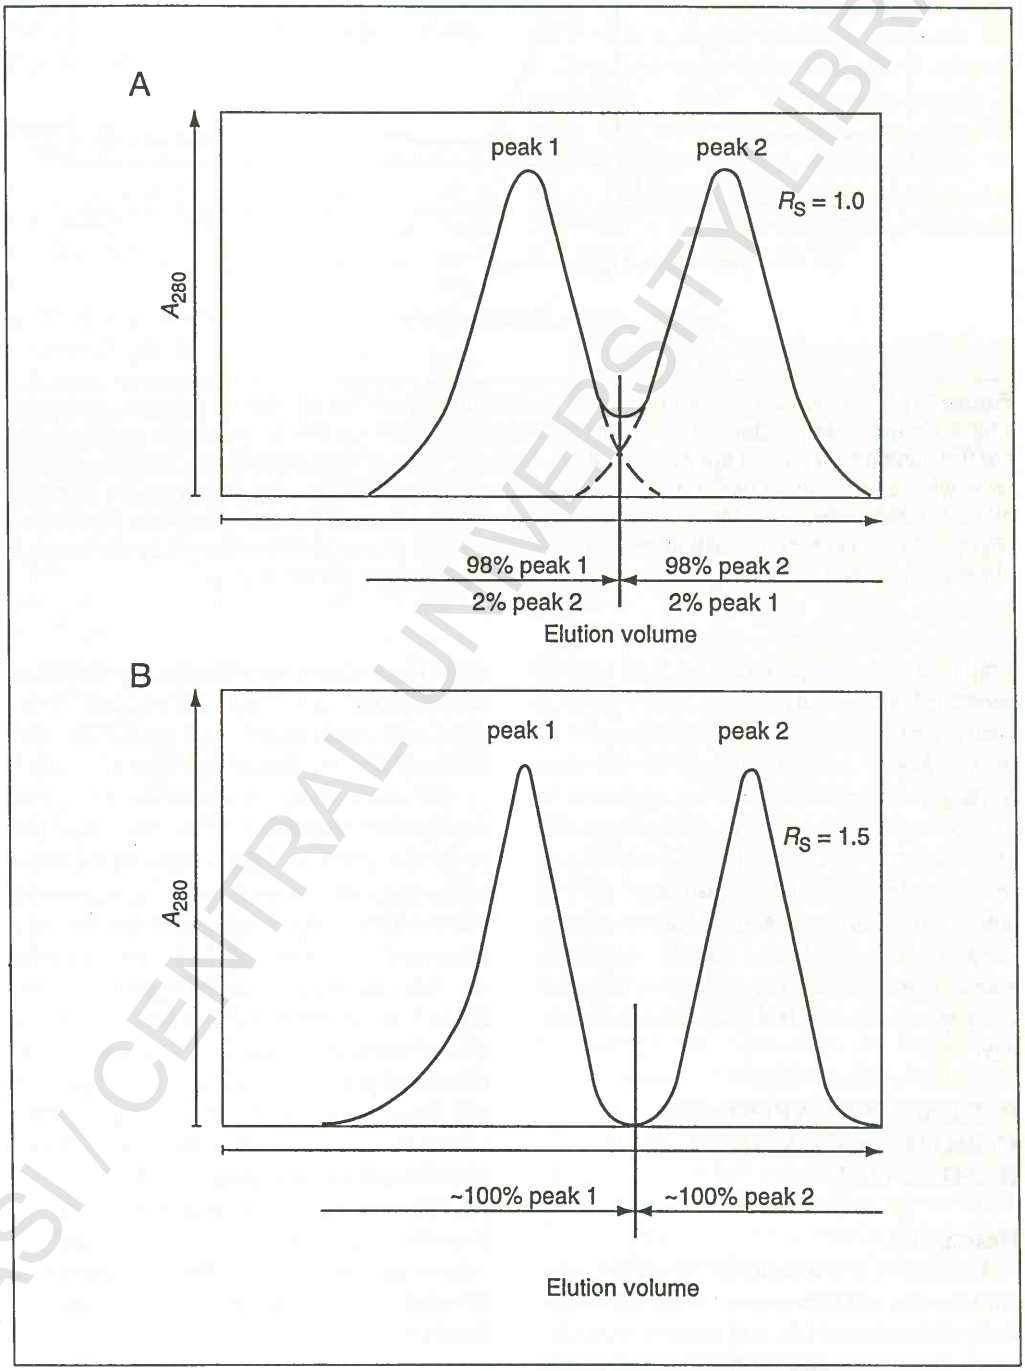

Figure 8.1.3 Separation results with different resolutions. **(A)** When R_s = 1.0, 98% purity has been achieved—i.e., 98% of the fraction collected at peak 1 consists of a single protein with the remaining 2% being contamination from the protein collected at peak 2; conversely, 98% of the fraction collected at peak 2 consists of a single protein with the remaining 2% being contamination from peak 1. **(B)** Complete (baseline) resolution requires that R_s >1.5. At this value, the peaks are completely separated from each other (i.e., the purity of each peak is >99.9%).

PCU IASI / CENTRAL UNIVERSITY LIBRARY

efficiency, and selectivity of the system. Each of these factors must be considered and controlled to achieve success. The theoretical expression for resolution is Equation 8.1.2, where k is the average capacity factor for the two peaks, N is the efficiency factor for the system, and α is the selectivity factor of the medium.

$$R_s = \frac{1}{4}\left(\frac{k}{1+k}\right)\left(N^{-2}\right)\left(\frac{\alpha-1}{\alpha}\right)$$

Equation 8.1.2

The impact of various experimental factors on resolution in various stages of protein purification is discussed for specific chromatographic techniques in subsequent units of Chapter 8.

Capacity

The capacity or retention factor (k) is a measure of retention of a sample component. It should not be confused with the loading capacity of a column, which is expressed as milligrams of sample bound per milliliter of gel and represented by the area under a peak. The capacity factor may be calculated for any individual peak in a chromatogram. For example, the capacity factor for peak 2 in Figure 8.1.4 is derived from Equation 8.1.3, where V_{R2} is the elution volume of peak 2 and V_m is the volume of the mobile phase (i.e., the total bed volume).

$$k = \frac{V_{R2} - V_m}{V_m}$$

Equation 8.1.3

In Equation 8.1.2 for R_s, presented in the discussion of Resolution, k is the average of k_1 (capacity factor for peak 1) and k_2 (capacity factor for peak 2).

Adsorption techniques such as ion exchange, HIC, chromatofocusing, RPC, and affinity chromatography can have high capacity factors because experimental conditions can be manipulated so that the elution volume for a peak can exceed the total bed volume (V_m as is the case with peaks 2 and 3 in Fig. 8.1.4.) However, in gel filtration, which is a non-adsorptive technique, all peaks must elute within the volume V_m–V_o as is the case with peak 1 in Fig. 8.1.4. The impact of experimental conditions on capacity at various stages of protein purification are discussed for different purification techniques in subsequent units of Chapter 8.

Efficiency

The efficiency factor (N) is a measure of zone broadening (peak width) occurring on a column. It can be calculated for any given peak from Equation 8.1.4, where V_R is the elution volume (i.e., the total volume of eluant that has

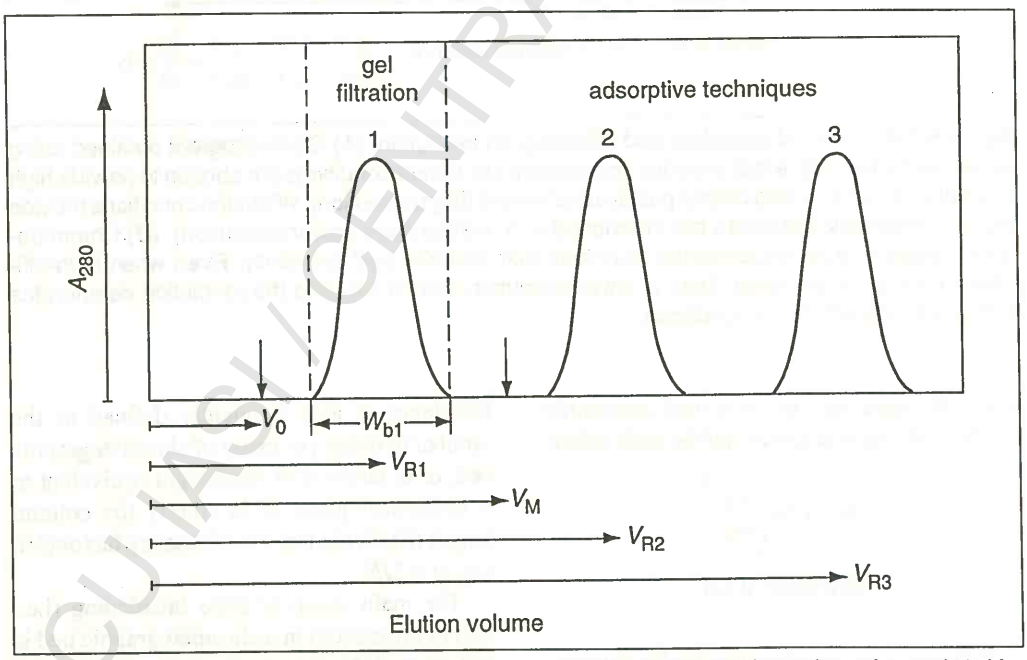

Figure 8.1.4 Hypothetical chromatogram. V_o = void volume; V_{R1} = elution volume for peak 1; V_{R2} = elution volume for peak 2; V_{R3} = elution volume for peak 3; V_M = volume of mobile phase; W_{b1} = peak width for peak 1; W_{b2} = peak width for peak 2.

FCU IASL / CENTRAL UNIVERSITY LIBRARY

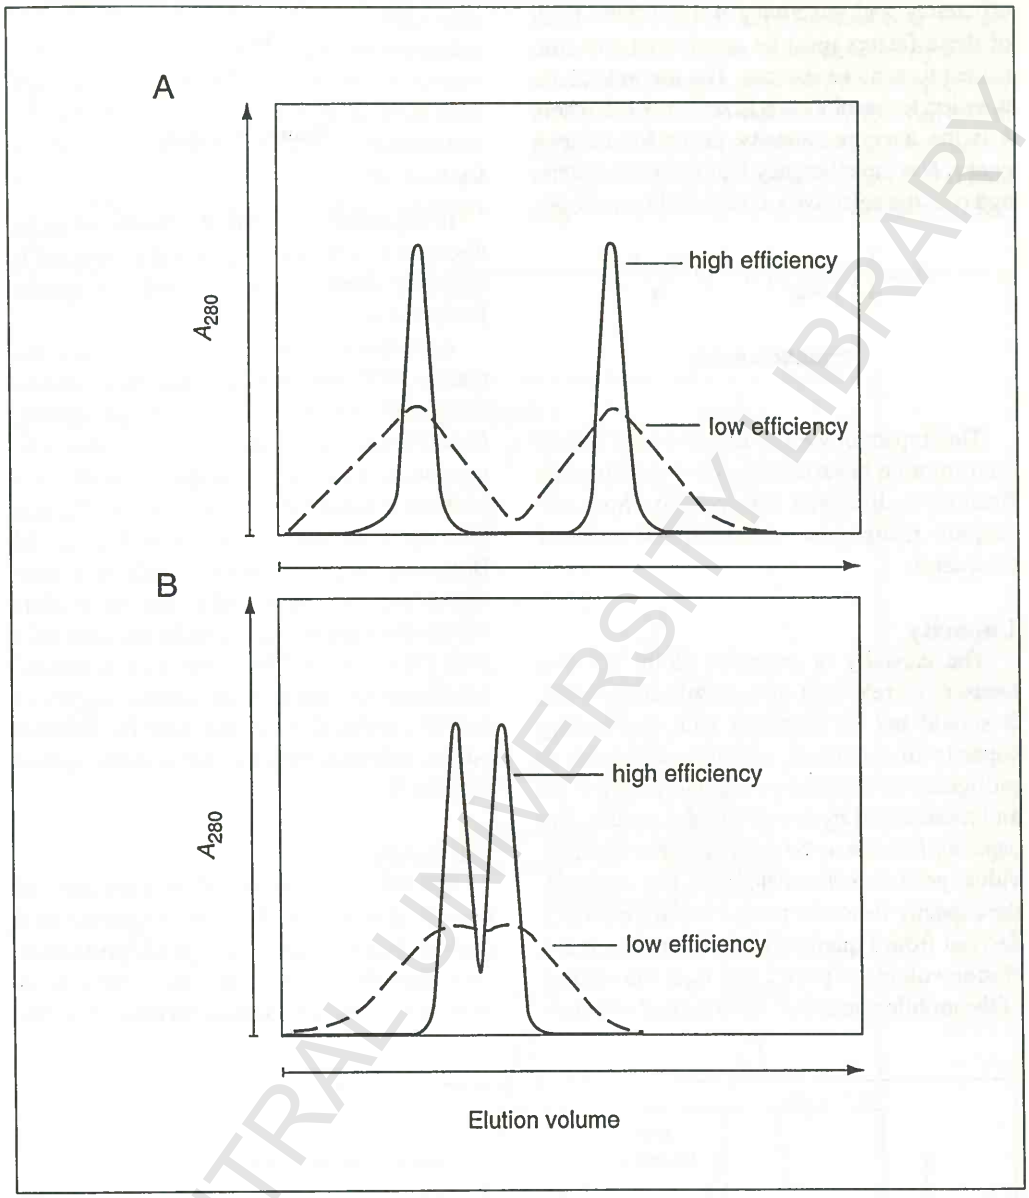

Figure 8.1.5 Effect of selectivity and efficiency on resolution. (**A**) Chromatogram obtained using experimental technique that provides good selectivity. Where conditions are chosen to provide high efficiency, two narrow and distinct peaks are obtained (high resolution). When the conditions provide only low efficiency, the peaks are broadened and overlap more (lower resolution). (**B**) Chromatogram obtained using experimental technique that provides bad selectivity. Even when high-efficiency conditions are used, there is lower resolution than in (A), and the resolution deteriorates further with low-efficiency conditions.

passed through the column at peak maximum) and W_h is the peak width at half the peak height.

$$N = 5.54\left(\frac{V_R}{W_h}\right)^2$$

Equation 8.1.4

Efficiency (N) may be expressed as the number of theoretical plates for the column under specific experimental conditions (see *UNIT 8.3*). Efficiency is also frequently defined as the number of plates per meter of chromatographic bed, or in terms of H, the height equivalent to a theoretical plate. H is simply the column length (L) divided by the efficiency factor (N); i.e., $H = L/N$.

The main cause of zone broadening (i.e., loss of efficiency) in a chromatographic bed is diffusion. Diffusion perpendicular to the flow is restricted by the walls of the column. Therefore, longitudinal diffusion is the primary fac-

PCU IASI / CENTRAL UNIVERSITY LIBRARY

tor contributing to zone broadening. While a protein is adsorbed to the medium, little or no diffusion takes place, but once the protein is unbound, diffusion begins. The amount of diffusion that occurs is proportional to the time required for the material to emerge from the system. Loss of efficiency resulting from diffusion is minimized if the distances available for diffusion in the mobile phase, gel beads, and system are minimized. In practice, efficiency increases with increasing uniformity in particle size and with decreasing bead size. Good experimental technique is required for high efficiency. Unevenly packed chromatography beds and trapped air will lead to channeling, zone broadening, and consequent loss of resolution. Loss of efficiency also stems from system effects such as dead volumes in the system, poor mixing during gradient formation, and pulsations in flow.

Selectivity

Selectivity of a chromatographic medium defines the ability of that medium to separate peaks (i.e., it is a measure of the distance between two peaks in a chromatogram; see Fig. 8.1.5). The selectivity factor (α) can be calculated from a chromatogram using Equation 8.1.5, where k_2 is the capacity factor for the second peak (see discussion of Capacity), k_1 is the capacity factor for the first peak, V_{R2} is the elution volume of the second peak, V_{R1} is the elution volume of the first peak (see Fig. 8.1.2), and V_m is the volume of the mobile phase.

$$\alpha = \frac{k_2}{k_1} = \frac{V_{R2} - V_m}{V_{R1} - V_m} \approx \frac{V_{R2}}{V_{R1}}$$

Equation 8.1.5

Selectivity is more important than efficiency (N) in determining resolution because R_s is directly proportional to selectivity, but is proportional only to the square root of efficiency (see Fig. 8.1.5 along with Equation 8.1.1 and Equation 8.1.2 for R_s in the discussion of Resolution). Hence, a four-fold increase in efficiency is required to double resolution, as compared with a two-fold increase in selectivity. In practice, selectivity depends partly on the chromatographic technique employed but can usually be controlled by manipulating experimental conditions, such as the pH and ionic strength of the mobile phase. Because this can be done easily and predictably, selectivity is the factor that is exploited to achieve maximum resolution in column chromatography rather than efficiency, which is fixed by the particle size and uniformity of the medium selected.

Ion-Exchange Chromatography

Ion-exchange chromatography separates biomolecules on the basis of charge characteristics. Charged groups on the surface of a protein interact with oppositely charged groups immobilized on the ion-exchange medium. As illustrated in Figure 8.2.1, the charge of a protein depends on the pH of its environment (the operating pH). The pH at which the net charge of a protein is zero (i.e., where the number of positive charges equals the number of negative charges) is known as the isoelectric point (pI). When the operating pH is greater than the pI, the protein will have a net negative charge, and should bind to anion-exchange media, which are positively charged. When the operating pH is less than the pI, the protein will have a net positive charge, and should bind to cation-exchange media, which are negatively charged.

The Strategic Planning section outlines the basic steps in planning and carrying out ion-exchange chromatography to separate proteins. Basic Protocol 1 describes batch adsorption of protein to an ion-exchange medium followed by elution using a step gradient of increasing salt concentration. This technique accommodates a wide range of sample volumes and is most often used in the capture stage of protein purification (*UNIT 8.1*). Batch techniques have minimal system requirements. The Alternate Protocol describes use of a step gradient of increasing pH in batch purification. Basic Protocol 2 describes adsorption of protein to an ion-exchange medium in a column, followed by elution with a linear gradient. Basic Protocol 2 provides a higher resolution than Basic Protocol 1, and is therefore used in the intermediate purification and polishing stages of protein separation (*UNIT 8.1*). Support Protocol 1 describes a pilot experiment to determine initial conditions for batch or column chromatography (i.e., pH required for binding, change in pH or salt concentration required for elution, and available capacity of a medium). Support Protocol 2 describes a means of calculating the dynamic capacity (*UNIT 8.1*) of an ion-exchange column, Support Protocol 3 describes methods for producing continuous gradients of pH and salt concentration to elute proteins from ion-exchange columns, Support Protocol 4

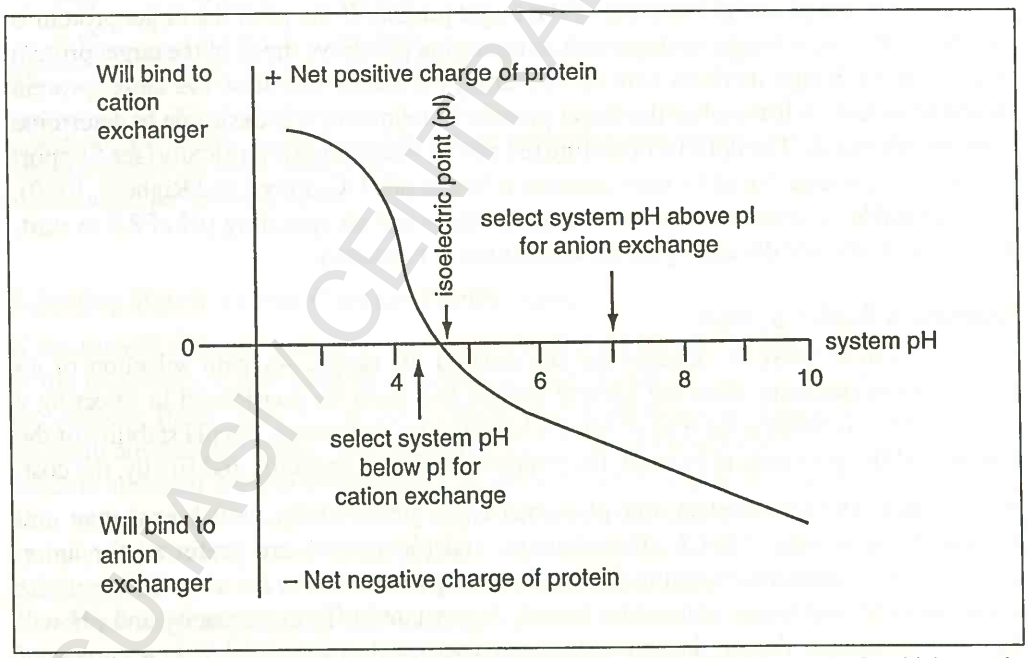

Figure 8.2.1 Net charge of a protein as a function of pH, showing the pH ranges in which protein is bound to anion or cation exchangers. The pH range over which the protein is stable may be only a small fraction of the binding range; this must also be taken into consideration when choosing an ion-exchange medium.

describes regeneration of used ion-exchange media, and Support Protocol 5 details storage of ion-exchange media.

STRATEGIC PLANNING

There are a number of basic steps in developing an ion-exchange method for protein purification. First, an appropriate ion-exchange medium must be selected, as well as the optimal operating pH and buffer system for the medium and sample (see following discussions on Selecting an Ion-Exchange Medium and Selecting a Buffer System). It is then necessary to decide whether batch or column chromatography is appropriate given the physical characteristics of the sample, the sample volume to be used, and the availability of suitable equipment (see following discussion on Selecting Batch Versus Column Purification). Next, pilot experiments are conducted to determine conditions for binding and eluting the protein (see Support Protocol 1). It is also necessary to make sure that the capacity of the medium is sufficient to isolate the desired quantity of protein (see Support Protocol 1 and Support Protocol 2). When these initial conditions have been determined, the medium and sample are prepared, the sample is bound to the medium, unbound sample components are washed away, and bound sample components are selectively eluted and collected (see Basic Protocol 1, Basic Protocol 2, or Alternate Protocol). The medium may then be cleaned and regenerated (see Support Protocol 5). Finally, results are evaluated and conditions optimized if necessary (see Critical Parameters).

Selecting an Ion-Exchange Medium

A wide variety of ion-exchange media are commercially available, but no miracle medium exists that is best for every protein purification. Criteria for selecting an ion-exchange medium include the specific requirements of the application, the pI and molecular size of the sample components (i.e., target protein and contaminants), and the available equipment (e.g., pumps and columns).

It is necessary to begin by selecting either anion or cation exchange. This requires knowledge of the pI and pH stability of the target protein. If the pI of the target protein is known, an anion-exchange medium with an operating pH above the pI of the target protein or a cation-exchange medium with an operating pH below the pI of the target protein should be selected. If the pI of the target protein is unknown, it is desirable to determine it before beginning. The optimal operating pH can be determined empirically (see Support Protocol 1). Because the pI for most proteins is below pH 7 (Gianazzi and Righetti, 1980), it is reasonable to select an anion-exchange medium and an operating pH of 8.5 to start, then evaluate the results and optimize conditions as necessary.

Selecting a Buffer System

A buffer system must be selected for the desired pH range. As with selection of an ion-exchange medium, there are several factors that must be considered in selecting a buffer system, including the type of ion exchange to be performed, the pH stability of the sample and the pH range to be used, the required buffering capacity, and finally, the cost.

Anionic buffers (e.g., acetate and phosphate) are preferred for cation exchange and cationic buffers (e.g., Tris·Cl, ethanolamine, and piperazine) are preferred for anion exchange. It is important to ensure that the buffering ion will have the same charge as the ion exchanger, and hence will not be bound. A constant buffering capacity and pH will thus be maintained during the ion-exchange experiment. Table 8.2.1 lists a variety of buffers useful for anion and cation exchange. Additives to be included in the buffers (e.g., detergents or protease inhibitors) should also carry the same charge as the ion-exchange medium, to preclude binding.

Selecting Batch Versus Column Purification

If the sample volume is large in relation to the size of the pumps and columns available in the laboratory, batch adsorption techniques (see Basic Protocol 1) are appropriate for the capture stage (*UNIT 8.1*) of purification. Batch methods, in which the sample and medium are directly mixed without use of a column, are employed to reduce the sample volume and total protein content prior to column chromatography. Batch techniques are also very useful for capture of the target protein from extremely crude samples (e.g., samples containing particulates and/or aggregates). In batch methods the flow and packing characteristics of the medium are of minor importance, but economy and capacity are of primary importance. Ion-exchange media suitable for batch purification at the capture stage of protein purification are presented in Table 8.2.2.

High resolution is required in the intermediate purification and polishing stages of protein purification (*UNIT 8.1*) and this can only be achieved using column chromatography.

However, higher-than-necessary resolution is frequently traded off for greater throughput (i.e., amount of material processed in a defined time). The packing and flow characteristics of the medium are of primary importance when using column chromatography. Columns packed with smaller beads usually require higher operating pressures than columns packed with larger beads. However, smaller beads offer higher resolution, resulting from the increased efficiency that comes with decreasing bead size (*UNIT 8.1*). Larger beads are desirable for applications requiring higher throughput. A medium with the smallest bead size that will provide the necessary throughput (and whose operating pressure can be accommodated by available equipment) should be selected. Table 8.2.3 lists a variety of media suitable for column purification at various stages in the purification process. See *SUPPLIERS APPENDIX* for contact information of suppliers of these media, all of whom provide technical support for selection and use of specific media.

Capacity of Ion-Exchange Media

The amount of ion-exchange medium required for a particular application will be determined by the protein capacity of the medium (i.e., the amount of protein that can be bound to the matrix) at the chosen pH. The amount of medium required will in turn determine the size of column required. The capacity of an ion-exchange medium is dependent on a variety of factors, including charge and molecular size of the components in the sample and experimental conditions employed (also see *UNIT 8.1*).

The number of charged groups on a specified amount of matrix that can participate in ion exchange is termed **ionic** or **total** capacity. However, ion-exchange media are porous and the ion-exchange groups are usually distributed throughout the bead. The amount of protein that will bind is dependent on the ability of the sample components to diffuse into the bead, and this ability is related to the molecular size of the components and the pore structure of the matrix (see *UNIT 8.3*). In addition, large molecules such as proteins can bind to multiple ion-exchange groups (or sterically hinder other molecules from binding) depending on the shape and surface-charge distribution of the protein, as well as the spatial

orientation of the exchange ligands on the matrix. These factors are taken into account in the available and dynamic capacity of a matrix or column.

Available capacity is defined as the amount of a specific protein that will bind to an ion-exchange medium at a defined pH, salt concentration, and sample concentration in a batch purification process. When medium is packed in a column, the amount of a specific protein that will bind is dependent on many of these factors, but also on the column dimensions and flow rate. The capacity of a column operating under defined conditions is termed the **dynamic capacity**. The dynamic capacity is typically less than the available capacity for the same sample under the same operating conditions.

Ion-exchange media in which the charge state of the ligand is sensitive to the operating pH are termed weak ion exchangers. The usable pH range of weak ion exchangers is narrower than that of strong ion-exchange media, in which the charge on the ligand used for exchange is constant (i.e., insensitive to pH). Ion-exchange media with DEAE (diethylaminoethyl) or CM (carboxymethyl) groups as the ligand for exchange are considered weak ion exchangers. Because the ionic capacity of weak ion-exchange media is variable, strong ion-exchange media are recommended for pilot experiments (see Support Protocol 1).

When selecting ion-exchange media for batch or column purifications, the amount of medium required should be estimated from the manufacturer-supplied capacity data for a protein similar in size to the target protein to be purified. Be aware of what type of capacity (i.e., ionic, available, or dynamic) is being reported and the experimental conditions under which the reported capacity was determined (see Table 8.2.3). A general recommendation is to begin pilot experiments at ~10% of the published capacity data, then determine the capacity for your system.

Preparing Solutions

All aqueous solutions for use in ion-exchange chromatography should be prepared with distilled or deionized water (Milli-Q purified or equivalent). Solutions and samples for column chromatography should be filtered, degassed, and equilibrated to the appropriate temperature prior to use. Special attention must be given to any additives to be included in the buffer to be sure that they will not bind to the column (see preceding discussion on Selecting a Buffer System). If the chosen additives increase the viscosity of the mobile phase, the flow rate should be decreased.

Chromatography Systems

Column techniques typically result in higher resolution than batch techniques, and should be used during the intermediate purification and polishing stages (*UNIT 8.1*) of a purification procedure. However, to achieve high resolution, an appropriate chromatography system is required. A chromatography system may be described simply by the functional operations required to perform a chromatographic separation. The minimum functions required (Fig. 8.2.2) include a buffer delivery system capable of gradient formation, a mechanism for introducing sample into the system, the column itself (properly packed with the appropriate ion exchanger), an in-line UV monitor suitable for use at 280 nm, a chart recorder, and a fraction collector to preserve the separation. Additional unit operations may include system controllers for automated operation as well as data-acquisition systems. The equipment required to perform each of these unit operations is ultimately determined by the chromatography medium and column selected. Specifically, the operating pressure and flow characteristics of the packed column will be the most important factors for selecting equipment to fit the column, or for selecting columns to fit existing equipment.

RCU IASRI CENTRAL UNIVERSITY LIBRARY

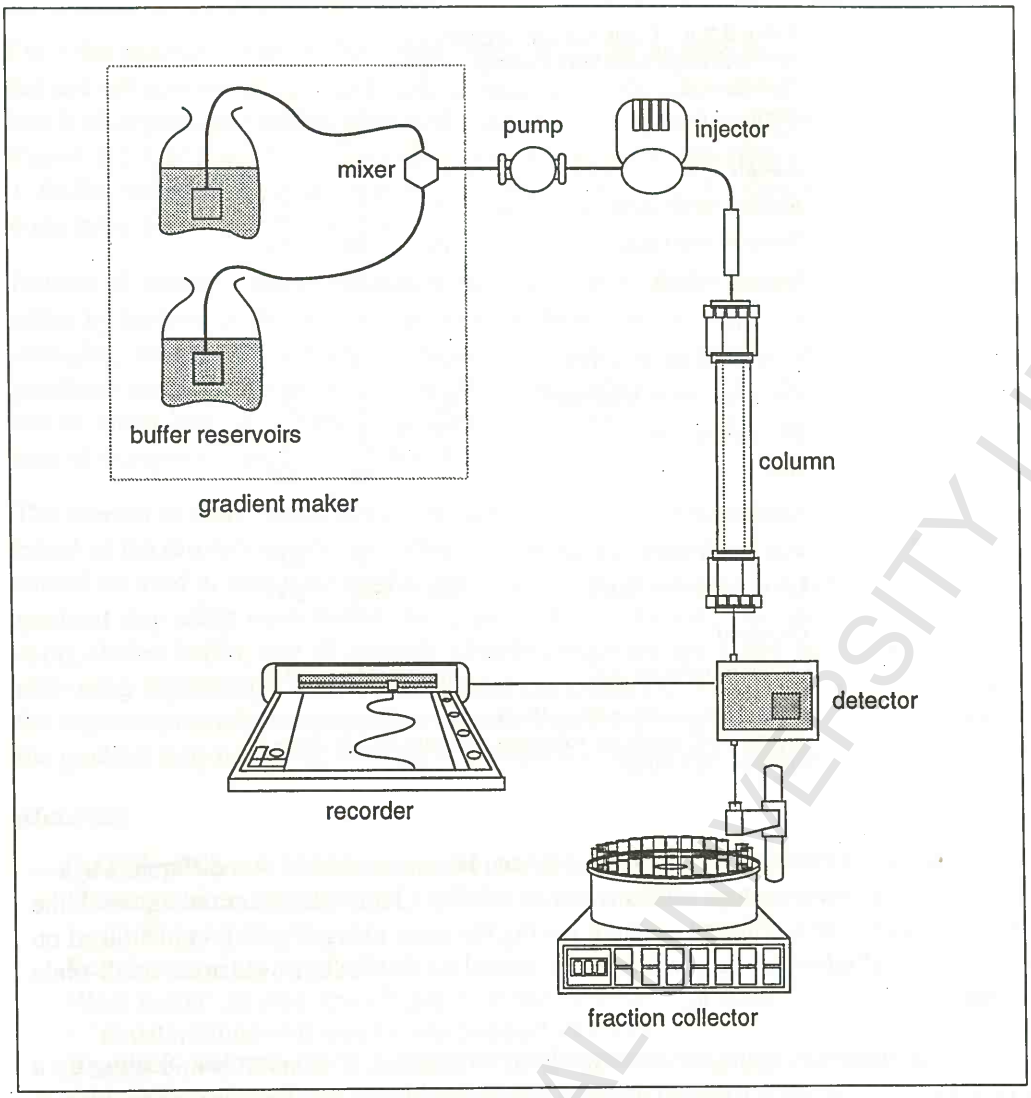

Figure 8.2.2 Liquid column chromatography system with gradient maker.

It is highly recommended that prepacked columns be used and that the manufacturer be consulted prior to purchase as to equipment requirements for proper operation. This will save time and money and increase the probability of success. If columns are to be packed in the laboratory, the manufacturer's packing instructions for the medium should be followed and column efficiency and function should be tested with representative standards prior to use with the actual sample. There is no single packing methodology that is optimal for all types of media. Examples of packing techniques suitable for use with ion exchangers are included in *UNIT 8.4*. Table 8.2.3 lists a variety of ion-exchange media available either in prepacked columns and/or in bulk for packing in the laboratory. Several manufacturers offer inexpensive disposable ion-exchange columns, suitable for many applications, that can be operated using only a syringe.

Scale-Up Conditions

Ion-exchange separations are typically developed and optimized on a small scale before the entire sample is committed. It is thus important to choose an ion exchanger that will allow simple and convenient scale-up, so that methods established on a small column can be applied more or less directly to a larger one.

B.C.U. „M. I... SCU" IAŞI

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

Table 8.2.4 Scale-up Calculations for Ion-Exchange Column Chromatography

Scale	1×	10×	100×
Sample			
Sample concentration (mg/ml)	1	1	1
Sample load (mg)	10	100	1000
Sample volume (ml)	10	100	1000
Column			
Column diameter (cm)	0.5	1.6	5
Cross-sectional area (cm^2)	0.2	2	20
Bed height (cm)	5	5	5
Bed volume (ml)	1	10	100
Flow Rate			
Volumetric flow (ml/min)[a]	2	20	200
Linear velocity (cm/hr)	300	300	300
Gradient			
Gradient volume (ml)	20	200	2000

[a]Linear flow (cm/hr) multipled by the cross-sectional area of the column (cm^2) equals the volumetric flow rate (ml/hr); cm/hr × cm^2 = cm^3/hr = ml/hr.

Scaling up in ion-exchange chromatography can be approached in two different ways—either the same ion-exchange medium can be used in a larger-diameter column with the same bed height, or a different medium having the same charged group immobilized on a matrix with a higher throughput can be substituted for the medium used in the small-scale separation.

The former approach, using the same medium throughout, is the simplest. Scaling up a separation with the same medium and bed height used in the small-scale optimization is achieved by employing simple scale factors to adapt the flow, gradient volume, and sample load to the increased volume of a larger-diameter column. The scale factor for the required increase in flow rate is the ratio of the cross-sectional area of the larger column to that of the smaller column (i.e., the factor by which the total flow of solution through the column must be increased so that the same linear velocity used in the small-scale experiment is maintained). The increase in gradient volume and sample loading are directly proportional to the increase in column volume. Table 8.2.4 shows an example of changes that must be made to various parameters for a 10- and 100-fold increase in scale.

BASIC PROTOCOL 1

BATCH ADSORPTION AND STEP-GRADIENT ELUTION WITH INCREASING SALT CONCENTRATION

This protocol describes adsorption of a protein to an ion-exchange medium by direct mixing of the protein-containing sample and the medium (in this case, an anion-exchange gel). This batch purification is in contrast to column purification (see Basic Protocol 2), in which the gel is packed in a column and the sample is passed through it. Batch adsorption is particularly useful where large volumes of sample are involved, which is usually the case in the capture stage of protein purification (*UNIT 8.1*). The equipment used here is sufficient for sample volumes up to 1.5 liter. Larger samples may be divided and processed with parallel apparatuses, or processed sequentially on a single apparatus. Different-sized funnels and side-arm flasks may be used when appropriate.

RCU IASE/CENTRAL UNIVERSITY LIBRARY

Once the starting conditions have been determined (see Support Protocol 1), the range of pH and salt concentration where binding and elution occur is well defined. Conditions for batch adsorption and elution used in this procedure are based on the results, presented in Figure 8.2.3, of a test tube pilot experiment performed as described in Support Protocol 1. Buffer volumes and equipment were chosen on the basis of a sample volume of 1 liter containing 50 to 1000 mg of total protein.

Elution of sample components adsorbed to an ion-exchange medium can be achieved either by increasing the salt concentration of the mobile phase, as in this protocol, or by changing its pH (see Alternate Protocol). In batch techniques, discontinuous (step) gradients are used for elution. Column chromatography (see Basic Protocol 2) allows the use of either step or continuous gradients. Formation of continuous gradients requires special equipment (see Basic Protocol 2 and Support Protocol 3).

The number of incremental steps to include in a step gradient must be judged empirically based on the resolution achieved. Ideally (as in the procedure described here), three steps should be used in which all weakly bound materials are desorbed and eluted in the first gradient step using wash buffer, the target protein is eluted in the second gradient step using elution buffer, and all strongly adsorbed materials are eluted in the third gradient step using regeneration buffer. A minimum increment of 50 mM NaCl is recommended for experiments using step-gradient elution with increasing salt concentration. Steps in the gradient may be added, omitted, or modified as determined empirically.

Materials

QAE Sephadex A-25 (Pharmacia Biotech) or equivalent anion-exchange gel
Binding buffer: 20 mM Tris·Cl, pH 7.5 (or other buffer as determined empirically; see Support Protocol 1)
Protein sample to be purified
Wash buffer: 20 mM Tris·Cl (pH 7.5)/100 mM NaCl (or other buffer/salt solution as determined empirically; see Support Protocol 1)
Elution buffer: 20 mM Tris·Cl (pH 7.5)/350 mM NaCl (or other buffer/salt solution as determined empirically; see Support Protocol 1)
Regeneration buffer: 20 mM Tris·Cl (pH 7.5)/2 M NaCl (also see Support Protocol 5)

Boiling water bath (optional)
500-ml sintered-glass filter funnel, medium porosity
Three 2000-ml side-arm flasks
Conductivity meter

Swell and equilibrate ion-exchange gel

1. Add 10 g QAE Sephadex A-25 to 1 liter binding buffer and swell 2 days at room temperature or 2 hr in a boiling water bath.

   The volume of swollen gel will be ~70 ml.

2. Mount 500-ml sintered-glass filter funnel on 2000-ml side-arm flask and apply suction.

   Centrifugation (~5000 × g, 1 min) may be used instead of filtration to collect the gel, and may be preferred for processing small sample volumes. It is also possible to simply allow the gel to settle under gravity, then decant or aspirate the supernatant; this may be preferable for very large-scale operations.

3. Gently swirl swollen gel to resuspend. Pour gel slurry into funnel as fast as the fluid level in funnel permits, allowing buffer to collect in flask. Continue until all gel has been collected. Release suction after all buffer has been removed.

EDINBURGH CENTRAL UNIVERSITY LIBRARY

IMPORTANT NOTE: *Never use a magnetic stir bar to resuspend chromatography medium. This can damage beads by grinding them against the bottom of the vessel, resulting in fine particles that can slow the filtration process.*

4. Add 200 ml binding buffer to funnel and resuspend gel using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer.

5. Repeat step 4 at least three times to ensure equilibration.

   The gel is considered equilibrated when the pH and salt concentration of the eluant are the same as those of the binding buffer. If the procedures here are followed, there is little need to measure pH and salt concentration of the eluant because the gel is swollen and washed in binding buffer and the chance of error is very small. The worst-case scenario is that the target protein will not bind (see Troubleshooting). The repeated washings are more for the removal of fines than for adjustment of pH or salt concentration.

6. Add enough binding buffer to cover gel (~100 ml, to produce an ~50% slurry) and allow gel to stand in funnel until sample has been prepared.

Adsorb sample to gel

7. Adjust pH and salt concentration of protein sample to be purified to initial optimal values.

   For a pilot experiment to determine optimal initial values for pH and sale concentration, see Support Protocol 1.

   Samples prepared by salt precipitation may require desalting prior to ion exchange (see UNIT 8.3). The salt concentration of a sample can be reduced by adding distilled water until a desired salt concentration is achieved, as measured by a conductivity meter.

8. Combine gel and sample in 2000-ml beaker or wide-mouth flask.

   The ~50% gel slurry is swirled and poured from the funnel; transfer may be aided with a rubber policeman, spoon, stir rod, or wash bottle containing binding buffer.

9. Gently mix sample and gel by swirling every 15 min or shake on a platform shaker at sufficient rate to maintain gel in suspension. Allow 1 to 2 hr for binding at room temperature or 3 to 4 hr at 4°C.

   IMPORTANT NOTE: *Excessive shaking may result in foaming and possible denaturation of the target protein.*

10. Collect gel by filtration as in step 3. Save filtrate for assay.

    This filtrate is saved in case the target protein did not bind. All filtrates should be kept until the fraction containing the target protein has been identified. Storage conditions depend on the stability of the target protein; as a general rule they should be refrigerated to minimize microbial growth. Bacteriostatic agents may be added for prolonged storage.

11. Add 100 ml binding buffer to funnel and resuspend gel using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer. Repeat three or four times, pooling all washings with the filtrate from step 10.

    The gel containing the bound sample may be packed in a column for subsequent elution steps (see Basic Protocol 2).

Elute with step gradient of increasing salt concentration

12. Transfer the sintered-glass funnel to the top of a clean 2000-ml side-arm flask.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

13. Add an equal volume of wash buffer to gel in funnel and resuspend using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer. Save filtrate.

The wash buffer is the first step of the gradient. The filtrate will contain sample components that were weakly adsorbed to the gel (see annotation to step 10).

14. Measure absorbance of filtrate at 280 nm using wash buffer as blank.

15. Repeat steps 13 and 14 until the last filtrate shows no significant absorbance at 280 nm. Pool and save the filtrates.

16. Transfer the sintered-glass funnel to the top of a clean 2000-ml side-arm flask.

17. Add an equal volume of elution buffer to gel in funnel and resuspend using a stirring rod. Allow resuspended gel to stand 5 min, then apply suction to remove buffer. Save filtrate.

The elution buffer is the second step of the gradient. The filtrate will contain the sample components that were more strongly adsorbed to the gel and should include the target protein.

18. Measure the absorbance of the filtrate at 280 nm using elution buffer as a blank.

19. Repeat steps 17 and 18 until the last filtrate shows no significant absorbance at 280 nm. Pool and save the filtrates for assay and subsequent purification of the target protein.

If gel is to be reused, continue with remaining steps. Otherwise, discard the gel.

Regenerate ion-exchange medium for reuse

20. Transfer the sintered-glass funnel to the top of a clean 2000-ml side-arm flask.

21. Add an equal volume of regeneration buffer to gel in funnel and resuspend using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer. Repeat five times and discard filtrates.

The regeneration buffer removes strongly bound materials from the gel. See Support Protocol 5 for additional considerations in regenerating ion-exchange media.

22. Repeat step 11 for a total of five washes to reequilibrate the gel with binding buffer.

23. Check the pH and conductivity of the last filtrate to ensure that the gel is properly equilibrated.

See Support Protocol 5 for information on storing ion-exchange media.

pH-BASED STEP-GRADIENT ELUTION

ALTERNATE PROTOCOL

The net charge of a protein is pH dependent. Therefore, altering the pH of the mobile phase to make it closer to the pI of a protein can change its net charge, causing it to desorb and elute from an ion exchanger. Continuous pH gradients are very difficult to produce at constant salt concentration because charge characteristics of sample components, buffering ions, and ion-exchange media depend on the pH of the system. pH-based step gradients are much easier to produce and more reproducible.

The first basic protocol can be modified for pH-gradient elution by selecting a buffer at a pH suitable for elution, based on results obtained in a pilot experiment (see Support Protocol 1). This elution buffer is then used in steps 17 to 19 of the first basic protocol. Incubation times and buffer volumes should be increased by 20% when using pH elution.

BU ARI CENTRAL UNIVERSITY LIBRARY

When scouting methods for ion exchange, it is best to start with changes in salt concentration (see Basic Protocol 1) as this technique is simpler and more reproducible. Elution with pH change is only recommended when the ion-exchange behavior of the sample is well known and the resolution required cannot be attained with a change in salt concentration. pH elution may also be appropriate in cases where it provides a superior ionic/pH environment for loading in the next chromatographic step. A combination of increasing salt concentration and pH change may also be used for elution.

BASIC PROTOCOL 2

COLUMN CHROMATOGRAPHY WITH LINEAR GRADIENT ELUTION

Column chromatography is generally preferred to batch chromatography (see Basic Protocol 1), especially where high resolution is required, although it accommodates smaller sample volumes. Column chromatography requires specialized equipment to achieve high resolution, including a column containing the medium and a fluid-delivery system appropriate for the pressure and flow rate at which the column is to be operated. It is the technique preferred for the intermediate purification and polishing stages of protein purification (*UNIT 8.1*). Also in contrast to the first basic protocol, this technique uses a linear gradient for elution. Although more difficult to produce than step gradients (see Basic Protocol 1), linear gradients lead to better resolution (see Support Protocol 3).

The example presented here uses a Resource Q anion-exchange column from Pharmacia Biotech, which may be used with either HPLC (high-performance liquid chromatography) or FPLC (fast protein liquid chromatography) systems. Optimal conditions for other columns should be obtained from the manufacturer. Procedures mentioned in the protocol steps should be carried out according to the manufacturer's instructions for the particular chromatography system being used.

NOTE: All buffers, media, and other system components should be filtered, degassed, and equilibrated to the same temperature before use.

Materials

Liquid chromatography system (FPLC or HPLC)
Elution buffer: binding buffer (see Basic Protocol 1 and Support Protocol 1) containing 1 M NaCl
Binding buffer (see Basic Protocol 1 and Support Protocol 1)
Resource Q chromatography column (1-ml packed bed volume; Pharmacia Biotech)
Protein sample to be purified

Conductivity meter
0.22-µm filter

Prepare chromatography system

1. Set up the liquid chromatography system according to manufacturer's instructions, without the column in-line.

2. Test system performance by running a blank gradient ranging from 0% to 100% elution buffer in 20 ml at a constant flow rate of 5 ml/min.

   See Figure 8.2.2 for a diagram of a typical column chromatography system. The gradient is formed by placing binding and elution buffer in the appropriate buffer reservoirs (see Support Protocol 3 for detailed discussion of continuous gradient formation).

BCU IASI CENTRAL UNIVERSITY LIBRARY

Stability of the column at extremes of pH must be considered when choosing binding and elution buffers. The working stability of the Resource Q column is pH 2 to 12, and the stability for cleaning is pH 1 to 14.

The flow rate for the test should be appropriate for the column to be connected. For the Resource Q column, the recommended flow rate is 1 to 10 ml/min and the maximum operating pressure is 4 bar.

3. Test for system leaks and ascertain monitor stability according to system documentation. Test accuracy of gradient composition using conductivity meter.

Adding 0.1% (v/v) acetone to the elution buffer used in step 2 will allow observation of gradient composition at 280 nm using the UV monitor. Do not include acetone in the elution buffer used for the chromatographic run.

Prepare column

4. Purge system with binding buffer to remove any air, then install column in system.

New columns may require precycling prior to use; consult product documentation. Used columns may require cleaning or removal of storage solution prior to use (see Support Protocol 4).

5. Wash column with 5 V_c (5 ml for Resource Q column) of elution buffer at a flow rate of 5 ml/min and check for leakage.

V_c refers to the packed bed volume of a column and is calculated according to the equation $V_c = \pi r^2 \times L$, where r is the radius of the column and L is the bed height (i.e., the height of the packed medium in the column). As the Resource Q column used here has a packed bed volume of 1 ml, the column is washed with 5 ml of elution buffer. Consult product literature to find V_c for other columns.

6. Equilibrate column with 5 to 10 V_c of binding buffer at 5 ml/min. Collect one fraction at the end of the equilibration stage and measure pH and conductivity to ensure the pH and salt concentration of the fraction are the same as that of binding buffer.

If the pH and salt concentration of the fraction are not the same as that of the binding buffer, continue passing binding buffer through the column until equilibration is complete.

Purify protein sample and regenerate column

7. Adjust pH and salt concentration of sample to binding conditions determined in Support Protocol 1. Filter sample prior to injection using a 0.22-μm filter to remove particulates that may clog system or column.

For initial experiments, a sample containing 25 mg total protein is appropriate.

For columns packed with beads of average diameter ≥90 μm, a 1-μm filter may be used; for columns packed with beads of average diameter 34 to 90 μm, an 0.45-μm filter may be used. The 0.22-μm filter is appropriate for columns packed with beads of average diameter <34 μm (e.g., the Resource Q). Alternatively, the sample may be centrifuged 5 min at 20,000 × g to remove particulates.

8. Inject sample into column by opening sample injection valve. Begin fraction collection.

1-ml fractions are generally sufficient.

The flow rate during sample injection should be reduced for concentrated samples. It may be increased for dilute samples.

9. After all sample is injected, wash column with 3 to 5 V_c of binding buffer at 5 ml/min to remove unbound or weakly bound materials.

The monitor signal should be allowed to approach the baseline before continuing.

BCU LASS CENTRAL UNIVERSITY LIBRARY

10. Elute with a linear gradient of 0% to 100% elution buffer in 20 V_c (20 ml).

    Sample-injection valves should be closed to reduce the system dead volume before beginning gradient.

11. Regenerate column by washing with 5 V_c of elution buffer.

12. Reequilibrate column by washing with 5 to 10 V_c of binding buffer.

13. Assay fractions for target protein. Pool fractions containing target protein for further processing.

SUPPORT PROTOCOL 1

TEST TUBE PILOT EXPERIMENT TO DETERMINE STARTING CONDITIONS FOR ION-EXCHANGE CHROMATOGRAPHY

Before beginning an ion-exchange separation (Basic Protocol 1 or 2), the pH and salt concentration required for binding the target protein and the change in pH or salt concentration required for elution must be determined empirically. Once the initial binding conditions have been determined, the available protein capacity (for batch chromatography) is determined to predict the amount of medium that must be used for a given amount of sample. Dynamic capacity (for column chromatography) may be determined as in Support Protocol 2. This protocol is most appropriate when the sample is not strictly limited—e.g., when milligram quantities of a recombinant protein are available. If sample is scarce, a column method should be substituted.

As illustrated in Figure 8.2.3, aliquots of the protein-containing sample to be purified are mixed in test tubes with small quantities of ion-exchange gel that have been equilibrated with a series of buffers of different pH. The optimal binding pH is chosen on the basis of disappearance of target protein in the supernatant at a certain point in the series, then the process is repeated with another series of test tubes containing gel equilibrated with a series of salt solutions of different concentrations. The optimal salt concentrations for binding and elution are chosen respectively, on the basis of disappearance, then reappearance at another salt concentration, of protein in the supernatant. Finally, aliquots containing increasing protein concentrations are mixed with the gel in a buffer under the optimal binding pH and salt concentrations previously determined. The available capacity of the gel is then determined on the basis of the point where unbound protein appears in the supernatant.

The stability of the target protein at extremes of pH must be considered—i.e., the pH range chosen for the purification should be compatible with retention of structure and activity. In general, this can be evaluated with a crude preparation by incubating aliquots at a series of pH values, then performing the structural or functional assay at the optimal pH value.

NOTE: The method presented here is for anion exchange with increasing salt concentration for elution. Differences for cation exchange are noted where appropriate. Select cation-exchange buffers from Table 8.2.1.

Materials

20 mM piperazine, pH 5.0, 5.5, and 6.0 (prepare from 100 mM stock)

Figure 8.2.3 Results of a typical test tube pilot experiment for selecting initial conditions for anion-exchange chromatography. Series of tubes with protein and ion-exchange medium at (**A**) varying pH (to select binding and elution pH); (**B**) constant pH, varying NaCl concentration (to select binding and elution salt concentrations); (**C**) constant pH and NaCl concentration, varying protein concentration (to determine available capacity). The binding pH here will be ≥7.5; the elution pH will be ≤5.0; the binding salt concentration will be ≥0.15 M; the elution salt concentration will be >0.3 M; and the available capacity will be >50 mg/ml.

15-ml test tubes
Centrifuge with rotor accommodating 15-ml test tubes (optional)

Determine optimal binding pH

1. Set up a series of test tubes, numbered 1 to 8, containing different buffers as follows:

   tube 1: 5 ml 20 mM piperazine, pH 5.0
   tube 2: 5 ml 20 mM piperazine, pH 5.5
   tube 3: 5 ml 20 mM piperazine, pH 6.0
   tube 4: 5 ml 20 mM bis-Tris propane, pH, 6.5
   tube 5: 5 ml 20 mM bis-Tris propane, pH 7.0
   tube 6: 5 ml 20 mM Tris·Cl, pH 7.5
   tube 7: 5 ml 20 mM Tris·Cl, pH 8.0
   tube 8: 5 ml 20 mM Tris·Cl, pH 8.5.

2. Shake bottle of Q Sepharose Fast Flow to resuspend gel. Pour 25 ml of gel slurry into a graduated cylinder, then allow gel to settle. Adjust volume of liquid above gel to equal the volume of settled gel (i.e., prepare 50% slurry), then resuspend with a glass rod.

3. Add 2 ml of 50% slurry of Q Sepharose Fast Flow to each tube and mix.

BOU INSTITUTE CENTRAL UNIVERSITY LIBRARY

SP Sepharose Fast Flow (Pharmacia Biotech) or equivalent may be used for cation exchange.

4. Allow gel to settle to bottom of tube or centrifuge 1 min at ~5000 × *g*, room temperature.
5. Decant supernatant from each tube and replace with 5 ml of the same buffer added in step 1. Gently shake or vortex to resuspend gel, then let tubes stand 2 min.
6. Repeat steps 4 and 5 three times to equilibrate gels in each tube.
7. Decant supernatants and resuspend each equilibrated gel in 1 ml of the same buffer added in step 1.
8. Set up eight identical aliquots (≥1 ml) of the protein to be purified in tubes numbered 1 to 8, each containing 0.1 to 1 mg total protein. Adjust the pH of each to obtain eight different pH values corresponding to those of tubes 1 to 8 in step 1.

   Quantity of protein to be used depends on availability of sample and extinction coefficient of target protein. pH may be adjusted by titrating with acid or base using pH paper or by diluting 1:1 with buffer of desired pH.

9. Add the corresponding pH-adjusted protein aliquot to each of the 8 tubes from step 7. Mix gently for 10 min by periodic swirling, then allow gel to settle.

   If the salt concentration of the sample is too high, no binding will occur. It is therefore recommended that the sample be desalted into the appropriate buffer as in UNIT 8.3.

10. Assay supernatant from each tube for the target protein.

    Measuring the absorbance of the supernatant at 280 nm is usually sufficient. Figure 8.2.3 shows a set of possible results. A decrease or absence of target protein activity (or absorbance) in the supernatant indicates binding. Specific assays for the target protein may also be used.

11. Select the lowest pH at which the highest quantity of target protein is bound to use as the binding pH for further work. Select the highest pH where no binding occurs as the elution pH.

    For anion exchange, it is best to select a binding pH no more than 0.5 to 1 pH unit (pH 7.5 to 8.0 in Fig. 8.2.3) above the highest pH at which no binding occurs. If too high a pH is chosen, elution becomes difficult and high salt concentrations may be required.

    For cation exchange, select a binding pH 0.5 to 1 unit below the lowest pH where no binding occurs. Select the lowest pH where no binding occurs as the elution pH.

Determine salt concentration for binding and elution

12. Set up a series of test tubes, numbered 1 to 10. Using the binding buffer selected in step 10 in place of the different buffers in step 1, perform steps 1 to 7 to equilibrate the Q Sepharose Fast Flow with buffer in all ten tubes.
13. To each tube, add the same amount of the protein to be purified that was added to the tubes in step 8, equilibrated in the binding buffer selected in step 10.
14. Mix contents of tubes gently for 10 min, then allow gel to settle.
15. Decant supernatants from each tube and discard. Wash gel two times with 5 ml of the binding buffer, allowing the gel to settle and decanting the supernatants after each addition of buffer.

BCU IASI CENTRAL UNIVERSITY LIBRARY

16. Add 2 ml of the binding buffer to each tube, then sequentially add water and 4 M NaCl to each tube as follows:

tube 1: 1.90 ml H_2O and 0.10 ml 4 M NaCl (0.10 M NaCl final)
tube 2: 1.80 ml H_2O and 0.20 ml 4 M NaCl (0.20 M NaCl final)
tube 3: 1.70 ml H_2O and 0.30 ml 4 M NaCl (0.30 M NaCl final)
tube 4: 1.60 ml H_2O and 0.40 ml 4 M NaCl (0.40 M NaCl final)
tube 5: 1.50 ml H_2O and 0.50 ml 4 M NaCl (0.50 M NaCl final)
tube 6: 1.40 ml H_2O and 0.60 ml 4 M NaCl (0.60 M NaCl final)
tube 7: 1.30 ml H_2O and 0.70 ml 4 M NaCl (0.70 M NaCl final)
tube 8: 1.20 ml H_2O and 0.80 ml 4 M NaCl (0.80 M NaCl final)
tube 9: 1.10 ml H_2O and 0.90 ml 4 M NaCl (0.90 M NaCl final)
tube 10: 1.00 ml H_2O and 1.00 ml 4 M NaCl (1.00 M NaCl final).

17. Mix contents of tubes gently for 10 min, then allow gel to settle.

18. Assay supernatant from each tube for the target protein.

Figure 8.2.3 shows a set of possible results. Presence of target protein in the supernatant indicates elution of the target protein.

19. Select the highest salt concentration at which no elution occurs as the maximum salt concentration allowable for binding target protein and for washing away unbound sample components. Select a salt concentration at least 0.05 M above the concentration where no protein binds to the gel as the salt concentration for elution.

Determine available capacity

20. Prepare a buffer/salt solution with the binding pH selected in step 10 and the binding salt concentration selected in step 19.

21. Set up a series of test tubes numbered 1 to 10. Using the buffer/salt solution prepared in step 20 in place of the different buffers in step 1, perform steps 1 to 7 to equilibrate the Q Sepharose Fast Flow with buffer/salt solution in all ten tubes.

22. Add aliquots of sample to each tube to obtain the following amount of target protein:

tube 1: 10 mg
tube 2: 20 mg
tube 3: 30 mg
tube 4: 40 mg
tube 5: 50 mg
tube 6: 60 mg
tube 7: 70 mg
tube 8: 80 mg
tube 9: 90 mg
tube 10: 100 mg.

23. Mix gently for 10 min, then allow gel to settle.

24. Assay supernatant from each tube for the target protein.

Figure 8.2.3 shows a set of possible results. Presence of target protein in supernatant indicates that the available capacity has been exceeded.

25. Select the highest protein concentration at which the target protein does not appear in the supernatant as the available capacity.

Calculate the amount of ion-exchange medium needed for batch purification based on 50% of the available capacity (UNIT 8.1). If a column system is used in pilot experiments, however, it is best to determine the dynamic capacity of the medium (see Support

BCU ASTON CENTRAL UNIVERSITY LIBRARY

Protocol 2). However, 20% of the available capacity is a safe and reasonable starting point for pilot experiments using column chromatography.

SUPPORT PROTOCOL 2

MEASUREMENT OF DYNAMIC (COLUMN) CAPACITY AND BREAKTHROUGH CAPACITY OF ION-EXCHANGE COLUMNS

For chromatographic separations that will be performed on a routine basis as well as separations that will be scaled up, it is necessary first to optimize conditions with respect to resolution and to determine the capacity of the medium with respect to the target protein (see Support Protocol 1). Knowledge of the capacity allows optimal use of the gel medium in terms of cost and yield, and also allows working limits to be set on the sample load to ensure robustness of a particular purification step. After capacity has been determined, the separation can be optimized with respect to time. There are two capacity terms that commonly appear in the literature (in addition to available capacity; also see Support Protocol 1 and *UNIT 8.1*): dynamic capacity and breakthrough capacity.

The dynamic (or column) capacity is the capacity of an ion-exchange column under defined conditions of flow rate, pH, salt concentration and sample concentration. The breakthrough capacity (Q_B) for a system is obtained by calculating the amount of protein that has been absorbed by the column when the sample is first detected in the effluent, or when the recorder signal reaches some arbitrarily defined percent of full-scale deflection. Breakthrough capacity values at 50% full-scale deflection (Q_{B50}) are commonly reported in the literature. However, it is generally recommended to use only 10% to 20% of the published Q_B as the practical capacity of the column to ensure high recovery of the target protein.

***Additional Materials** (also see Basic Protocol 2)*

Ion-exchange gel of unknown capacity, and column
Elution buffer capable of eluting target protein in single step of salt concentration or pH (e.g., 2 M NaCl; see Support Protocol 1)

1. Pack a defined amount of the ion-exchange gel into the column.

   See UNIT 8.3 for guidelines on column packing. Normally, a quantity of gel sufficient to give a packed bed volume of ~1 ml is sufficient. In the case of a prepacked column, the amount of gel is predetermined. The packed bed volume (V_c) is calculated according to the equation $V_c = \pi r^2 \times L$, where r is the radius of the column and L is the bed height (i.e., the height of the packed medium in the column).

2. Prepare chromatography system and column (see Basic Protocol 2, steps 1 to 6) using the optimal binding and elution conditions determined in Support Protocol 1.

   Do not exceed 75% of the flow rate used for packing. The effect of flow rate on capacity should be determined in a true optimization.

3. Prepare protein solution and inject into column (see Basic Protocol 2, steps 7 and 8). Apply solution continually until the recorder shows >50% full-scale deflection, then stop.

   The absorbance of the binding buffer corresponds to 0% and the absorbance of the sample corresponds to 100% full-scale deflection.

4. Wash column with binding buffer until 0% full-scale deflection is approached.

5. Elute proteins with a buffer providing a single-step increase in salt concentration or pH. Continue collecting eluant until recorder shows ≤2% full-scale deflection, then pool fractions.

   A typical chromatogram for this procedure is presented in Figure 8.2.4.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

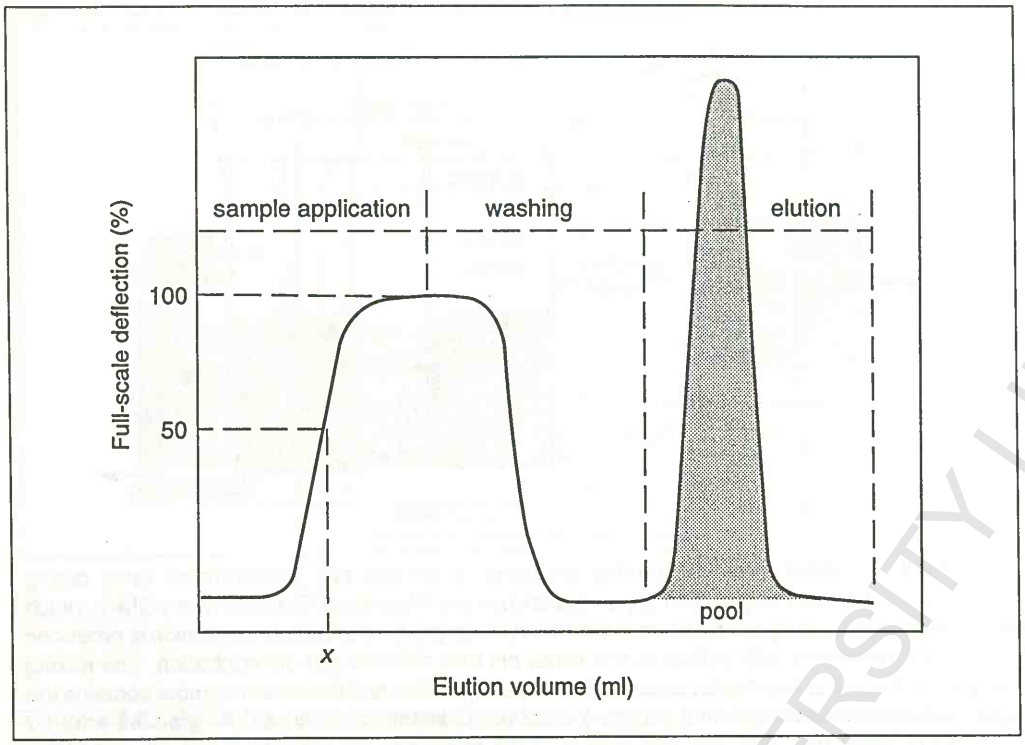

Figure 8.2.4 Typical chromatogram for determining the capacity of an ion-exchange column. The volume of eluant (x) at 50% full-scale deflection is used to calculate the breakthrough capacity (Q_{B50}).

6. Assay pooled fractions from step 5 for target protein. Calculate maximum amount of protein (A) that can be bound to the column according to the equation $A = C_p \times V$, where C_p is the protein concentration of the pooled fractions (mg/ml) and V is the volume of the pooled fractions (ml).
7. Calculate the column (dynamic) capacity (mg/ml) using the equation *dynamic capacity* $= A/V_c$.
8. Calculate breakthrough capacity (Q_{B50}) using the equation $Q_{B50} = (C_s \times x)/V_c$, where C_s is the concentration of protein in the original sample and x is the volume of sample that has been applied to the column at the point where 50% full-scale deflection has been attained.

If Q_{B50} greatly exceeds the dynamic capacity, then the target material may still be adsorbed on the column, and the elution conditions should be reexamined.

See Figure 8.2.4 for graphical depiction of these variables.

GRADIENT-FORMATION TECHNIQUES

SUPPORT PROTOCOL 3

Simple Gradient Mixers

Gradient mixers of the type shown in Figure 8.2.5 can generate linear pH or salt gradients in gravity-based or one-pump chromatography systems. Similarly designed gradient mixers used for casting electrophoresis gels may also be used for chromatography. The reservoir closest to the column is filled with the binding buffer and the second reservoir is filled with an equal volume of the elution buffer. The gradient begins when the valve between the two reservoirs is opened. Continuous mixing is required in the reservoir closest to the column to ensure gradient linearity and reproducibility.

BOWLES / GENERAL UNIVERSITY LIBRARY

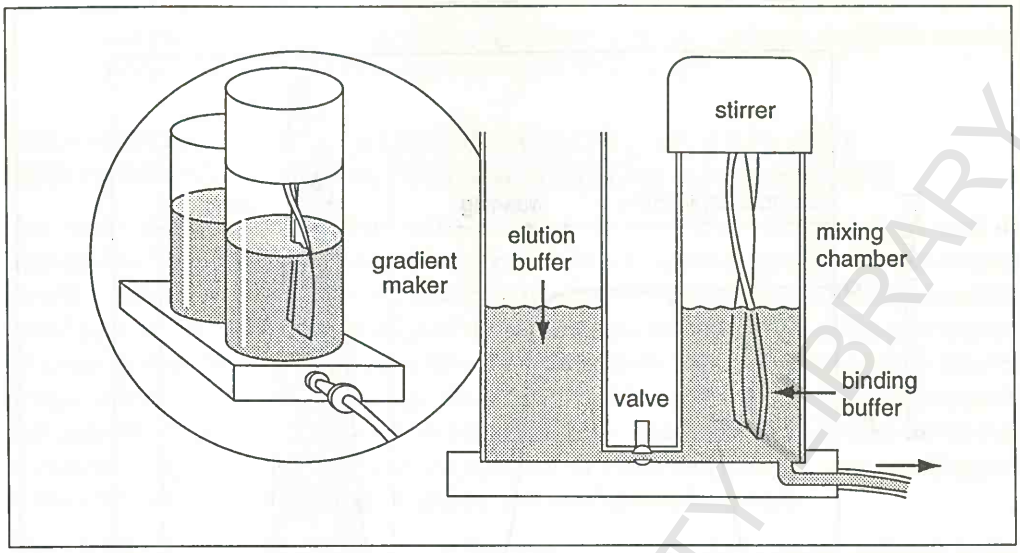

Figure 8.2.5 Gradient mixer for forming gradients of pH and salt concentration used during ion-exchange chromatography. The apparatus shown is a Pharmacia Gradient Mixer GM-1, which can be used for preparing gradients up to 500 ml. A linear gradient of salt concentration is produced by filling the reservoirs with buffers at the same pH and different salt concentration. The mixing chamber contains the lower-salt-concentration (binding) buffer, and the other chamber contains the higher-salt-concentration (elution) buffer. A continuous linear or nonlinear pH gradient may be produced by filling the reservoirs with buffers at the same salt concentration and different pH. A gradient of increasing pH is used for cation-exchange separations, and a gradient of decreasing pH is used for anion-exchange separations. The buffer chambers are joined by a channel controlled by a valve, and outflow from the mixing chamber is controlled by another valve.

Gradient Mixing with Multichannel Peristaltic Pumps

Peristaltic pumps that can accommodate three or more pumping channels simultaneously (Fig. 8.2.6) can be used to form linear or complex gradients (see Critical Parameters). Linear gradients are easily formed by using the same size tubing for all channels, pumping with one channel from the elution buffer reservoir to the binding buffer reservoir, and pumping with the other two channels from the binding buffer reservoir to the column. Continuous mixing is required in the binding buffer reservoir closest to the column to ensure gradient linearity and reproducibility.

Switch-Valve-Based Gradient Mixing

Switch-valve-based gradient formation is useful for forming step, linear, and complex gradients (see Critical Parameters). Gradients are formed by proportioning variable amounts of binding buffer and elution buffer through a single three-way valve using a system controller. When programmed to deliver 10% elution buffer, the controller will open the valve port for binding buffer 90% of the time and the port for elution buffer 10% of the time. As higher switching rates are required for lower flow rates to ensure gradient accuracy, high-quality system controllers will vary the rate at which the valve switches (i.e., the number of switching events per unit time) as a function of flow rate. A dynamic mixer should be included in the flow path just after the proportioning valve to ensure gradient accuracy. Switch-valve-based gradients are generally not very accurate from 1% to 10% elution buffer (90% to 99% binding buffer) or from 1% to 10% binding buffer (90% to 99% elution buffer). Therefore, the ionic strength of the binding and elution buffers may be adjusted to allow a gradient of the desired composition to be formed by mixing the two buffers in the range of 20% to 80% elution buffer (80% to 20% binding buffer).

RCU IASI - CENTRAL UNIVERSITY LIBRARY

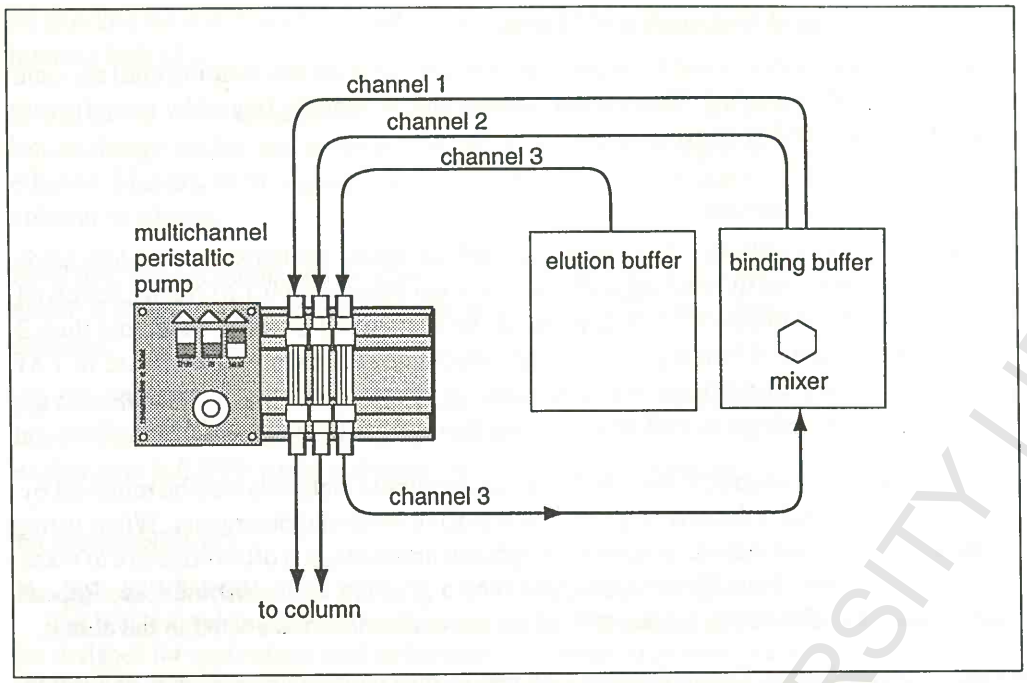

Figure 8.2.6 Peristaltic pump accommodating three pumping channels for continuous gradient formation.

Gradient Formation by Autoblending

Some chromatography systems allow gradient formation over a range of both pH and salt concentration. Four solvents—a high-pH buffer, a low-pH buffer, a concentrated salt solution, and water—are blended via four two-way valves. A system controller proportions the high- and low-pH buffers to achieve the desired pH gradient while simultaneously proportioning the concentrated salt solution and water to achieve the desired salt-concentration gradient. Gradients formed in this way are usually difficult to reproduce but may be useful for scouting initial binding and elution conditions.

Gradient Formation with Twin Pumps

Use of two positive-displacement pumps, as in HPLC and FPLC systems, provides the highest degree of accuracy, precision, and reproducibility in gradient formation. One pump delivers binding buffer while the other delivers elution buffer. A system controller allows gradient formation simply by controlling the flow rate of each pump. A dynamic mixer should be included in the flow path, after the pumps and before the column, to ensure gradient accuracy.

CLEANING AND REGENERATION OF ION-EXCHANGE MEDIA

SUPPORT PROTOCOL 4

Proper maintenance of chromatography media is as much an art as protein purification itself. Knowing what kind of contaminating material from the sample is bound to the column helps in selecting a regime for maintaining good column hygiene. It is best to practice preventative maintenance by regenerating the medium after every run, using a high-salt buffer or large change in pH, and periodically cleaning the column and checking the system flow characteristics. If any increase in column back-pressure is noted, the column should be cleaned as soon as possible. Once enough contaminant has bound to a column to reduce or block the flow, it is probably too late to save the medium without investing considerable time and effort.

BOSTON / CONTRA COSTA COUNTY LIBRARY

Routine Washing of Columns and Media

Columns or bulk media should be washed after every run with salt solution until an ionic strength of ≥2 M is reached. This should remove any substances bound by ionic forces. This is recommended after every run.

Removal of Contaminants

Alkali-soluble contaminants. Contaminants such as lipids, proteins, and nucleic acids can usually be removed by washing with 2 to 3 column volumes of 0.1 M NaOH, followed by 2 to 3 column volumes of Milli-Q purified (or equivalent) distilled water and then 2 to 3 column volumes of binding buffer. Many media can tolerate brief exposure to 1 M NaOH if harsher conditions are required to remove contaminants; however, manufacturer's guidelines should be consulted regarding pH stability of the medium.

Hydrophobic contaminants. Lipids and other hydrophobic materials may be removed by washing with alcohol solutions (e.g., 70% ethanol) or nonionic detergents. When using alcohols or organic solvents to remove hydrophobic materials, it is often effective to wash first with a gradient from 0% to 100%, and then a gradient from 100% to 0%. Repeat washing with the alternating gradients until no contaminants are detected in the eluant.

Metallic contaminants. Contamination with metals may cause blue or gray discoloration at the top of an ion-exchange column. These metals can originate from impurities in buffer salts or water, or they can leach from metallic system components in contact with buffer solutions. Metal contaminants may usually be removed by treating the column with several column volumes of 10 mM HCl (i.e., pH 2) saturated with EDTA. Manufacturer's guidelines should be checked for pH stability of medium and column before exposure to mild or strong acid solutions.

Precipitated materials. Precipitated materials that have accumulated in a column are very difficult to remove. Unless the precipitated material can be physically removed by removing the gel at the top of the column, the material will have to be resolubilized. Detergents, urea, and guanidine·Cl can be introduced to help dissolve contaminants. The viscosity of concentrated solutions used for cleaning may require very low flow rates. The column may be equilibrated and incubated in 6 M urea, then washed with distilled water and buffer. Degradative enzymes (e.g., proteases and lipases) may also be introduced in an attempt to degrade precipitates on the column; however, enzymatic cleaning can be quite expensive. It may be useful to reverse the direction of flow through the column (i.e., from bottom to top) when attempting to remove particulate material from the top of the bed.

SUPPORT PROTOCOL 5

STORAGE OF ION-EXCHANGE MEDIA

Bacterial and microbial growth can seriously interfere with the chromatographic properties of any chromatography medium and endanger the sample as well. Prior to storage, all media should be cleaned and sanitized. During prolonged experiments or storage (i.e., >24 hr at room temperature or 48 hr at 4°C), a bacteriostatic or antimicrobial agent should be added to the ion exchanger. Antimicrobials chosen to be added for storage should not bind to the ion exchanger and should be easily removed when the gel is to be reused.

Treatment with 1 M NaOH for 1 hr will sanitize most media by lowering the bacterial count 100-fold, and will help solubilize dead cells (Pharmacia Biotech, 1993). Storage of sanitized media in 0.1 M NaOH will not leave any toxic materials on the column—a significant consideration in pharmaceutical production. Manufacturer's guidelines should

BCU IAS CENTRAL UNIVERSITY LIBRARY

be checked for stability of the medium and column in NaOH. Silica-based media will not tolerate high pH.

Exposure to 70% ethanol for 3 to 4 hr can be used to sanitize most media. Most ion-exchange media and columns can be stored for prolonged periods of time in 20% ethanol. Manufacturer's guidelines should be checked for stability of the medium and column in ethanol.

Effective antimicrobial agents appropriate for use with anion-exchange media include either 0.001% phenyl mercuric salts or 0.002% chlorohexidine, in weakly alkaline solution.

An effective antimicrobial agent for use with cation-exchange media is 0.005% merthiolate in weakly acidic solution. An agent that is effective for use with either anion or cation exchangers is 0.05% trichlorobutanol in weakly acidic solution.

COMMENTARY

Background Information

The first ion exchangers were synthetic resins designed for applications such as demineralization, water treatment, and recovery of ions from waste. Early ion-exchange resins were tightly cross-linked hydrophobic polymers, highly substituted with ionic groups, and had very high capacity for small ions. The high degree of cross-linking provided mechanical strength, but the limited porosity restricted use of these media with large molecules. In addition, the high charge density resulted in very strong binding, and the hydrophobic matrix tended to adsorb and denature labile biological materials. The first ion exchangers designed for use with biomolecules were developed by Peterson and Sober (1956). These cellulose-matrix ion exchangers were very hydrophilic and had little tendency to denature proteins, but had low capacities and poor flow characteristics. Modern ion-exchange media have very high capacity, often >100 mg/ml. Modern particle technology has significantly increased the mechanical strength and flow characteristics of ion-exchange media so that separations that once required hours or days may now be completed in a few minutes.

Ion-exchange can easily be coupled to other methods of protein separation in a multistep purification. Samples purified by ion exchange can typically be applied to a hydrophobic-interaction chromatography (HIC) medium simply by adding NaCl (or other salts) to a concentration sufficient for binding (*UNIT 8.4*). Samples to be further purified by chromatofocusing or an additional round of ion exchange will require desalting (*UNIT 8.3*). Samples may usually be applied directly to gel-filtration columns (*UNIT 8.3*) with no intervening treatment.

Critical Parameters

The most critical aspects of any ion-exchange experiment are selection of the appropriate ion-exchange medium and of the initial conditions for binding and elution of the target protein or contaminants. Once these parameters are selected, conditions can be optimized with respect to the three primary parameters of any chromatographic separation—i.e., resolution, capacity, and speed. These three parameters are mutually exclusive. Resolution will typically decrease when the sample load is increased and when the flow rate is increased (to increase speed). It is generally recommended that resolution be optimized first, then capacity, and finally speed.

Optimization of resolution

This parameter is most easily optimized by controlling the selectivity (*UNIT 8.1*) of the medium through manipulation of binding and elution conditions. Construction of chromatographic titration curves followed by optimization of the shape of the elution gradient is a common approach to achieving maximum resolution.

Chromatographic titration curves can be constructed by performing a series of anion- and cation-exchange experiments at different pH values as in Figure 8.2.7. For each of these experiments, the elution salt concentrations (in mM NaCl) for sample components A, B, and C are plotted on the y axis and the operating pH is plotted on the x axis. It is then simple to observe the pH ranges within which optimal resolution between the various sample components is achieved. The different sample components are usually detected by UV absorption, but may also be viewed by other means (e.g., fluorescence or bioactivity). Data for chroma-

BALDWIN-WALLACE UNIVERSITY LIBRARY

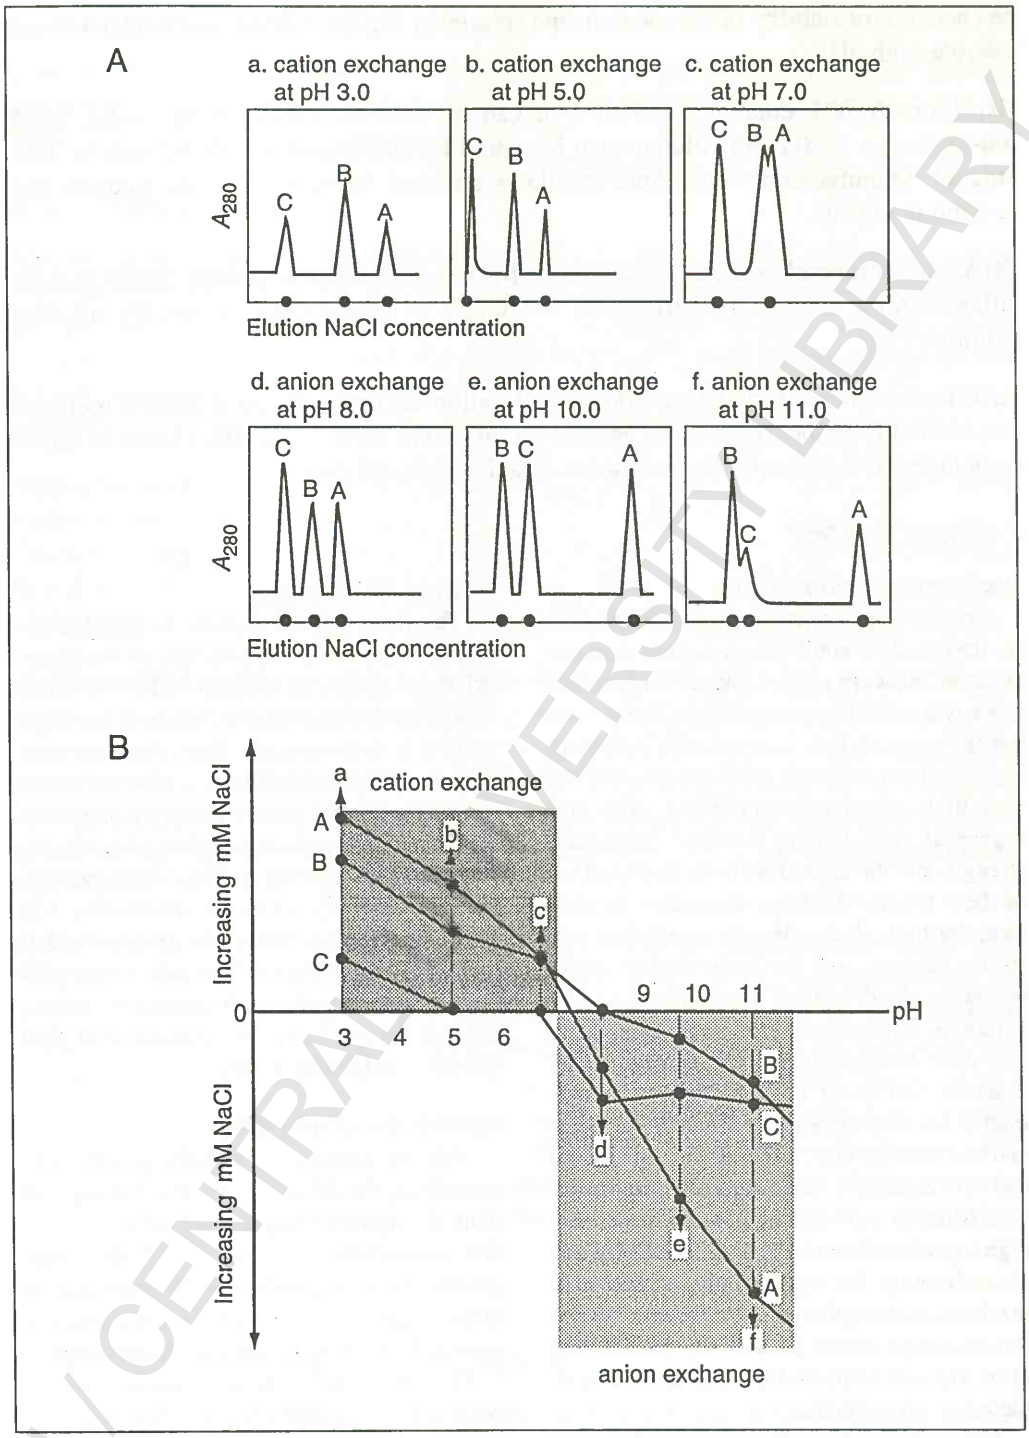

Figure 8.2.7 Construction of a chromatographic titration curve. (**A**) Six chromatographic separations (a to f) of a sample containing proteins A, B, and C are carried out at six different operating pHs using a linear gradient of increasing salt concentration. (**B**) The elution ionic strengths for components A, B, and C (*y* axis) are plotted against the operating pH (*x* axis) for experiments a to f. Note that the salt concentration in mM NaCl (*y* axis) is ascending in both directions. The optimal resolution with respect to component A occurs below pH 5 with cation exchange and above pH 9 with anion exchange.

BCU IAS / CENTRAL UNIVERSITY LIBRARY

tographic titration curves can often be generated by fast screening with low-volume gradients (e.g., 5 to 10 V_c) and low sample mass (e.g., <1 mg).

After optimization of resolution with respect to pH, the shape of the elution gradient can be optimized. A gradient can be conceptually divided into segments, and each segment may have a different gradient shape. Gradient shapes include linear, concave, convex, and step. Complex gradients are constructed by using different gradient shapes in consecutive segments. The slope (e.g., mM NaCl per minute) of a linear segment is constant, that of a concave segment continually increases, that of a convex gradient continually decreases, and that of a step gradient approaches infinity. Resolution between sample components in any segment can usually be increased by decreasing the gradient slope in that segment. However, decreasing the gradient slope will increase the peak volume during elution, the gradient volume, and the time of the separation. Step gradients can provide the most concentrated fractions, and are desirable when minimizing sample volume is of primary importance. Use of concave gradients in the initial part of a segment and convex gradients in the later part of a segment can improve resolution. The capabilities of available equipment must be considered in the construction of complex gradients. Simple gradients that do not stress the performance limits of the system will result in robust methods that are insensitive to small changes in sample or buffer composition and gradient shape, thereby increasing probability of success.

To construct a complete gradient profile, it is first necessary to identify the gradient range where desorption of the target protein occurs, as well as the gradient slope that provides optimal resolution. A single-step elution is then done at a salt concentration just below the range of where the target protein elutes, to remove weakly bound material. The target protein is then desorbed and eluted. A single-step elution at a high salt concentration will then remove tightly bound sample components and prepare the ion-exchange gel for regeneration. This approach, using step gradients before and after the range of interest, can provide simple, robust methods that are easy to scale up, and will save time and reagents.

Different ion-exchange media offer different selectivities (*UNIT8.1*). If adequate resolution for a specific stage in a purification cannot be obtained with a specific ion-exchange medium, it may be desirable to select an alternate ion exchanger with a different functional group, or to use a different chromatographic technique at this stage in the separation. Salts other than NaCl may be used in elution, but there are no specific effects from different salts on the separation in ion-exchange chromatography, other than differences in concentration. Brewer et al. (1989) provides a good review of the effects of nonbuffering ionic species in ion exchange.

Optimization of capacity

When optimum resolution has been achieved, the effect of increasing sample load on resolution should be evaluated to determine the optimal balance of resolution and capacity utilization. The procedure for determining the dynamic (column) capacity is described in Support Protocol 3 and can be performed using the conditions for optimal resolution (as determined above) to elute the target protein. Once the capacity is determined under the optimal elution conditions, the effect of changes in sample load on resolution can be investigated to identify optimal conditions. It is generally recommended that only 10% to 20% of the dynamic capacity be used to ensure high recoveries of the target protein.

Optimization of throughput

Once optimal conditions for resolution and capacity have been determined, the flow rate in each gradient segment may be increased and the effect on resolution and capacity monitored to complete the optimization process.

Troubleshooting

Common problems encountered during ion-exchange experiments, their potential causes, and suggested solutions are outlined in Table 8.2.5.

Anticipated Results

A chromatogram illustrating typical results of an ion-exchange column chromatography experiment (i.e., of Basic Protocol 1) is shown in Figure 8.2.8.

The goal of any purification step is the pure target protein obtained at the end of the day. The chromatogram is only a record for comparison and is deceptive at best. Great care should be exercised in interpreting a chromatogram—i.e., the results from assays performed on fractions collected must be used in interpreting the chromatogram and inferring the identity of any given chromatographic peak.

PURDUE UNIVERSITY LIBRARY

Table 8.2.5 Troubleshooting Guide for Ion-Exchange Chromatography

Problem	Possible cause	Solution
The protein does not elute in the salt gradient	Buffer pH is incorrect	Use buffer pH closer to pI of the protein
	Salt concentration is too low	Use more concentrated elution buffer
Protein does not elute in pH gradient	Buffer pH is incorrect	Calibrate pH meter and prepare new solutions
Protein elutes in wash phase	Salt concentration of binding buffer is too high	Decrease salt concentration of binding buffer
	Salt concentration of sample is too high or pH is wrong	Perform buffer exchange on sample
	Column is not properly equilibrated	Repeat or prolong equilibration until conductivity is constant
	Ionic detergents or other additives are absorbed to column	Clean column
Resolution is less than expected	Gradient slope is too steep	Use shallower gradient or include plateau in gradient
	Flow rate is too high	Run separation at lower flow rate
	Proteins or lipids have precipitated on columns	Clean and regenerate column
	Sample has not been filtered properly before application to the column	Regenerate column, filter sample, and repeat chromatography
	Proteins in sample have formed aggregates that bind strongly to gel	Use urea or detergents to clean column
	Column is poorly packed	Check packing by running a colored compound and observing the band. Repack column if necessary.
	Too much sample mass has been loaded onto column	Clean and regenerate column. Decrease sample load and repeat run.
	Detector flow cell volume or mixing spaces in or after column are too large	Change flow cell or reduce all post-column volumes
Leading or very rounded peaks observed in chromatogram	Column is overloaded	Decrease sample load and repeat run
	Column is poorly packed	Check packing by running a colored compound and observing the band. Repack column if necessary.
	Column needs regeneration	Clean and regenerate column. If this does not help, replace with new one.
Tailing of peak is observed in the chromatogram	Sample is too viscous	Reduce amount of protein, or remove nucleic acids from sample.
	Precipitation of protein has occurred in column filter and/or at top of the gel bed	Clean column, exchange or clean filter.
	Column is poorly packed	Check packing by running a colored compound and observing band. Repack column if necessary.
Previous elution profile cannot be reproduced	Buffer pH and/or ionic strength are incorrect	Prepare new solutions
	Sample has deteriorated during storage	Prepare fresh sample
	Proteins or lipids have precipitated on column	Clean and regenerate column

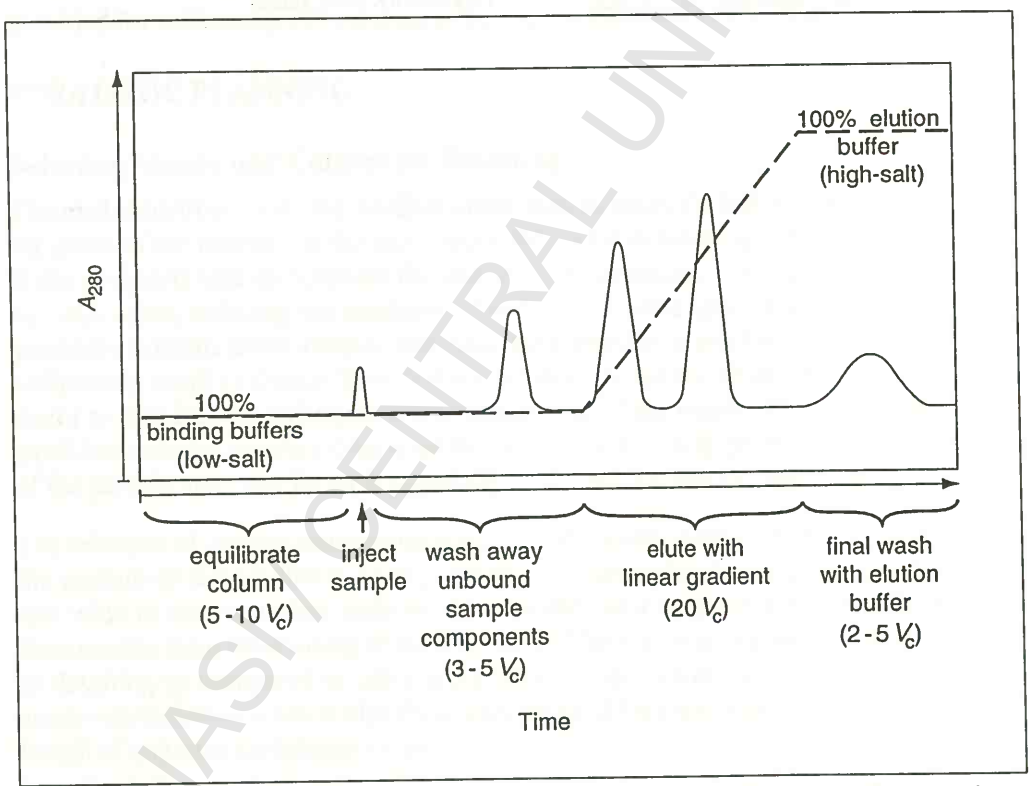
Table 8.2.5 Troubleshooting Guide for Ion-Exchange Chromatography, continued

Problem	Possible cause	Solution
	Sample has not been filtered properly	Regenerate column, filter sample carefully and repeat step
	Equilibration was incomplete	Repeat or prolong equilibration until conductivity is constant
Recovery of activity is low but recovery of protein is normal	Target protein is not stable in the elution buffer and is therefore inactivated	Change elution conditions
	Enzyme separated from cofactor or other substance needed for activity	Test by pooling all fractions and repeating assay
	Microbial growth has occurred in the column	Clean column and store gel in 20% ethanol or other antimicrobial agent[a]
Protein amount in the eluted fractions is much less than expected	Protein was degraded by proteinases	Add proteinase inhibitors to buffers
	Protein adsorbed to filter during sample preparation	Use another type of filter or add detergents to buffer
	Microbial growth occurred in the column	Clean column and store gel in 20% ethanol or other antimicrobial agent[a]

[a]Microbial growth rarely occurs in columns during use, but steps should always be taken to prevent infection of packed columns, buffers, and gel suspensions; see Support Protocol 5.



100% elution buffer (high-salt)
A_{280}
100% binding buffers (low-salt)
equilibrate column (5-10 V_c)
inject sample
wash away unbound sample components (3-5 V_c)
elute with linear gradient (20 V_c)
final wash with elution buffer (2-5 V_c)
Time

Figure 8.2.8 Chromatogram representing typical results of stages of an ion-exchange column chromatography experiment. A linear gradient of 0% to 100% elution buffer is used as in Basic Protocol 2. The broken line superimposed on the chromatogram represents the composition of the elution gradient (100% binding buffer to equilibrate column and remove unbound sample components, followed by a linear gradient from 100% binding buffer to 100% elution buffer to elute bound proteins and a final wash with 100% elution buffer). V_c represents the packed bed volume of the column.

UNIVERSITY OF CENTRAL ASIA LIBRARY

Time Considerations

If all necessary equipment is available and functioning properly, it should be possible to develop a chromatographic method in a day. With automated systems (e.g., HPLC and FPLC) and modern ion-exchange media, method development may require just a few hours. However, the most time-consuming aspect in developing a purification step is typically the determination of protein purity in the fractions collected, which will always depend on the specific protein of interest. The key to minimizing the time required for such determinations is to strive for high resolution and a minimum number of fractions.

Gel-Filtration Chromatography

Gel filtration (GF) separates proteins solely on the basis of differences in molecular size. Separation is achieved using a porous matrix to which the molecules, for steric reasons, have different degrees of access (i.e., smaller molecules have greater access and larger molecules less). The matrix is packed into a chromatographic column, the sample mixture applied, and the separation accomplished by passing an aqueous buffer (i.e., the mobile phase) through the column. Protein molecules that are confined in the volume outside the matrix beads will be swept through the column by the mobile phase and the sample is thus eluted in decreasing order of size. The protein zones eluted are detected by an in-line UV monitor and fractions are collected for subsequent specific analysis or further preparation steps.

GF is often used to condition samples prior to further purification by adsorptive techniques. It is also frequently used in the final polishing stage (*UNIT 8.1*) to remove a few remaining contaminants with surface properties similar to the target protein (e.g., for polishing monomers from oligomers).

Three basic protocols are provided in this unit, corresponding to the major applications of gel filtration. GF is used for desalting or group separation (see Basic Protocol 1), in which the target protein and contaminating solutes differ substantially in molecular size. It is also used for protein fractionation (see Basic Protocol 2), where proteins with only a small size difference must be separated. A third application is in characterizing the molecular dimensions of proteins (see Basic Protocol 3). A Support Protocol is also provided for calibrating GF columns to be used in estimating molecular size.

STRATEGIC PLANNING

Selecting Matrix and Column for Desalting

The exclusion limit—i.e., the smallest-sized protein molecule that will be excluded from the pores of the matrix—is the most important factor in selecting a matrix for desalting. If the protein is able to permeate the matrix, flow-dependent zone broadening (see *UNIT 8.1*) will occur, reducing the resolution. On the other hand, gels of very small pore size generally contain more matrix, and thus have smaller separating volumes. A gel of sufficiently small exclusion limit, but not smaller, should therefore be selected. Another factor to take into consideration is the particle size of the matrix. This should not be too small because the pressure drop over the column is inversely proportional to the square of the particle size; this factor is especially important for gravity flow columns.

The selection of column dimensions (i.e., the bed volume of the column) is influenced by the amount of sample that is to be processed. Columns for desalting are typically short and wide to accommodate large sample volumes and keep the processing time short. Because the zone broadening of the column will have a limited effect on the peak width in desalting as compared to other applications of gel filtration—e.g., protein fractionation—short columns run at high flow rates are used for large-scale desalting. The typical length of columns for laboratory use is ~10 cm.

Columns for desalting vary greatly in size and sophistication, ranging from Pasteur pipets plugged with glass wool to prepacked high-performance GF columns. The scale of operation (*UNIT 8.1*) for which they are used also varies widely, with applications ranging from micropreparative cleanup of a 50-µl reduction/alkylation mixture using a 0.9-ml column to industrial de-ethanolization of 12 liters of human serum albumin using a 75-liter

column. Incidentally, columns for both these procedures may be packed with Sephadex G-25—of course, of different particle size.

Some gel-filtration media suitable for laboratory-scale desalting are listed in Table 8.3.1, and some empty columns that can be used with these media are listed in Table 8.3.2. A partial compilation of disposable prepacked columns for desalting is found in Table 8.3.3. This table also contains information about spin columns for use with a centrifuge. Spin columns require special techniques, and they are presently not widely used for desalting proteins; therefore no protocols for their use have been included in this unit. More information about spin columns can be obtained from the suppliers.

Selecting Matrix and Column for Protein Fractionation

Suitability of a gel for protein fractionation may be judged from "typical runs" made with synthetic protein mixtures, the results of which are published by suppliers. The solute of interest should ideally be eluted in the first part of the chromatogram, but not too close to the void volume. A matrix with a distribution coefficient (see Basic Protocol 3) of ~0.2 to 0.4 has been reported to yield maximum resolution (Hagel, 1989). This corresponds to an elution volume of ~1.5 to 2 times the void volume. A long bed and a matrix with a large pore volume will increase the peak-to-peak distance between the proteins and thus increase the resolution of the system (also see Critical Parameters and *UNIT 8.1*). Another way to increase resolution is to employ a GF matrix of small particle size, which will reduce the zone width of the protein bands. The flow rate will also affect resolution. As in the case of desalting, the maximum sample volume that can be processed depends upon the bed volume and the pore volume of the packed bed. Thus, there are many parameters to consider when optimizing protein fractionation by GF. In the worst case, a suitable matrix may have to be found by trial and error.

Commercial prepacked columns for protein fractionation often sacrifice column length and pore volume in favor of small particle size. This results in columns that are optimized for fast separation at the expense of some reduction in the maximum sample volume that can be loaded. Therefore, traditional columns packed in the laboratory are often still a good alternative for purification of large volumes of sample. If time is critical in the separation (e.g., in proteinase removal), fast column operation is of course advantageous. Matrices of large particle size will permit protein fractionation at low operating pressure.

RCU IAS/CENTRAL UNIVERSITY LIBRARY

Some matrices suitable for protein fractionation are listed in Table 8.3.4, and some empty columns suitable for use with these media are listed in Table 8.3.5. Table 8.3.6 lists some prepacked columns for protein fractionation. Columns and media are selected on the basis of the difficulty of the separation (i.e., how small the size difference is between the proteins to be separated) and whether scaleup will be required (i.e., the availability of a variety of columns with different diameters that can be packed with bulk media facilitates linear scaleup).

PSU HASLER CENTRAL UNIVERSITY LIBRARY

A matrix of small particle size will permit preparation of columns of high efficiency (i.e., low zone broadening) at the expense of high pressure drops and greater cost. Also, smaller particles generally have smaller pore volumes. The net effect of the relationships between these parameters is that the prepacked columns listed in Table 8.3.6 have resolving power of the same order of magnitude, although protein fractionation may be carried out faster on the columns that have particles of small size.

A final factor to consider in choosing a matrix for protein fractionation is the likelihood of matrix-solute interactions (e.g., as in the case of lectins on gels containing glucose-type structures).

Selecting Matrix and Column for Molecular Size Determination

A matrix with high resolving power is recommended for determination of molecular size as well as for protein fractionation (see Table 8.3.4, Table 8.3.5, and Table 8.3.6 for

[a]Data as reported by the manufacturers.

[b]In general, matrices of natural polymers (e.g., Superdex, Sephacryl, or Superose) have larger pore volumes than silica-based materials (e.g., TSK SW, Protein-Pak, Bio-Sil SEC, or GF-250/450).

[c]Selectivity of materials (see *UNIT 8.1*) decreases with increased width of the fractionation range and also with decreased pore volume.

[d]Abbreviations: BR, Bio-Rad; DU, DuPont; PB, Pharmacia Biotech; TH, Toso Haas; WA, Waters. Addresses and phone numbers of suppliers are provided in the *SUPPLIERS APPENDIX*.

BU ASI / CENTRAL UNIVERSITY LIBRARY

matrices and columns suitable for both these applications). However, certain other criteria that are important for selecting a matrix and column for size determination differ from those for protein fractionation. First, when analyzing samples containing several proteins of varying molecular size (e.g., protein digests) a matrix of sufficient separation range is needed. As selectivity (see *UNIT 8.1*) inherently limits separation range, the separation range may not be optimal using a matrix of high selectivity. Second, because peak broadening is not critical as long as the peaks are resolved, short (e.g., 30-cm) columns operated at high flow rates may be used. However, in situations where the effluent is continuously monitored with a mass-sensitive detector (see Basic Protocol 3), complete resolution between peaks is essential. In this case the criteria used for protein fractionation may be applied.

BASIC PROTOCOL 1

DESALTING (GROUP SEPARATION)

Desalting, or group separation, is used to separate the target protein from low-molecular-mass contaminants. The purpose might be to remove salt prior to lyophilization, or to remove low-molecular-mass reagents—e.g., a reductive cleavage mixture from a preparation step (*UNIT 11.1*) or polybuffer from chromatofocusing. Desalting is also used to change from one buffer to another—e.g., to decrease ionic strength prior to ion-exchange chromatography (*UNIT 8.2*). The pore size of the matrix is selected to exclude the protein of interest while allowing maximum permeation of the contaminants. This is beneficial in three ways. First, because the protein does not penetrate into the pores, little dilution of the sample will take place except where the sample volume is very small. Second, because the protein is unable to diffuse into the pores, no flow-sensitive zone broadening (*UNIT 8.1*) that results from slow mass-transfer will take place. Hence, the flow rate may be kept high during the desalting. Third, because the protein and the low-molecular-mass solutes are maximally separated, very large sample volumes may be applied before contamination of the protein band becomes evident. Thus, very large sample volumes may be applied and desalted in a short time without dilution of the sample.

The procedure described here uses a closed column system and a pump; annotations explain variations needed in some of the steps if an open-bed column and gravity flow are used. The GF matrix is swelled, the column is packed, and the void volume and total volume of the column are determined in preliminary runs using high- and low-molecular-weight solutes. This information is used to determine the maximum sample volume to apply for the unknown protein to be desalted. Guidelines for estimating approximate sample volumes to use for desalting are also given. Alternative steps are provided for using this procedure either to determine elution volume or to desalt a protein for preparative purposes (or further analysis). Elution volumes must be determined to ascertain the exact void volume and total volume of a column in preparation for desalting. It is also necessary to measure the elution volume for certain protein analyses—e.g., for determining molecular size (also see Basic Protocol 3).

Materials

GF matrix (Table 8.3.1) or prepacked GF column (Table 8.3.3) with appropriate exclusion limit for protein of interest (also see Strategic Planning and Critical Parameters)
GF desalting buffer (see recipe)
Colored marker: 0.2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B_{12}
Void marker (see recipe)
Total liquid volume marker (see recipe)
Protein sample to be desalted
90°C water bath (optional)

RCU IAS/CENTRAL UNIVERSITY LIBRARY

Buchner or sintered-glass funnel
GF chromatography column (see Critical Parameters and Table 8.3.2) with column extension (optional), adaptors, and buffer reservoir (Fig. 8.3.1)
Carpenter's level
Peristaltic pump (Fig. 8.3.1)
0.22-µm filter: any 0.22-µm filter for buffer; protein-compatible for sample
Detector (optional; Fig. 8.3.1)
Chart recorder (optional; Fig. 8.3.1)
Sample applicator: sample application loop (e.g., Superloop, Pharmacia Biotech) or syringe
Fraction collector (optional; Fig. 8.3.1)

NOTE: Small-scale desalting of multiple samples may be carried out using spin columns and a centrifuge. At present, spin columns are primarily used for preparing microliter-sized samples of oligonucleotides; however, they are equally useful for small-volume protein samples. As the procedure is different from that described here, manufacturer's instructions should be consulted (see Table 8.3.3 for suppliers).

BOSTON CENTRAL UNIVERSITY LIBRARY

Prepare gel

If GF matrix is supplied dry:

1a. Calculate the amount of dry matrix needed from the swelling factor given by the manufacturer and the approximate bed volume of the column to be packed. Add the calculated amount of dry gel to a volume of GF desalting buffer equal to twice the calculated final gel volume (i.e., twice the approximate bed volume of the column).

2a. Carefully stir suspension with a glass rod. Let gel swell overnight at room temperature or for 3 hr in a 90°C water bath, stirring as needed to keep gel in suspension.

Do not use a magnetic stirrer, as this may break fragile gel particles.

3a. Allow gel bed to settle, then remove fines and broken beads by decanting the hazy solution. Repeat decantation (four to five times if necessary) until bed settles as a sharp zone, then dilute so that final slurry is 50% (v/v) settled gel and 50% (v/v) GF buffer.

Careful removal of fine particles will prevent the nets that support the column end pieces from being blocked, and will also permit a higher flow rate through the column.

If GF matrix is supplied preswollen:

1b. Wash gel with an excess of GF buffer on a Buchner or sintered-glass funnel to remove storage buffer.

In some products, the gel slurry is obtained by simply shaking the gel bottle, and this can be used to pack the column without further preparation. If this type of gel is used, skip steps 1b to 3b and proceed directly to step 4.

Gel particles may adhere to the glass wall of the funnel; therefore, to avoid contamination from other types of gels (e.g., ion-exchange media), it is important to ensure that glassware used is clean.

2b. If gel contains fines, remove by decantation as in step 3a.

3b. Dilute so that final slurry is 50% (v/v) settled gel and 50% (v/v) GF buffer.

Pack column

4. Examine column to ensure that it is clean and that the support nets are undamaged. If necessary, supply column with new support nets.

5. Mount column on a stable laboratory stand, using a carpenter's level to ensure that it is vertical. Equip column with an extension that together with the column will hold the complete volume of the gel slurry (i.e., twice the volume of the settled gel).

If <50% of the column volume is to be packed, there is no need for a column extension.

6. Remove air from outlet tubing and end piece of column by injecting GF buffer into outlet tubing (using syringe or peristaltic pump) until support net is covered with 0.5 cm of buffer. Close outlet of column.

7. Inject GF buffer into inlet tubing of adaptor until net is wetted, while holding outlet upwards to ensure that air easily escapes from net. Place adaptor in a beaker containing GF buffer until it is time to use it.

8. Swirl gel slurry from step 3a or b and pour entire slurry into column along a glass rod tilted toward the inner wall of the column or column extension. Fill the remaining space with GF buffer by carefully pouring buffer along glass rod so as to cause minimum disturbance of the gel layer. Put lid on column extension (or put top adaptor on column).

Small columns (e.g., 1 cm i.d., 5-cm length) to be used for preliminary experiments

RCU IASI CENTRAL UNIVERSITY LIBRARY

where optimum resolution is not critical may be quickly prepared by adding the gel slurry to the chromatographic tube, letting the gel settle by gravity, and washing the bed with one column volume of GF buffer before applying the sample.

9. Fill buffer reservoir with GF buffer and place at a level higher than the pump. Connect reservoir to pump using a large-i.d. tube.

   This step is to ensure a free flow of buffer to the pump head.

10. Purge pump with GF buffer and attach outlet from pump to inlet of column or column extension. Open outlet of column and start pump at flow rate recommended by manufacturer for the gel/column combination used. Continue flow until height of gel bed becomes constant (typically 1 to 4 hr).

    If no manufacturer's recommendation is available, use a flow rate 50% higher than that to be used in the separation.

    If column is to be packed by gravity flow—i.e., by attaching the buffer reservoir directly to the inlet of the column—the actual flow rate must be monitored (e.g., by continuously weighing the effluent, or in the simplest case, by using a graduated cylinder) or controlled by a pump placed after the column. In the latter case it is necessary to check that the free gravity flow exceeds the pump flow—i.e., that the pump is serving to reduce the flow to a constant value.

    The flow rate caused by gravity depends upon the hydrostatic pressure, determined by the difference in height between the air inlet in the buffer reservoir and the outlet tubing from the column. However, because the pressure drop over the column increases with the height of the packed bed, the free gravity flow rate will decrease during packing if the hydrostatic pressure is kept constant. Gravity flow rate may be increased by lowering the outlet tube or raising the buffer reservoir.

11. Turn pump off, close column outlet, remove column extension, adjust bed height if necessary, and adjust inlet adaptor so that it is flush with the bed surface.

    Avoid trapping air under the support net.

    Adjustment of the bed height is recommended only to remove excess gel. This is done by carefully swirling the upper part of the gel surface with a spatula and sucking the excess slurry out with a Pasteur pipet or tubing attached to a pump. If a crater or uneven surface is produced, the gel should be swirled so that a sharp bed surface is obtained before adjusting the inlet adaptor atop the bed. If the bed is too short the column should be repacked, although in most cases the old gel can be reused and added to new slurry prepared as in steps 1a to 3a or 1b to 3b before repacking.

12. Reattach column to pump, open column outlet, and resume flow conditions used in step 10 for 1 hr to stabilize column bed height. Readjust the adaptor so that it is flush with the new bed surface.

    In some cases it is desirable to lower the inlet adaptor a few millimeters into the gel surface to make sure that there is contact between adaptor and gel.

    Stabilizing the bed at a higher flow rate than that to be used during the separation will prevent the bed from shrinking as a result of "after-packing" during the run. If a gap appears between the adaptor and the bed surface, step 12 must be repeated at an increased flow rate before experiments are carried out. A space between the adaptor and the bed surface will act as a mixing chamber; the effect on separation will depend on the separation problem at hand.

13. Inspect packed bed visually for cracks, trapped air, and particle aggregates by observing the light scattered from a light source held behind the column. Chromatograph a colored marker (2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B_{12}) as in steps 20 to 23, and ascertain that the zone produced is horizontal and sharp.

    Quality of the packed bed need not be as high for desalting as for protein fractionation

B.C.U. „M. EMINESCU" IAŞI
CHITIE

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

(see Basic Protocol 2); therefore evaluation of the packed bed may be performed by visual inspection. However, it is important for it to be free of cracks and for a colored sample to produce a sharp horizontal zone.

Air bubbles would be a major problem and should be avoided at all costs (see Troubleshooting).

If column is to be stored, GF buffer containing 0.02% (w/w) sodium azide or 20% (v/v) ethanol as antibacterial agents should be prepared, then two column volumes of this mixture should be pumped through the column. The outlet is then closed and the column stored in the buffer/antibacterial agent at room temperature for several months. See recipe for GF buffer for precautions concerning azide.

Prepare and test the GF system

14. Calculate amount of GF buffer necessary for the run and filter this amount plus a 50% excess through a 0.22-µm filter. Adjust pH if necessary and pour filtered buffer into buffer reservoir.

    If the column is going to be used for a prolonged time, it is good practice to continuously deaerate the GF buffer by heating the buffer slightly with heat from a light bulb, or to use a degasser.

15. Assemble GF system according to manufacturer's instructions or Figure 8.3.1, placing detector and chart recorder (if used) in line but leaving column off line. Attach buffer reservoir to pump and purge pump with GF buffer with column off line.

    If the system is run by gravity flow alone, the risk of the column running dry may be eliminated by placing the end of the outlet tubing higher than the inlet adaptor or placing a loop of the tubing from the reservoir with its bend at a lower level than the outlet.

    Detection of salt may be accomplished in line by conductivity or off line by flame photometry or conductimetry. Colorimetric detection of proteins is readily done at 280 or 254 nm; the latter wavelength provides higher sensitivity. Refer to Chapter 3 for specific methods of protein detection.

16. Connect outlet of pump to column via the injection valve, run system with GF buffer at flow-rate settings to be used for separation, collect fractions with fraction collector, and note actual flow rate of the pump (e.g., by weighing collected fractions or measuring them with a graduated cylinder).

    If the concentration of the solute is detected by in-line monitoring, use of a two-channel recorder set at different sensitivities (e.g., 100% and 10% full-scale) is recommended to ensure that the peaks of unknown solutes are not off-scale.

    The actual flow rate of the system must be determined with the column installed because the flow rate from a peristaltic pump or similar device depends upon the back-pressure of the system.

Determine separating volume of column

17. Determine the void volume of the system (V_o) by running a void marker and obtaining the elution volume according to steps 20 to 23.

    The sample volume for determination of void volume and total liquid volume (steps 17 and 18) is not critical and may typically be 1% to 2% of the bed volume. However, correction of the calculated elution volume is needed if large sample volumes are applied (see annotation to step 23a). See Figure 8.3.2 for graphical depiction of void and total liquid volume.

    The markers for void volume and total liquid volume may be mixed and run together.

    Void volume (V_o) is typically 30% to 33% of the bed volume of a nonrigid (e.g., agarose) gel and 36% to 40% of the bed volume of a rigid (e.g., silica) gel.

BCU IASI CENTRAL UNIVERSITY LIBRARY

18. Determine the total liquid volume of the system (V_t) by running a total liquid volume marker and obtaining the elution volume according to steps 20 to 23.

Total liquid volume (V_t) is typically 85% to 95% of the geometric bed volume ($\pi r^2 L$, where r is the inner radius of the column) for a nonrigid gel and 70% to 80% of the bed volume for a rigid gel. Because solute-matrix interactions may occur, it is advisable to check that the total liquid volume is smaller than the bed volume and perhaps run several different total liquid volume markers to confirm the result.

19. Calculate the separating volume of the column (V_i) as $V_t - V_o$.

The separating volume (V_i) is the amount of liquid that will pass through the column from the point where large proteins begin to emerge to the point where small solutes are eluted. It is equal to the pore volume of the bed, which is typically 50% to 65% of the bed volume of a nonrigid gel and 30% to 50% of the bed volume of a rigid gel.

Prepare, apply, and chromatograph the sample

20. Dissolve sample to be desalted in GF buffer. Filter through a 0.22-µm protein-compatible filter.

If possible, let sample solution reach room temperature before being applied to column to reduce viscosity effects. This is more important for large sample volumes.

The influence of the sample volume on the resolution (see Critical Parameters) is related to the need for column efficiency (see Basic Protocol 2 and UNIT 8.1). Too large a sample volume may ruin the separation of closely eluting proteins in a separation where high efficiency and narrow peaks are required. This is of primary interest in protein fractionation (see Basic Protocol 2), whereas in desalting, conditions are chosen to yield maximum separation of the protein from contaminants. To this end, column efficiency is less important, and very large sample volumes may be applied. See Critical Parameters for guidelines on optimal sample concentration.

When GF is performed for analytical purposes, the sample concentration should be as small as possible within the sensitivity of the detection method employed. For preparative purposes, on the other hand, the concentration should be as high as possible. The limiting factor in the latter case is the viscosity of the sample divided by the viscosity of the GF buffer (relative viscosity). At relative viscosities >1.5, the hydrodynamic instability of the trailing edge of the zone may cause distortion of the

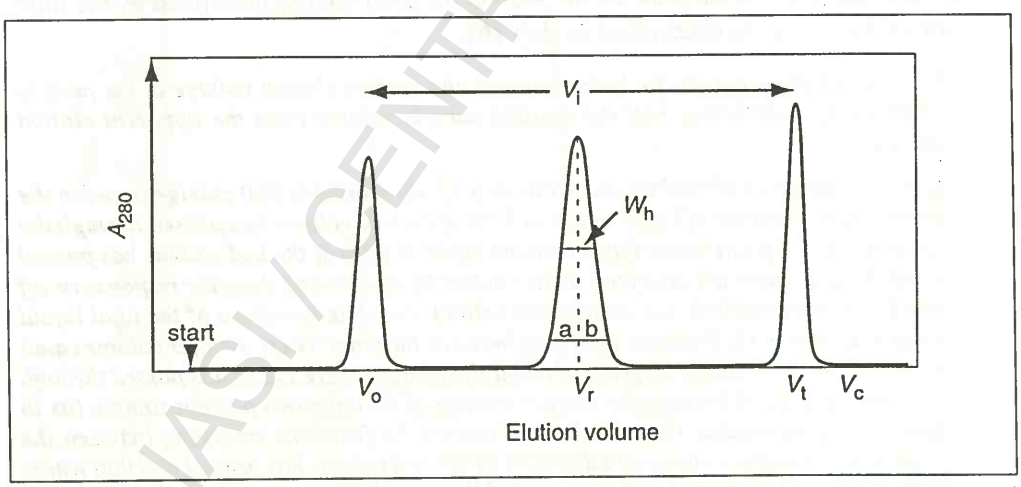

Figure 8.3.2 Chromatogram illustrating the separating volume (V_i) of gel filtration as determined by the void volume (V_o) and the total liquid volume (V_t). The total bed volume (V_c) is equal to the total liquid volume plus the matrix volume. Column efficiency is calculated as $N = 5.54(V_r/W_h)^2$, where N is the efficiency of the column in terms of number of theoretical plates, V_r is the elution volume of the peak, and W_h is the peak width at half peak height. The symmetry of the peak is calculated at 10% peak height as b/a, where b is the width of the tailing part of the peak and a is the width of the leading part of the peak.

UNIVERSITY LIBRARY

protein zone (resulting from invasion of less viscous eluant into the more viscous zone; called "viscous fingering"), which will ruin the separation. It is generally safe to use protein concentrations up to 50 mg/ml and in some cases up to 70 mg/ml, whereas concentrations of 100 mg/ml often result in viscous fingering. However, when large sample volumes are applied—e.g., in desalting—the low dilution factor will result in a high concentration of protein in the peak, hence lower concentrations than these may be required to avoid viscosity effects.

21. Open outlet from column, turn on pump, and let two bed volumes of GF buffer pass through the column. Turn on detector and recorder and allow baseline to stabilize.

22. Load sample applicator with the appropriate volume of sample for desalting, not exceeding the separating volume determined in step 19. Switch the sample application valve to the load position and put a start mark on the chart recorder paper (or start a stopwatch if no chart recorder is used).

    Smaller sample volumes are used for protein fractionation than for desalting, and much smaller sample volumes are used for analysis.

    Before injecting, flush injector loop with excess sample to avoid trapping air bubbles, which otherwise may end up in the top of the column.

    If the separating volume of the column has not been determined, the maximum sample volume may be estimated as ~50% of the bed volume for nonrigid media and ~30% of the bed volume for rigid media. For a first attempt at desalting, 50% of these volumes should be applied (i.e., 25% and 15% of the bed volume for nonrigid and rigid media, respectively).

    If an open-bed column is used, gently add GF buffer to the top of the column with a Pasteur pipet or similar device, then open the outlet from the column and continue adding GF buffer until two bed volumes of buffer have passed through. Let the last portion of buffer penetrate the gel without the gel surface becoming dry; this is facilitated by using a top filter on the bed. Gently apply the sample to the clear gel surface or the top filter using a micropipet (or a Pasteur pipet if large volumes of sample are to be desalted).

23a. *To determine elution volume:* Pass GF buffer through the system at the appropriate flow rate and follow detector response with recorder while collecting fractions. Construct a chromatogram and calculate elution volume as the time from the start point to the apex of the peak for the protein (or other solute) multiplied by the flow rate of the pump (as determined in step 16).

    If large sample volumes are being applied, the correct elution volume of the peak is obtained by subtracting half the applied sample volume from the apparent elution volume.

    For determination of void volume as in step 17, the fractions that emerge between the point where a volume of buffer equal to 25% of the bed volume has passed through the column and the point where buffer volume equal to 50% of the bed volume has passed through the column are analyzed (either in line by monitoring detector response or off line by another method; see annotation below). For determination of the total liquid volume as in step 18, fractions emerging between the point where a buffer volume equal to 75% of the bed volume has passed through and that where 125% has passed through are analyzed. To determine the elution volume of an unknown protein sample (as in determining molecular size; see Basic Protocol 3), fractions emerging between the point where a buffer volume equal to 25% of the bed volume has passed and that where 125% has passed through are analyzed. Allowing 125% to pass through will permit the entire peak to be traced.

    If fractions are to be collected for subsequent off-line analysis to determine where elution occurs (e.g., by photometry at 280 nm to detect Blue Dextran 2000 or proteins, or conductivity to trace the salt peak), start and stop the fraction collector to sample fractions at the volumes stated above. The fraction size should be large enough to

PCU IASLIC CENTRAL UNIVERSITY LIBRARY

permit accurate assay of the solute of interest; often 1 ml or 1/50 of the bed volume (whichever is smallest) is a suitable fraction size. The prefraction (i.e., the amount of liquid eluted from the point of sample application to the start of fraction collection for analysis) should be sampled in a vessel of known weight. The elution volume is calculated from the volume of the fractions by adding half the volume of the peak fraction and the volume of the prefraction, then subtracting half the sample volume. For dilute aqueous buffers (e.g., 0.5 M) a density of 1 may be assumed for converting weight to volume. If the experiment will take a long period of time, it is advisable to minimize evaporation by sealing the fraction cups with Parafilm.

If an open-bed (gravity flow) column is used, carefully add a volume of GF buffer that corresponds to the void volume of the column reduced by half the sample volume—unless the sample volume is <4% of the bed volume, in which case add 1 void volume of buffer. If the column is operating correctly, the effluent collected should contain no protein. Add GF buffer in ≤1 ml increments if the column has a bed volume <50 ml, collect fractions, assay for proteins, and calculate elution volumes as described above.

23b. *To desalt a protein:* Pass a volume of GF buffer equal to the void volume reduced by half the applied sample volume through the column, and collect a waste fraction. Place a vessel that can hold 1.5 times the applied sample volume under the column, then add a volume of GF buffer equal to the applied sample volume. Collect the desalted protein.

Depending upon the efficiency of the desalting system, these quantities may have to be adjusted (i.e., the volume collected in the second fraction may need to be decreased in order to preclude contamination from substances that elute later). If system effects (e.g., mixing after the column) are substantial or the column is badly packed (e.g., contains cracks in the bed), it will be necessary to pass more GF buffer through the column than the void volume minus half the sample volume before sampling the protein (see Critical Parameters). Figure 8.3.3 shows a sample chromatogram of optimized desalting of 400 ml hemoglobin.

The desalting step may be continuously monitored by simultaneous in-line detection

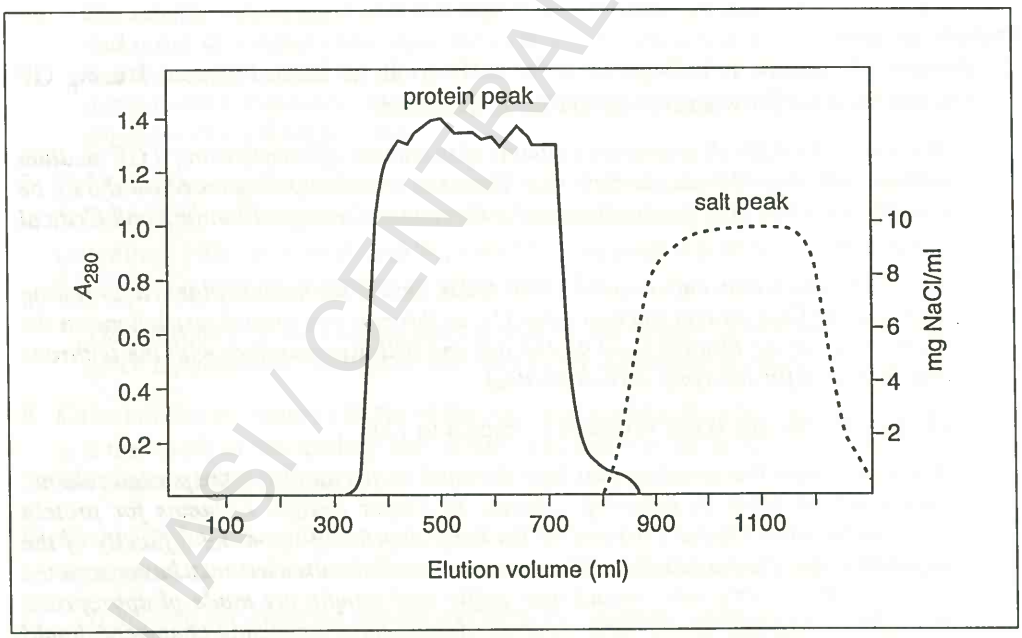

Figure 8.3.3 Chromatogram illustrating desalting of proteins by gel filtration. A 4 × 85–cm column packed with Sephadex G-25 is used. The sample consists of 400 ml hemoglobin (protein peak; solid line) in NaCl (salt peak; broken line). Note that the sample volume is close to the pore volume of the packed matrix, i.e., 490 ml. No correction for sample volume has been made. Calculation from the figure yields V_0 = 560 ml – 200 ml = 360 ml, which is 31% of the geometric column volume (V_c). Reproduced from Flodin (1961) with permission of the *Journal of Chromatography.*

UNIVERSITY LIBRARY / CENTRAL UNIVERSITY OF IASI

of the protein zone by absorbance at 280 nm and in-line detection of the salt peak by conductivity.

24. Wash column with ≥1 column volume of GF buffer containing an antibacterial agent. Close column outlet and store column.

    See recipe for GF buffer for acceptable antibacterial agents.

BASIC PROTOCOL 2

PROTEIN FRACTIONATION

Protein fractionation refers to the separation of proteins of similar molecular size for purification purposes. The objective may be to separate dimer and higher aggregates from a pharmaceutically active protein or peptide. Requirements for the column and system are therefore substantially higher for protein fractionation than for desalting.

The same materials and methodology described for desalting are used for protein fractionation. However, selection of matrix and column (see Strategic Planning) is more critical in this procedure, as are the quality of the column packing and control over experimental conditions (e.g., temperature and flow rate). The protocol includes steps for determining the column efficiency (see also *UNIT 8.1*) to evaluate the fitness of a packed column for use in protein fractionation.

Materials

GF matrix (see Table 8.3.4) or prepacked GF column (see Table 8.3.6) with appropriate selectivity for protein of interest (also see Strategic Planning and Critical Parameters)
GF fractionation buffer (see recipe)
Colored marker: 0.2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B_{12}
Low-molecular-weight marker (e.g., 5 mg/ml acetone or 2 M sodium chloride)
Protein sample to be fractionated
GF chromatography column (see Critical Parameters and Table 8.3.5)

Prepare column

1. Prepare GF matrix as in steps 1a to 3a or 1b to 3b of Basic Protocol 1 using GF fractionation buffer wherever GF buffer is indicated.

   It is generally difficult to prepare columns of maximum efficiency using a GF medium with a small (e.g., 10-μm) particle size. The need to scale up the procedure should be considered when selecting medium and column (see Strategic Planning and Critical Parameters).

   The GF fractionation buffer must be selected in light of the method planned for testing purity of the final protein fraction (step 11), as this may put special restrictions on the buffer (e.g., azide absorbs light at 254 nm and will also interfere with the anthrone reaction used for assaying carbohydrates).

2. Pack the column (see Basic Protocol 1, steps 4 to 12).

   Because protein fractionation puts high demands on the quality of the packed column, care must be taken in selecting columns of proper design. Columns for protein fractionation are typically 30 to 100 cm long, depending upon the difficulty of the separation and the particle size of the medium used. Columns used must be constructed so that parts coming into contact with buffer and sample are made of appropriate materials. Long tubings and other sources of dead space or mixing chambers should be avoided. The pressure resistance of the column should be compatible with the expected pressure drop of the bed. See Strategic Planning and Critical Parameters for details concerning column selection.

3. Check quality of column packing visually (see Basic Protocol 1, step 13).

BCU IASH LIBRARY CENTRAL UNIVERSITY

4. Assemble and test the system (see Basic Protocol 1, steps 14 to 16).

Place system and column in an environment not subject to temperature variations (e.g., the column should not be exposed to direct sunlight). If the system is to be used in a cold room, the influence of temperature on viscosity must be considered. Zone broadening of proteins and the pressure drop of the system are proportional to the viscosity of the buffer, and the flow rate will have to be adjusted accordingly.

Successful, reproducible protein fractionation requires a constant flow rate. This may be achieved using a peristaltic or high-precision pump whose flow rate is regularly checked. Continuous monitoring of the effluent is necessary to ensure proper sampling of the fraction of interest. Detection may be carried out at 280 or 254 nm to trace proteins containing aromatic amino acids, or at lower wavelength (e.g., 214 or 206 nm) to measure absorption by peptide bonds. Other parts of a protein fractionation system that might be of use include a fraction collector, (although in the simplest case it is possible to collect the fraction of interest by using a switch valve), and a chromatography controller, which permits automatic fractionation of the protein of interest.

Evaluate column

5. Chromatograph a colored marker (2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B_{12}; see Basic Protocol 1, steps 20 to 23) and ascertain that the zone produced is horizontal and sharp.

A volume of marker solution 1% to 4% of the bed volume should be applied. The zone produced by a colored sample must be horizontal and sharp for packing to be considered acceptable.

If the supplier recommends a different method than this for evaluating column packing, that method should ordinarily be used.

6. Chromatograph a low-molecular-weight marker (e.g, 5 mg/ml acetone or 2 M sodium chloride; see Basic Protocol 1, steps 20 to 23) and construct a chromatogram to determine the column efficiency.

The sample volume applied in this step may contribute considerably to the peak width and result in a falsely low value for column efficiency. It is therefore recommended that the sample volume not exceed 0.9%, 0.5%, and 0.4% of the bed volume for columns packed with GF matrices having average particle diameter of 100 μm, 30 μm, and 10 μm respectively (Hagel, 1985).

7. Calculate the number of theoretical plates per column according to the equation $N = 5.54(V_r/W_h)^2$, where N = number of theoretical plates per column, V_r = elution (retention) volume of peak, and W_h = width of the peak at half peak height. See Figure 8.3.2 for a graphical depiction of these variables.

The efficiency of the column corresponds to the number of theoretical plates under given experimental conditions. See UNIT 8.1 for discussion of column efficiency.

8. Calculate the asymmetry factor of the peak according to the equation $A_s = (b/a)$, where a is the width of the leading part of the peak and b is the width of the tailing part of the peak at 10% peak height.

9. Compare the plate number and asymmetry factor obtained for the column with the acceptance limits for these parameters in the manufacturer's documentation.

If no data for expected column performance is given, calculate the plate height (H) according to the equation $H = L/N$, where L is the length of the packed bed and N is the number of theoretical plates calculated in step 7. As a rule of thumb, H should be about three times the average particle diameter of the matrix for a good column and twice the average particle diameter for an excellent column. Plate heights of five times the average particle diameter or more are generally not accepted for high-resolution chromatography. The asymmetry factor should be 1.0 ± 0.2.

BOSTON BIOMEDICAL RESEARCH INSTITUTE LIBRARY

Table 8.3.7 Practical Velocities for Protein Fractionation or Size Determination[a]

Solute molecular weight (Daltons)	Nominal eluant velocities (cm/hr) at a support particle size of (μm):						
	2	5	10	15	30	50	100
1,000	507	203	101	68	34	20	10
5,000	293	117	59	39	20	12	6

The flow rate used will influence the broadening of the solute peak; suggested flow rates for GF matrices of different particle size are given in Table 8.3.7.

Perform chromatography and evaluate results

10. Dissolve, apply and chromatograph protein sample to be fractionated (see Basic Protocol 1, steps 20 to 23).

Start by applying a small fraction of the sample to get a rough idea of the separation and to calculate optimum conditions for the actual run. A sample volume of ~1% to 4% of the bed volume has been found to be optimal for protein fractionation using a medium of 30-μm particle size, depending upon the processing rate (i.e., amount of substance processed per unit time) of the system (Hagel et al., 1989). As a general rule,

BCU IASI / CENTRAL UNIVERSITY LIBRARY

a sample volume of 2% of the bed volume can be applied. A chromatogram illustrating protein fractionation where dimers and higher aggregates are separated from the target monomeric form of the protein is given in Figure 8.3.4.

Optimum sample volume depends upon many experimental factors; discussion of optimization strategies have been published (Hagel et al., 1989; Hagel and Janson, 1992). In general, the larger the bead size used, the larger the sample volume that may be applied before the initial resolution is lost. This is due to the fact that smaller bead sizes normally result in more efficient columns that produce narrower peaks; hence the influence of sample volume on peak width is more detrimental.

11. Check the purity of the collected fraction(s).

Suitable methods of determining purity include HPLC and electrophoresis (see Chapter 10 for electrophoresis).

DETERMINATION OF MOLECULAR SIZE

BASIC PROTOCOL 3

The third important application of gel filtration is in determining molecular size. To accomplish this, a GF column is calibrated with reference samples of known molecular size (see Support Protocol). Gel filtration is then carried out on an unknown protein solute as in Basic Protocols 1 and 2, and the molecular size of that solute is then inferred from the calibration curve, which relates elution volumes or distribution coefficients on the calibrated column to the molecular sizes of the different reference samples. If the relationship between the molecular size and mass is known, the mass of the solute may be calculated. However, because the shapes of biological molecules vary considerably (e.g., proteins may be spherical or ellipsoidal, or in some cases more or less rod-shaped), the calculation of molecular mass (M_r) from elution volume must be done with great care. If the shape of the molecule under study is not known, the experiment will yield only its estimated solvated size. The influence of solute shape on size may be exemplified by the fact that the radius of gyration (one estimate of size) is proportional to $M_r^{1/3}$ for spherical molecules (e.g., some proteins), to $M_r^{1/2}$ for molecules shaped like flexible coils (e.g., dextrans and denatured proteins), and to M_r for rod-shaped molecules (e.g., fibrous proteins and DNA fragments of intermediate length). Thus, gel filtration is very suitable for estimating the molecular size but generally not the molecular mass of unknown solutes.

Materials

GF matrix or prepacked GF column (see Table 8.3.4, Table 8.3.6, Strategic Planning, and Critical Parameters)
GF fractionation buffer (see recipe; note variations for size determination)
GF chromatography column (Table 8.3.5)
High-precision pump
Protein sample for size determination

1. Prepare gel, pack column, then assemble and test GF system (see Basic Protocol 1, steps 1 to 16) using GF fractionation buffer wherever GF buffer is indicated.

For high-precision analytical gel filtration, the temperature of the chromatographic bed is often kept constant by using a jacketed column and circulating water from a temperature-controlled water bath. This makes the instrument setup more complicated, and the need for this precaution must be assessed on a case-by-case basis (e.g., if the column is calibrated at every other run, as is possible with high-speed gel filtration, there is little need for temperature control).

A high-precision pump must be used to ensure accurate and constant flow rate, which is of utmost importance for achieving reliable results in molecular size determinations. In addition to a UV detector for determining protein concentration, a detector for viscosity and/or light scattering—e.g., one employing multiple-angle laser light scat-

BOURNEMOUTH UNIVERSITY LIBRARY

tering (MALLS)—may be used for assay of molecular size or (indirectly) molecular mass. A mass spectrometry detector—e.g., one employing electrospray ionization mass spectrometry (ESI-MS)—may be used for assay of molecular mass.

If denatured standards are to be used in the calibration to eliminate the influence of molecular shape (see Support Protocol), 6 M guanidine hydrochloride (see recipe for GF buffers in Reagents and Solutions) is used as the GF fractionation buffer in this and subsequent steps.

Once a column has been calibrated (see Support Protocol), it is important to check column performance by determining the elution volume of one of the reference samples used for calibration as part of the routine testing of the system.

2. Determine the void volume (V_o) and the total liquid volume (V_t) for the system (see Basic Protocol 1, steps 17 and 18).

3. Calibrate column (see Support Protocol). Check flow rate during calibration by sampling effluent and weighing fractions.

   Calibration of the column (and chromatography of the sample) may be carried out under denaturing conditions to eliminate the effects of molecular shape. Variations in procedure are described in the Support Protocol.

   There are no general restrictions on the flow rate as long as the protein of interest separates from contaminating solutes (ideally, baseline separation should be achieved). A high flow rate will not influence the qualitative information sought—i.e., the position of the peak maximum. Thus, qualitative information may be obtained by very fast gel filtration; however, the danger of shear effects at high flow rates on elongated solutes must be considered. If a high-precision pump is used, there is less need to check the flow rate for every run (though in the author's experience this is a good practice because any pump may malfunction). If constant flow rate can be taken for granted, time may be substituted for volume in the calculations.

   For both the calibration (see Support Protocol) and the run to determine molecular size of the unknown sample, the elution volume should generally be corrected for the contribution from the sample volume (see Basic Protocol 1, step 23a). However, if the sample volume is kept constant throughout the entire investigation it may arbitrarily be regarded as a part of the dead volume of the system, and no correction is necessary.

4. Apply, elute, and chromatograph unknown sample (see Basic Protocol 1, steps 20 to 23). Prepare a chromatogram and calculate elution volume. Check flow rate by sampling the effluent and weighing fractions.

   The same applied sample volume should be used for the unknown sample as for the size standards (see Support Protocol).

   If denatured standards were used in the calibration to eliminate the effects of molecular shape (see Support Protocol) the sample must be denatured. Elution is then carried out using 6 M guanidine hydrochloride as the GF buffer.

   Often the calculations are performed on a time basis using an integrator or chromatography software (Pharmacia Biotech).

5. Calculate molecular size of unknown sample components using the calibration graph constructed in the support protocol.

   If two different detectors were used for the reference standards and the sample (e.g., a refractive index detector for calibration with dextran standards and a UV detector for the protein sample), a correction factor for the difference in volume between the two detectors must be used in the calculations.

   The estimate of molecular size will be correct only if there are no sample-matrix or sample-sample interactions (in fact, gel filtration has been used to study these self-association processes). The size estimate will be an apparent gel-filtration size

BCU IASI / BIBLIOTECA UNIVERSITARA

which, together with data about the molecular mass (e.g., from mass spectrometry), will yield information about molecular shape.

6. Continue to run GF buffer through column until the next run is to be made.

It is important to continue flushing the column to maintain column characteristics and avoid the need for recalibration (also see Critical Parameters). If the next run is not to be made for a long time, the flow rate may be reduced and buffer recirculated through a filter to the buffer reservoir (also see Critical Parameters). Before reusing the column after a long period of rest, the validity of the calibration curve should be checked by running two or three reference samples covering the range of interest and calculating their molecular size from the old calibration curve. The apparent size should agree with the assigned size within ±5% error.

COLUMN CALIBRATION

SUPPORT PROTOCOL

Molecular size standards for column calibration should ideally be of the same shape and type as the molecules under study (e.g., globular proteins, fibrous proteins, or peptides). In cases where this requirement cannot be met, the column can be calibrated with other suitable reference substances of known size (e.g., dextrans). An apparent size may thus be assigned to the unknown and the actual size then inferred from the relationship between the shape of the different molecules. It is thus possible to use dextran as a reference for the estimation of Stokes radius for globular proteins (Hagel, 1993). However, a general shape parameter governing separation of all types of molecules by gel filtration has not yet been found (Dubin et al., 1990).

When protein standards are used, the calibration curve will reflect small natural variations in the molecular shapes of proteins, which will decrease the precision of the curve. However, the procedure described here is very simple and will readily yield an apparent molecular mass or molecular weight, which in many cases is quite satisfactory.

The influence of protein shape on the calibration curve may be eliminated by disruption of noncovalent bonds with denaturing solvents (e.g., guanidine hydrochloride). Disulfide bonds are broken by reductive cleavage with a reagent such as DTT, and reoxidation is prevented by carboxymethylation. This treatment converts the shape of sample and reference proteins to random coils. The physical size of a random coil is larger than that of a compact molecule of equal mass; therefore a more porous gel is needed to separate the former species. Detergents may also be used to denature proteins. However, it must be noted that a protein-detergent complex is larger than the protein and that ionic detergents will introduce charged groups. Also, information about size or molecular mass obtained using detergent-denatured proteins may not be relevant to the native protein. As these types of treatment are frequently used to prepare proteins for analytical electrophoresis, the reader is referred to Chapter 10 for further details.

The influence of variation in shape on the calibration curve may also be eliminated by using as molecular size standards reference substances from a homologous class of nonprotein polymers—e.g., dextran or polyethylene glycol. Dextran has been used extensively as reference substance for calibration of gel-filtration columns. Calibration can be done by running a number of narrow fractions or one sample of broad size distribution.

Additional Materials (also see Basic Protocol 3)

Calibration standards (see recipe and Table 8.3.8)
6 M guanidine hydrochloride (see recipe for GF buffer)
In-line refractive-index detector

BU JAST CENTRAL UNIVERSITY LIBRARY

For calibration with native proteins

1a. Calibrate the column using protein standards (see Table 8.3.8) as in steps 20 to 23 of Basic Protocol 1 and construct a chromatogram.

It is practical to mix a number of the calibration standards and chromatograph them simultaneously so that the calibration may be completed in a few runs (see example in Figure 8.3.5).

2a. Plot the elution volume (V_r; i.e., the volume on the chromatogram from the injection point to the apex of the peak for a particular size standard) versus the logarithm of the molecular size, $\log_{10}R$, where R is the molecular radius of the calibration standard.

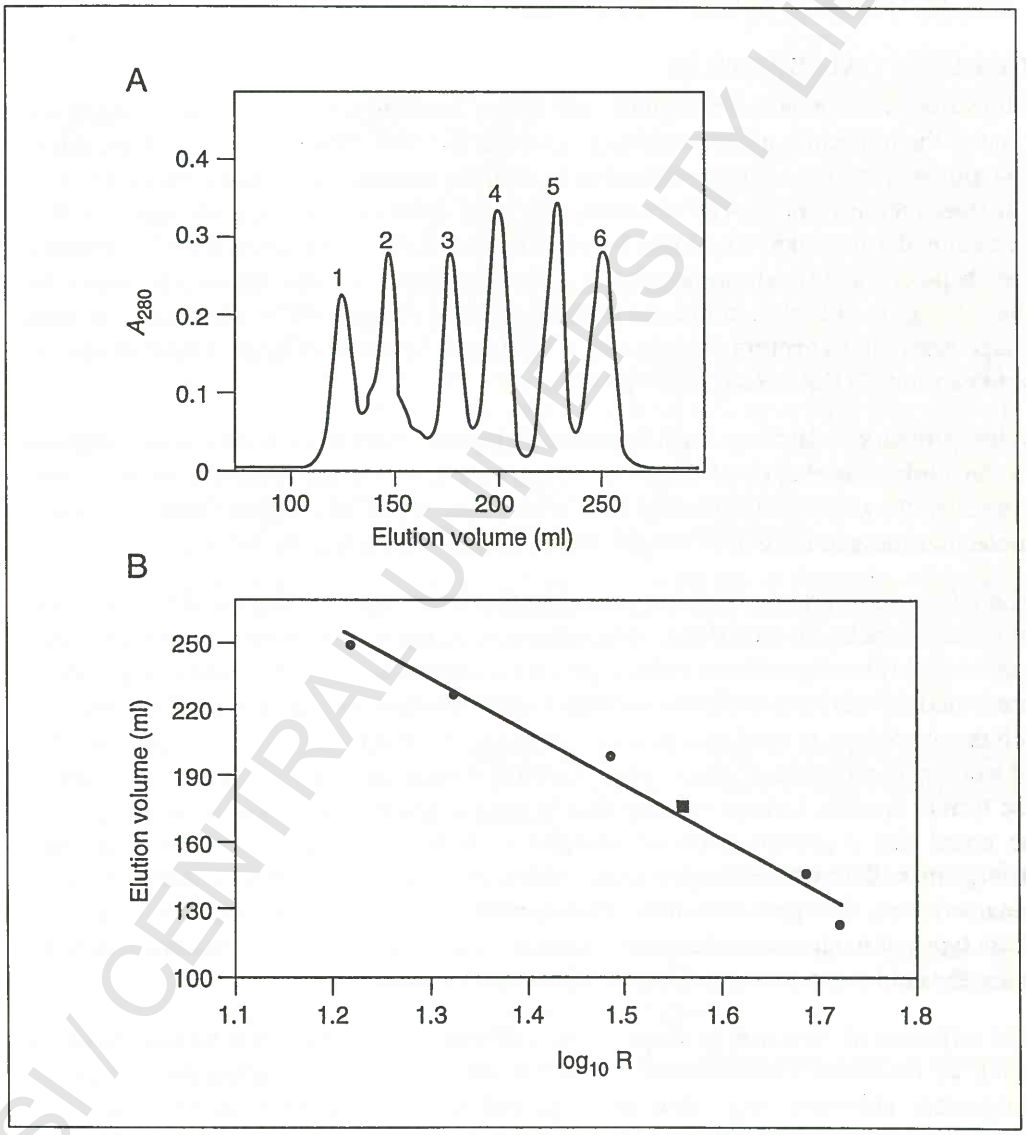

Figure 8.3.5 Calibration of GF column for determination of protein size. A K 26/70 column packed with Sephadex G-200 SF is used. (**A**) Chromatogram obtained for six size standards: 1, catalase; 2, aldolase; 3, bovine serum albumin; 4, ovalbumin; 5, chymotrypsinogen A; 6, ribonuclease A. (**B**) Calibration curve obtained by plotting the logarithms of the molecular radii ($\log_{10}R$) of the six standards (*x* axis) versus the elution volumes for peaks 1, 2, 4, 5, and 6 from panel A (filled circles). The curve was used for evaluating the size of bovine serum albumin (filled square; elution volume corresponds to peak 3 in panel A), giving an apparent size of 34.8 Å. The excellent agreement with the nominal molecular size value of 35.5 Å may be incidental. Repeating the procedure for peak 4 in panel A showed that a deviation of ~3 Å from the nominal value may be expected for proteins of globular shape. Panel A reproduced from Pharmacia Biotech (1991) with permission from the publisher.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Table 8.3.8 gives the molecular radii of commonly used calibration standards. A sigmoid curve should be obtained that is approximated by a straight line in the middle section (see Fig. 8.3.5).

If the sample volumes are not held constant, the elution volume must be normalized by setting the injection point at half injected volume.

The calibration curve is often made system-independent by plotting distribution coefficient (K_D) versus $\log_{10}R$. The distribution coefficient is calculated as

$$K_D = (V_e - V_o)/(V_t - V_o),$$

where V_e is the elution volume for a particular peak, V_o is the void volume for the column, and V_t is the total liquid volume for the column.

For substances belonging to a homologous series (e.g., dextrans), it is meaningful to plot elution volume versus the logarithm of the molecular mass ($\log_{10}M_r$). Where substances of different chemical nature are being used to calibrate the column, the preferable way to calibrate the column is by using the hydrodynamic volume V_h. This is calculated according to the equation $V_h = (\eta)(M_r)/N\nu$, where η is the intrinsic viscosity, M_r is the relative molecular mass, N is Avogadros number (6.02×10^{23} molecules per mole), and ν is a shape factor.

It is wise to check the accuracy of the calibration by deleting one point at a time from the calibration data set and calculating the size or mass of the protein represented by that point from the calibration curve obtained with the remaining data. The average absolute difference from the nominal value indicates the accuracy of the calibration (see Fig. 8.3.5).

For calibration with denatured standards

1b. Denature calibration standards according to a standard denaturing protocol.

2b. Carry out steps 1a and 2a above, using a column equilibrated in 6 M guanidine hydrochloride and using 6 M guanidine hydrochloride as the GF buffer in the cross-referenced steps of Basic Protocol 1.

Where denatured standards are used, denaturing conditions must be maintained in chromatography of the sample (see Basic Protocol 3).

For calibration with nonprotein polymer standards

1c. Using an in-line refractive index detector, run system until a stable baseline is obtained. Chromatograph a number of dextran calibration standards (see Basic Protocol 1, steps 20 to 23) that will give calibration points surrounding the protein under study, to obtain their elution volumes or distribution coefficients.

The proper number and size of calibration standards to be run may be quickly found by running first the unknown sample and then the necessary calibration samples that will be eluted close to the unknown protein.

Apply each standard individually or as a mixture of two dextrans of high and low molecular mass.

Using a two-channel recorder set at two different sensitivities may prevent the peak from running off-scale.

2c. Plot the elution volume (V_e) or distribution coefficient (K_D) versus the logarithm of the viscosity radius of dextran ($\log_{10}R_{vis}$).

The viscosity radius of dextran, R_{vis}, is related to the molecular mass (M) according to the equation $R_{vis} = 0.271 \times M^{0.498}$. Because dextran is a polydisperse polymer, the value of M used here is the molecular mass of dextran that corresponds to the peak apex, sometimes denoted M_p.

When two different detectors are used for calibration and chromatography of the sample—e.g., a refractive index detector for dextran standards and a UV detector for

BOKU-VIBT / CENTRAL UNIVERSITY LIBRARY

the protein sample—the difference in volume between the two detectors must be taken into account in calculation of elution volume.

Another procedure where the entire separation range of interest was calibrated in one run, using an integral calibration method, has been described (Hagel and Andersson, 1991; Hagel, 1993). Unfortunately, this simple and powerful method cannot yet be performed on routine basis because it requires data for the molecular mass distribution of the sample, and this information is, at the moment, not readily available in most cases.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

GF buffers

For desalting: Use a volatile buffer—e.g., 0.05 M ammonium hydroxide, 0.05 M acetic acid, 0.05 M ammonium acetate or 0.5 M ammonium bicarbonate—unless the step is for buffer exchange, in which case use the desired final buffer.

Distilled (Milli-Q purified or equivalent) water may be preferred to buffer as an eluent in some cases. This will yield adequate results with noncharged solutes; however, ionic interactions with the small amount of charged groups on the gel surface may disturb the purification of slightly charged molecules when water alone is used. Addition of a volatile bacteriostatic agent—e.g., chlorhexidine—may sometimes provide enough ionic strength to suppress such interactions.

For protein fractionation: Use 0.05 M sodium or potassium phosphate (pK_a = 2.1, 7.2, 12.4), 0.05 M Tris·Cl (pK_a = 8.1), or 0.05 M sodium or potassium acetate (pK_a = 4.8).

The buffering capacity of these buffers is adequate at a pH within ±0.5 units of the pK_a value. If the protein is to be freeze-dried, use of a volatile buffer or water is advantageous.

It is sometimes necessary to add 0.1 M sodium chloride to completely eliminate ionic interactions. If parts of the system that come into contact with the buffer are composed of steel, the sodium chloride should be replaced with 0.05 M sodium sulfate to prevent halide-induced corrosion. In some cases the ionic strength of the buffer will affect the sample, e.g., by disrupting aggregates. This effect can be eliminated only by changing the ionic strength.

For determining molecular size: Use the same buffers as for protein fractionation but select one that will preclude solute-matrix interactions (see Support Protocol). If the column is to be used for a long period, add preservatives to prevent bacterial growth. Make sure the buffer is compatible with the detection step (e.g., use a buffer with low salt content if mass spectrometry will be used for detection).

If calibration is to be conducted under denaturing conditions, 6 M guanidine hydrochloride is used as the GF buffer. Guanidine hydrochloride is a better denaturing agent than urea.

For all buffers: Add antimicrobial agent if buffer will be used for a long time, adjust the pH of the buffer, filter through a 0.22-µm filter, then recheck pH and readjust if necessary.

It is also recommended to degas the buffer prior to prolonged use. It is common practice to prepare fresh buffer once a week, but if an antimicrobial agent has been added it may be stored for 1 month or more. Antimicrobial agents used for GF buffers include ethanol added to a concentration of 20% (v/v), sodium azide added to a concentration of 0.02% to 0.05% (w/v), or chlorhexidine added to a concentration of 0.002% (w/v). Ethanol is not recommended for use with Sephadex gels as organic solvents cause the bed to shrink when used with this matrix.

BCU IASI CENTRAL UNIVERSITY LIBRARY

IMPORTANT NOTE: *Azide is a very potent antimicrobial agent and therefore widely used. However, handling of azide, especially the dry powder, requires special attention; please refer to information from the supplier for safety precautions. Frequent exposure to the dry powder may be avoided by preparing a stock solution (e.g., 20% w/v) from which aliquots (e.g., 1 ml azide stock solution to 1 liter GF buffer) may be drawn conveniently with a micropipet. Azide may form explosive salts in lead-pipe waste disposal systems; collect the effluent in waste bottles.*

Calibration standards

Table 8.3.8 provides a compilation of commercially available molecular size calibration standards and their suppliers. Some of these are available as kits (e.g., from Pharmacia Biotech). Protein standards should be prepared in the GF buffer that will be used in the molecular size determination. To prolong the life of the column, samples should be filtered through a protein-compatible filter prior to injection. The exact concentration to be prepared depends on the additives present (e.g., sucrose as stabilizer), detector sensitivity, and the zone broadening of the column. Concentrations of proteins in the range from 1 to 5 mg/ml are frequently used for calibration. It is possible to mix several standards to calibrate the separation range of interest in a few runs (it is seldom necessary to calibrate the entire separation range of the column).

Table 8.3.8 also lists some dextran fractions that are useful for calibrating the column in hydrodynamic volume, which makes comparing solutes of different shape easier.

Total liquid volume marker

5 mg/ml acetone, 10 mg/ml sodium azide, 0.1 mg/ml cytidine, 10 mg/ml sodium nitrate, and 2 M sodium chloride have been used for determination of total volume. A negative pulse from injection of water can also be used. In cases where interactions between matrix and solute must be eliminated, deuterium oxide can be used.

Acetone and cytidine are detected by UV absorbance at 280 nm, azide at 254 nm, and nitrate at 254 nm. Sodium chloride can be detected by flame photometry, conductivity, a sodium or chloride electrode, or precipitation of chloride with silver nitrate solution. A negative pulse from injection of water is detected by measuring the absorbance or refractive index of the buffer or by monitoring the conductivity of the effluent. Deuterium oxide is detected with a refractive-index detector.

Void marker

A suitable substance for determining void volume is a protein of the correct size (not too large and not too small), which may be selected by running a series of large proteins and observing which of them start to permeate the matrix. Other substances that have been used include 2 mg/ml Blue Dextran 2000 and DNA.

Blue Dextran 2000 has the advantage of being visible to the eye. Disadvantages are that small amounts of free dye may stick to the gel and a broad permeating peak may be visible in addition to the sharp excluded peak if the pore size of the gel is large enough (e.g., as with Sepharose 4B). This occurs because of the polydispersity of dextran. If the molecule is too large, so-called secondary exclusion effects, in which the sample is excluded from the narrow space where beads intersect, will yield a falsely low void volume. However, this phenomenon is only important in high-precision gel filtration and rarely has to be considered in desalting.

BCU IAS CENTRAL UNIVERSITY LIBRARY

Table 8.3.8 Molecular Size Standards for Calibration of Gel Filtration Columns

Standard	Molecular mass (M_r, Daltons)	$\log_{10}(M_r)$	Molecular size (radius, Å)[a]	Supplier[a]
Proteins[b]				
Thyroglobulin, bovine thyroid	669,000	5.825	85.0	PB
Ferritin, horse spleen	440,000	5.643	61.0	PB

[a]Abbreviations and symbols: — Not stated by manufacturer; BR, Bio-Rad; PB, Pharmacia Biotech; PC, Pharmacosmos; SI, Sigma. Addresses and phone numbers of suppliers are provided in the *SUPPLIERS APPENDIX*.

[b]The size of proteins may vary according to the source of information and the methodology used for determination—e.g., a value of 67.1 Å has also been assigned to ferritin (de Haen, 1987).

[c]Dextran is a polydisperse polymer and values given here—e.g., peak molecular mass—may vary from lot to lot. In cases where peak molecular mass is not stated by the supplier, the column is calibrated as elution volume versus $(M_w M_n)^{1/2}$, where M_w is the weight-average molecular mass and M_n is the average molecular mass. The molecular size of dextran is calculated according to the equation $R_{vis} = 0.2 > 1 \times M_{0.498}$ where R_{vis} is the viscosity radius and M is the molecular mass (Hagel, 1989).

COMMENTARY

Background Information

Although separation of molecules according to size had been noticed in the mid-1950s (Lindqvist and Storgårds, 1955; Lathe and Ruthven, 1956), the discovery of gel filtration (GF) may be attributed to Porath and Flodin (1959), who realized the potential of the technique and were the first to report using it to desalt proteins. Their discovery provided the basis for a new separation technology that rapidly gained widespread acceptance owing to the commercial availability of a suitable cross-linked gel-filtration matrix—Sephadex—introduced in 1959. Remarkably enough, after 35 years this matrix is still one of the premier choices for desalting of proteins (see Table 8.3.1). The use of gel filtration for determination of molecular size of proteins was described later (Andrews, 1970). Gel filtration was also rapidly established as an important tool for

RCU IASI / CENTRAL UNIVERSITY LIBRARY

determining the molecular mass distribution of polymers in aqueous (Granath and Flodin, 1961) and organic solutions (Moore, 1964), for which suitable methods were lacking at that time. Moore used cross-linked polystyrene–based media for his application, naming the technique gel-permeation chromatography. Thus, within a few years after the discovery of gel filtration, applications of the technique basically covered the present range.

During the following years, the focus was directed on investigating the mechanism behind gel filtration. Theories suggesting that the separation was regulated exclusively by diffusion of molecules were soon replaced by the explanation, accepted today, that the process is driven by loss of conformational entropy when free permeation of the matrix by a solute is hindered by steric factors (Casassa, 1967). Of course, diffusion affects peak width and thus also the degree of separation, but diffusion does not influence the elution volume of a solute. The definite impact of steric exclusion on the separation has led to the proposal to rename the technique "steric exclusion chromatography" (ASTM, 1978), but this term has not gained wide acceptance. Another generic designation sometimes used in the literature is size-exclusion chromatography (SEC). It is important to realize that all of these designations refer to the same basic separation principle, which the majority of protein chemists refer to as gel filtration.

Development of gel-filtration media was focused for a long period on natural polymers or hydrophilic polymers. The late 1970s saw the introduction of silica-based materials, which combined rigidity and small particle size to enable fast gel filtration. A few years later, natural polymers of enhanced rigidity were introduced, which made it possible to pack columns with matrices of 10-μm bead size. To distinguish these media from the traditional type, the designation of high-performance size-exclusion chromatography (HPSEC) was introduced. However, it has been recently pointed out that the advantage of HPSEC media lies not in performance (i.e., traditional media packed in long columns may have equal or even better resolving capacity) but in speed of operation (Hagel, 1992). In addition, none of these materials have the outstanding selectivity shown by some of the traditional matrices (e.g., Sephadex and Bio-Gel P). Therefore, development of matrices for gel filtration has now been directed toward increasing their selectivity, which is done by decreasing the apparent width of the pore-size distribution of the matrix. Development is also geared toward tailoring the apparent pore size of matrices for the separation of molecules in specific interesting areas of application (e.g., for polishing of recombinant peptides). Recently, some of these modern media have become available for separation of peptides and proteins of moderate size (Hagel, 1993).

Even though the theoretical framework for the separation mechanism in gel filtration is well understood, there are still some uncertainties as to which molecular size estimate the elution volume reflects (Dubin et al., 1990). It is generally agreed that Stokes radius is a poor measure of molecular size, especially if different types of molecules are being studied. The hydrodynamic volume seems to be a general size parameter for polymers, globular proteins, and DNA of a certain length (Potschka, 1987). It appears that more work needs to be done to resolve this fundamental issue.

Until recently, development of instrumentation for gel filtration has been modest. High-precision pumps and automated systems for injection, fraction collection, and calculation were introduced more than a decade ago. New equipment and technology being introduced includes multiple-angle laser light scattering (MALLS) detectors and in-line viscosity detectors, which provide information about the shape and size of molecules, and electrospray ionization mass spectrometry (ESI-MS), which has the power to provide in-line detection of molecular mass. ESI-MS combined with high-resolution gel-filtration columns provides a very powerful system for characterizing protein dimensions. Molecular size of solutes may also be determined with an in-line light-scattering or viscosity detector combined with a concentration-sensitive detector. It is now possible to obtain the exact molecular mass of small-to-medium-sized proteins by connecting an in-line mass spectrometer to the GF column. The advantages of using a mass-sensitive detector are that the system does not need to be calibrated, fluctuations in flow rate are not detrimental, and solute-matrix interactions or solute-solute interactions will not affect the molecular mass obtained. In this case, the column acts as a high-resolution separating device to resolve the sample components prior to determination of molecular mass by mass spectrometry.

BOULDER COLORADO UNIVERSITY LIBRARY

Critical Parameters

Optimization and scaleup of desalting

Optimization of desalting starts with selection of a matrix of suitable exclusion limit with maximum pore volume and proper particle size. The bed volume is dictated by the sample volume to be purified. The actual elution procedure to be used depends upon the dispersion of the chromatography system, which in turn is related to the particle size and the column length. The particle size will influence the pressure drop over the column; this may be a limiting factor determining the maximum possible flow rate, the maximum column length, and the possibility of scaling up to columns of large diameters (i.e., the pressure specification is often reduced for columns of large diameter). However, in this case the column length can be traded off for an increase in column diameter to keep the bed volume high (also see Strategic Planning, Selecting Matrix and Column for Desalting).

To maximize the sample volume that can be applied to a column

A gel matrix should be selected from which the protein is excluded (see Strategic Planning) and in which the contaminants are eluted close to the total liquid volume (See Basic Protocol 1). It should also have a small matrix volume.

The maximum sample volume that can be applied to a column is directly related to the pore volume of the packed bed (V_i). The pore volume is proportional to the geometric column volume. As a rule of thumb, the maximum sample volume that may be applied for desalting is 25% to 40% of the bed volume for the materials listed in Table 8.3.1. The lower figure applies to small columns (e.g., <10-ml bed volume) and the higher figure to large columns (e.g., 100-ml bed volume). After the bed length is determined on basis of the acceptable pressure drop (which is proportional to the bed length), the sample capacity is maximized by increasing the diameter of the column. This is done because the applicable volume is directly proportional to the cross-sectional area of the column. Limitations in applicable column length may be eliminated by using columns in series ("stacked columns").

The maximum volume that theoretically can be applied for desalting is equal to the separating volume of the system, which is calculated by subtracting the void volume from the total volume (see Basic Protocol 1 for steps to determine these quantities). To account for extra zone broadening effects, it is generally advisable to apply not more than 80% of the separating volume or even less—e.g., 50%—for small columns in which eddy dispersion (see discussion below) will contribute proportionally more to the zone broadening.

To optimize the yield of desalting

Sampling of the protein fraction must be adjusted according to the zone broadening of the sample (i.e., the width of the protein zone). For a well-packed column with a plate height (see Basic Protocol 2) roughly equal to two particle diameters, this parameter may be estimated as the sample volume plus the dispersion of the zone that occurs through different pathways in the packed bed—i.e., eddy dispersion. The peak width (w_b) is described by Equation 8.3.1, where V_t is the total liquid volume of the column, d_p is the particle size of the matrix, and L is the length of the packed bed. Thus, for a 5-ml NAP-5 column (0.9 × 2.8–cm bed dimensions) packed with Sephadex G-25 medium-particle matrix, which has a particle size of 175 µm, eddy dispersion adds ~0.6 ml to the sample volume. This is roughly equal to the maximum sample volume (i.e., the separation volume; see Basic Protocol 1) and thus the eluted fraction is twice the sample volume. However, for a much larger 4 × 85–cm column packed with Sephadex G-25 coarse-particle matrix, which has an estimated particle size of 300 µm, the eddy dispersion adds ~100 ml to the originally applied sample volume of 400 ml, giving a protein zone of 500 ml (see Fig. 8.3.3). If G-25 medium-particle matrix were used, the smaller particle size would in this case theoretically decrease the protein zone from 500 to 475 ml, at the expense of a pressure drop over the column three times higher than with the coarser medium.

$$w_b = 4(V_t)\left(\frac{2d_p}{L}\right)^{\frac{1}{2}}$$

Equation 8.3.1

To minimize the time of the separation

Use the highest possible flow rate for the desalting step. High flow rates are suitable for desalting because eddy dispersion effects are rather insensitive to flow rate. The limiting factors on the flow rate are the rigidity of the matrix and the pressure limitations of the system used. Because media with small pore volume are generally more rigid than those with

RCU IASI CENTRAL UNIVERSITY LIBRARY

large pore volume, the disadvantage of a smaller separating volume may be offset by increasing the applicable flow rate to keep productivity high when working with the former type of medium. Incomplete removal of fine particles from the medium prior to packing may reduce the flow rate of the column after use as a result of partial blockage of the outlet filter. Operating the column with the flow direction reversed may help to increase the applicable flow rate in such situations.

The total process time for repetitive runs to desalt large volumes may be further minimized by utilizing the dead time of the void fraction. To do this, samples are added, not after total liquid volume + sample volume + eddy dispersion volume, but after subtracting the void volume from the total process volume (i.e., the next sample is added before the salt peak of the previous sample has emerged). The saving in time may be in the range of 20% to 30%, but this practice can only be recommended for well-understood processes.

$$R_s = \frac{1}{4}\log_{10}\left(\frac{M_{r1}}{M_{r2}}\right) b \left[\frac{1}{\left(\frac{V_o}{V_i + K_D}\right)}\right] \left(\frac{L}{H}\right)^{\frac{1}{2}}$$

Equation 8.3.2

Optimization and scaleup of protein fractionation

There are two basic ways to optimize the resolution of a separation. One is to increase the peak-to-peak distance and the other is to decrease the peak widths. The resolution for gel filtration is described by Equation 8.3.2, where M_{r1} and M_{r2} are the molecular masses of the two sample components being separated, b is the slope of the selectivity curve ($dV_r/d\log M_r$), V_o is the void volume of the column, V_i is the pore volume of the bed, L the bed height and H the plate height of the column (i.e., the term $L/H = N$, the plate number). The impact of these parameters will be described below.

To increase the peak-to-peak distance

1. A matrix of high selectivity (see *UNIT 8.1*) should be chosen. The most important factor for optimizing protein fractionation is selectivity, which is the inherent ability of the matrix to resolve proteins of similar size. This factor is a function of the pore-size distribution of the matrix. Selectivity is often illustrated by a plot of the elution volumes of a series of reference substances versus the logarithm of the molecular size or molecular mass of those substances. A function of the elution volume (e.g., the distribution coefficient; see Basic Protocol 3) may be substituted for the elution volume in constructing a selectivity curve. The steeper the selectivity curve (i.e., the greater the absolute value of the slope b, defined above), the better the resolvability of proteins differing in size. The selectivity of different gels can be judged from the fractionation range stated by the manufacturer. Gels with a small fractionation range (in terms of $\log M_r$) will generally have higher selectivity than gels with a large fractionation range.

2. A gel of high pore volume should be selected. The pore volume of a matrix is often related to the particle size. Smaller particles need to resist a higher friction force from the high flow rates that are used with matrices of smaller bead size; therefore the matrix volume is generally larger and pore volume smaller when using these matrices. A traditional soft-gel matrix may have up to 98% pore volume whereas rigid matrices such as silica may have as low a pore volume as 52% (of the bead volume).

3. A column of sufficient length (L) should be selected. The resolution between peaks is proportional to the square root of the column length. The column length chosen for protein fractionation is usually optimized with respect to the particle size of the matrix—i.e., a 100-cm column is often chosen where the particle size is 100 μm, a 60-cm column where the bead size is 30 μm, and a 30-cm column where the bead size is 10 μm.

To decrease peak width

1. A material that yields a small void volume (V_o) should be selected. Reducing the void volume will decrease the dispersion of the protein band (as will minimization of all extra column dead volumes). Irregularly shaped or rigid particles generally yield beds with larger void volumes than spherical, nonrigid beads.

2. A material of small particle size should be used as this will affect the plate height (H; also see Basic Protocol 3). Zone broadening of proteins within a column is directly proportional to the square of the particle size. Therefore, smaller particles will yield smaller peak widths unless very large sample volumes are applied or large system effects are causing dispersion of zones.

3. The separation should be run at optimum

BOSTON UNIVERSITY LIBRARY

flow rate, as this will affect the plate height (H; see Basic Protocol 3). Zone broadening is caused by dispersion within the void volume of the chromatographic bed, or by nonequilibrium effects that occur in the separation process itself when the mobile-phase velocity in the extraparticle space is too high as compared with the diffusivities of the proteins and the diffusion distances in the matrix. Flow rates that will allow minimum zone broadening and complete equilibrium will in most cases be impractically low. Table 8.3.7 lists practical flow rates for different solute molecular weights and matrix particle sizes, which represent compromises with regard to these parameters.

Dissolving the sample

Care must be taken to assure that the sample is completely dissolved in the GF buffer. Conditions must be chosen so that spontaneously formed aggregates are dissolved and that aggregates that are to be removed are not dissolved merely to reaggregate in the fraction tube. Because gel filtration permits rather free choice of pH, ionic strength, and additives, it is generally not difficult to find suitable conditions.

Solute-matrix interactions

Solute-matrix interactions are generally to be avoided. Even though mixed-mode separations (i.e., separations on the basis of both molecular size and the solute-matrix interaction) have sometimes given good resolution, one must be concerned about the reproducibility of such mechanisms. Solute-matrix interactions may be specific or nonspecific, and the chemical basis may be an ionic or hydrophobic interaction. In the case of specific solute-matrix interactions, the only thing to do is to change the matrix to one based on a different chemistry. Ionic interaction can be suppressed by addition of an electrolyte; hydrophobic interaction can be reduced by adding an organic modifier (e.g., methanol, acetonitrile, or isopropanol) or by reducing the ionic strength of the buffer. Of course, avoidance of solute-matrix interactions is a prerequisite for estimating molecular size using a calibrated column (see Basic Protocol 3 and Support Protocol). Solute-matrix interactions can be uncovered by varying the composition of the mobile phase or temperature and noting the effect. Because ideal gel filtration is driven by entropy, temperature should not affect the elution volume of proteins (unless the temperature change affects protein size, which is a different issue).

Column maintenance

Column life is drastically reduced by introduction of air into the column, deposition of material on the bed surface, and use of flow rates that exceed the maximum flow rate. To protect valuable columns from air it is advisable to use an air trap, to degas the buffer, or to use a deaerator. Deposition of material is minimized by filtering both sample and buffer through a 0.22-μm filter prior to application. Exceeding the maximum flow rate or pressure (e.g., by failing to compensate for viscosity effects at low temperatures) will result in the bed being compressed. This may be avoided by using a flow or pressure sensor to shut down the pump if the limit is exceeded. To maintain the calibration of a column for molecular size determinations (see Basic Protocol 3 and Support Protocol), the flow through the column should never be turned off completely, but may be reduced (e.g., to 1/10) and the effluent recycled to the buffer reservoir through a filter. The buffer should be treated with preservatives and must be discarded when the column is put back in service. According to the author's experience, the lifetime of a column may be expected to exceed several years and calibration may remain valid for up to 1 year if the appropriate precautions are taken.

A parameter that reflects the possibility of bed compression is the void fraction—i.e., the void volume divided by the bed volume. This parameter is 0.26 for beds made up of tetrahedral, closely packed spheres and 0.40 for beds made up of randomly packed spheres. Experimentally determined void fractions vary from 0.30 to 0.47 because of the surface and packing properties of the matrix and the particle shape. Void fractions <0.30 may indicate compression of beads.

Flow rate

Flow rate must be carefully controlled, especially if the column is used for characterization of molecular size as in Basic Protocol 3. The actual flow rate of a pump seldom agrees with the nominal flow rate, so it is essential that the flow rate be checked regularly.

Troubleshooting

Gel filtration is a comparatively uncomplicated separation technique and troubleshooting is straightforward. Provided that the critical aspects of the technique (see Critical Parame-

BCU IASI - BIBLIOTECA UNIVERSITARĂ

ters) are kept under control, gel filtration can be expected to be relatively trouble-free. Problems that may arise most frequently are compression of the bed and consequent decrease in flow rate, air bubbles in the column, tailing or leading peaks, and peaks that elute in the "wrong place."

Bed compression and decreased flow rate

Compression of the bed most likely results from the maximum flow rate being exceeded during packing (see Critical Parameters). It may also arise from excessive packing of the column, which creates an inhomogeneously packed bed with a denser layer in the lower part of the column that will eventually collapse even at a moderate flow rate. A column found to have a compressed bed must be repacked.

Compression may also result from partial clogging of the inlet filter and the upper part of the bed. To save the column in such a case, the adaptor should be removed, the filter cleaned, contaminated upper matrix removed, the upper part of the bed swirled, and the bed restabilized (see Basic Protocol 1, step 11). If the column still does not perform as expected, it must be repacked.

Decrease in the flow rate often accompanies compression of the bed. If the gel contains fines, these may block parts of the outlet net, causing a decrease in flow rate. Reversing the direction of flow may restore normal conditions. If this is not successful, the column should be repacked after exhaustive decantation of fines (see Basic Protocol 1, steps 3a and 2b).

Air bubbles in column

Small air bubbles in the column may be due to failure to deaerate the buffer or to the introduction of bubbles during sample injection. Moving the column from a cold room directly to a warmer laboratory will also release air bubbles in the column and should not be done. An attempt may be made to remove the bubbles by pumping deaerated buffer through the column in the reverse direction. Heating the buffer slightly is sometimes successful, as the temperatures of the buffer and gel will equilibrate, allowing the warmer buffer to dissolve some air. This may have to be done at least overnight and perhaps for several days to be fully successful. A large air pocket situated right under the adaptor that has not been taken up by the buffer may be removed using the procedures for readjusting the adaptor to the bed surface (see Basic Protocol 1, step 11).

Tailing and leading peaks

Tailing peaks indicate a large dead volume somewhere in the system, solute-matrix interactions, or a bed that is packed too loosely. To check the system for extra dead volumes, another column or a dummy column of small volume should be packed and a sample run to see if the problem reproduces itself. If it does not, the problem can be attributed to the column, and a sample of a different substance should then be run to ensure that the effect is not caused by solute-matrix interactions. If the tailing probem is still noted, the defect probably lies in the column packing, and an attempt should be made to stabilize the bed at a higher flow rate (see Basic Protocol 1, step 11). If this does not help, the column should be repacked at a higher flow rate. Before doing this, however, it should first be ascertained that the tailing is really seen with the sample to be run under the actual conditions under which it is to be run. Slight tailing of a small solute may be negligible when compared to a large diffusion-regulated zone broadening of a protein. Tailing may also be caused by partial separation of a small amount of a solute of slightly smaller size or slightly different surface properties.

Leading (fronting) peaks indicate solute-matrix interactions or cracks in the bed. Solute-matrix interactions (e.g., ionic-exclusion effects) are detected by running a different substance and/or using a different buffer. If the problem is related to the column packing (i.e., cracks in the bed), the column must be repacked at a lower flow rate. As with tailing peaks, however, the actual sample should first be run under the actual conditions to be used to determine whether the effect of fronting on the separation is serious. Fronting may also be caused by partial separation of a small amount of slightly larger contaminant.

Peaks that elute in the wrong place

Peaks that elute prior to the void volume indicate ionic-exclusion effects. To suppress these effects, the ionic strength of the GF buffer should be increased. Solutes that elute after the total liquid volume indicate adsorptive effects. These may be masked by adding an organic modifier or by increasing or decreasing the ionic strength of the buffer (see Critical Parameters for discussion of solute-matrix effects).

Anticipated Results

The results from gel filtration are in general very predictable. Guidelines for optimization

PROPERTY OF CONTRA COSTA COUNTY LIBRARY

and scaleup are presented in Hagel et al. (1989) and Hagel and Janson (1992).

Time Considerations

Gel filtration using media of small particle size may generally be carried out in half an hour. Gel filtration using traditional larger-particle matrices are typically run for 5 hr.

Preparation (i.e., swelling) of the gel will take 3 hr to overnight, depending on the procedure chosen. Packing of the column takes 1 to 4 hr, and the subsequent stabilization of the packed bed takes 1 hr. Thus, a column is typically prepared in a day, and testing of the packing quality is carried out overnight.

Hydrophobic-Interaction Chromatography

There are many separation techniques available to the modern chromatographer, all of which exploit either the physicochemical or biological properties of the target molecule. Chromatographic techniques are generally divided into two broad categories—nonadsorptive and adsorptive—based on whether or not the target molecule interacts with the chromatographic matrix. The major nonadsorptive method is gel-filtration chromatography (*UNIT 8.3*), which separates molecules on the basis of size. Gel filtration is essentially a sieving technique; the molecules being fractionated do not adsorb to or interact with the matrix. All other chromatographic methods—ion-exchange chromatography (*UNIT 8.2*); affinity methods (Chapter 9), including metal-chelate affinity chromatography (MCAC); reversed- and normal-phase chromatography; and hydrophobic-interaction chromatography (HIC; the subject of this unit)—are adsorptive techniques. The basis for separation in adsorptive techniques is the existence of varying degrees of interaction between the chromatographic matrix and the molecules to be resolved.

Hydrophobic-interaction chromatography is used to separate proteins on the basis of the differing strengths of hydrophobic interaction between the proteins and a matrix containing immobilized hydrophobic groups. All proteins are to an extent hydrophobic. Most proteins contain some quantity of the hydrophobic amino acids (i.e., those with nonpolar R groups—alanine, phenylalanine, valine, tryptophan, leucine, isoleucine, and methionine). These amino acids are generally considered to be buried within the protein molecule as a result of the aqueous environment. However, because of folding constraints, some nonpolar amino acids are found on the surface of the molecule as distinct hydrophobic patches. These patches of hydrophobicity are most likely important in the maintenance of protein structure, and thus in determining the biological function of the molecule. The number of such hydrophobic patches and their degree of hydrophobicity is characteristic of a particular protein. The variation in relative hydrophobicity from one protein species to another makes it possible to selectively adsorb and elute proteins to and from a suitable hydrophobic matrix.

Application of HIC involves loading a protein mixture onto a matrix containing hydrophobic ligands in a high-salt environment, then eluting the proteins by decreasing the salt in the environment (e.g., using a descending salt gradient) or by some other method of adjusting the polarity of the water phase (e.g., by adding nonionic detergents or organic solvents).

HIC is often used in the early stages of a separation scheme, especially after a protein precipitation step carried out in the presence of salt, because the binding conditions used in HIC involve high salt concentrations. Elution conditions for HIC involve low salt concentrations; therefore the eluate from an HIC step is ready, in most cases, for application to an ion-exchange column, where binding occurs at low salt concentrations. For this reason, HIC and IEC are often used one after the other in purification strategies. Because binding of the target molecule to an HIC matrix is facilitated by high salt concentration, rather than by organic solvents as in reversed-phase chromatography, HIC is a mild technique that does not destroy the biological activity of the target molecule. HIC, IEC, and gel filtration are useful techniques to consider when developing a purification strategy for labile molecules whose biological activity would be affected by other separation methods.

The Strategic Planning section discusses the important parameters in designing and optimizing a separation by HIC, including preparing the sample and choosing a matrix, column, and buffer. Protocols are provided for packing and testing a column (see Basic

Protocol 1 and Basic Protocol 2 and Alternate Protocol); determining binding and elution conditions (see Support Protocol 1); eluting the sample (see Basic Protocol 3); and cleaning, regenerating, and storing HIC columns (see Support Protocol 2).

STRATEGIC PLANNING

The parameters to consider when selecting a matrix for hydrophobic-interaction chromatography (HIC) and optimizing a separation based upon hydrophobic interactions are: (1) ligand type and degree of substitution of the ligand in the matrix, (2) composition of the matrix support, (3) type and concentration of salt used in the buffer, and (4) pH, temperature, and additives used for the buffer. Table 8.4.1 lists some commercially available media for HIC. The most appropriate matrix will be one that allows the greatest amount of contaminant material to pass through the column during sample loading and initial rinsing. If scale-up is planned for the separation, the cost of items such as buffer additives and waste disposal should be considered for optimum process economy; for economic reasons the most appropriate matrix in such cases will also be one that allows use of the lowest concentration of salt in the binding buffer.

Table 8.4.1 Representative Matrices for Hydrophobic-Interaction Chromatography

Matrix	Matrix support composition	Supplier[a]
45 to 165–μm bead diameter (for capture and intermediate purification)		
Butyl Sepharose 4 Fast Flow	Agarose	PB
Phenyl Sepharose 6 Fast Flow	Agarose	PB
Octyl Sepharose 4 Fast Flow	Agarose	PB
Methyl Macro-Prep	Methacrylate	BR
t-Butyl Macro-Prep	Methacrylate	BR
Bio-Beads SM2, 4, 16, 7	Polystyrene divinylbenzene	BR
Toyopearl butyl	Methacrylate	TH
Toyopearl phenyl	Methacrylate	TH
30 to 50–μm bead diameter (for intermediate and polishing)		
Phenyl Sepharose High Performance	Agarose	PB
Bio-Beads SM	PS/DVB	BR
Toyopearl ether	Methacrylate	TH
Toyopearl butyl	Methacrylate	TH
Toyopearl phenyl	Methacrylate	TH
TSK ether 5-PW	Silica	TH
TSK phenyl 5-PW	Silica	TH
10 to 30–μm bead diameter (for polishing and analytical applications)		
Phenyl Superose	Agarose	PB
Alkyl (neopentyl) Superose	Agarose	PB
Toyopearl ether	Methacrylate	TH
Toyopearl butyl	Methacrylate	TH
Toyopearl phenyl	Methacrylate	TH
TSK ether 5-PW	Silica	TH
TSK phenyl 5-PW	Silica	TH

FCU IASI / CENTRAL UNIVERSITY LIBRARY

If the matrix does not seem to work at all at first, it should be tested again at a later stage in the purification scheme. It is valuable to perform a number of empirical screenings and pilot experiments (see Support Protocol 1) at each step in the purification before establishing a complete multistep separation scheme. Each of these experiments should test several different matrices. See *UNIT 8.1* for discussion of strategies in developing an overall separation scheme.

Ligand Type and Degree of Substitution

The type of immobilized ligand determines the selectivity of the HIC matrix. Generally, two types of ligand are used in HIC—alkyl-chain ligands of various lengths and the aryl (usually phenyl) ligand. Alkyl-chain ligands show true hydrophobic character. At constant ligand-substitution levels, the protein-binding capacities of HIC matrices increase with increasing alkyl-chain length—i.e., with increasing hydrophobicity. Matrices containing the aryl ligand demonstrate a type of mixed aromatic and hydrophobic interaction, because the phenyl ring has the potential for π-π interactions.

The protein-binding capacity of the matrix will increase with increasing degrees of substitution of the immobilized ligand. However, at very high levels of ligand substitution the apparent binding capacity of a matrix will reach a plateau, although the strength of binding will continue to increase in proportion to the degree of substitution. Thus, proteins bound to highly substituted matrices will be difficult to elute. It is worth noting that binding of the surface of a protein to an immobilized HIC ligand is a multipoint attachment, although the attachment between a peptide and an immobilized ligand is a single-point interaction.

Composition of Base Matrix

The support (base matrix) upon which the ligand is immobilized contributes to the selectivity of the HIC medium. The two most common base matrices in use for HIC are 4% and 6% cross-linked agarose, which are strongly hydrophilic carbohydrates, and the synthetic copolymer materials. The selectivity of an agarose-based matrix and a polymer-based matrix substituted with the same ligand will be different. It is possible to achieve the same results using either type of support, but only if the the adsorption and elution conditions are modified appropriately.

It is important to realize when evaluating matrices for HIC that a number of coupling chemistries can be used to attach the alkyl or aryl ligand to the base matrix. For HIC, a matrix should be employed that is prepared with a coupling chemistry in which no charge is imparted to the point of attachment between the base matrix and the hydrophobic ligand. Charge-neutral matrices are often prepared using ether coupling between the base matrix and the hydrophobic ligand. Ligands attached via cyanogen bromide chemistry will be charged, and should be avoided for true HIC.

A third consideration relative to the base matrix is the particle size. The smaller the particle, the higher the resolution achieved in the separation. Matrices with particle sizes ≤34 μm are considered high-resolution media. *UNIT 8.3* contains good discussion and references on the relationship between particle size and resolution. The practical drawback to using high-resolution media for all applications is that the pressure drop across a column bed is inversely proportional to the square of the matrix particle size. Thus, if larger columns (e.g., with bed heights >30 cm) are packed using a 34-μm matrix and the same pump, the back-pressure will increase, the flow rate will decrease, and the time required to achieve the separation will increase. Another complication is the contribution to pressure drop from the viscosity of the sample feed stream and wash buffers used in HIC, which often have a high salt content and are therefore more viscous than water at room

BOURNEMOUTH UNIVERSITY LIBRARY

temperature. Use of a gel matrix with particle size ≥90 µm allows use of reasonably high flow rates at lower back-pressures (e.g., 400 cm/hr at 1 bar). If two HIC steps are used in a separation scheme, it is practical to use a 90-µm matrix early in the purification, and a 34-µm matrix towards the end.

Choosing a Column, Pump, Detector, and Other System Components

Like most adsorptive techniques, HIC is carried out in short columns. A typical HIC column is packed to a bed height between 5 and 15 cm, but the bed height may be as long as 30 cm. Scale-up of an optimized separation is done by increasing column diameter while keeping the bed height constant. Wide columns (with an internal diameter between 1.6 and 5.0 cm) are appropriate for HIC. To achieve the appropriate bed height, it is helpful if the column is equipped with one or two flow adaptors.

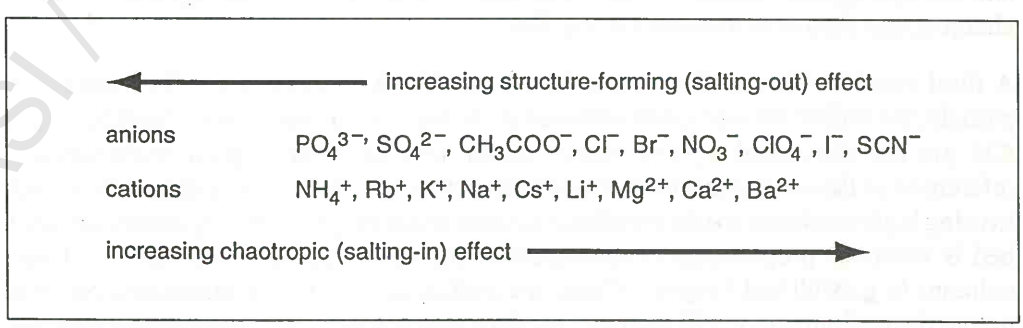
A pump should be chosen that is capable of delivering the appropriate flow rate required for HIC, typically between 100 and 600 cm/hr. Because of the high-salt buffers used, peristaltic or syringe pumps are recommended, rather than any type of pump with a ball-check valve. If a pump with a check valve must be used, care must be taken to ensure that no salt crystallizes in the valve seat.

A detector capable of absorbance measurements at 280 nm is used to detect the protein peak in HIC. A chart recorder and fraction collector are recommended.

Type and Concentration of Salt in Buffer

The interaction between the immobilized ligand and the protein is facilitated by the addition of one of the various salting-out salts (i.e., "structure-forming" salts that increase precipitation of hydrophobic compounds; see Fig. 8.4.1) to the equilibration buffer and sample. As the concentration of salt is increased for a particular sample, the amount of protein bound to the immobilized ligand also increases, almost linearly, up to a specific salt concentration. The proteins are then eluted from the column by decreasing the salt concentration, in either a step or continuous descending gradient (see Basic Protocol 3).

The effect of salts in hydrophobic interaction can be accounted for by reference to the well-known Hofmeister (lyophilic-lyophobic) series of anions and cations. Figure 8.4.1 reproduces the Hofmeister series for some anions and cations in terms of the degree to which they promote or inhibit protein precipitation. The most commonly used salts for HIC buffers are Na_2SO_4, NaCl, and $(NH_4)_2SO_4$, all of which have a high salting-out (structure-forming) effect as seen in Figure 8.4.1. Salts can also be listed in order of their effect on the surface tension of water. For more detailed discussion of the Hofmeister



increasing structure-forming (salting-out) effect
anions
PO_4^{3-}, SO_4^{2-}, CH_3COO^-, Cl^-, Br^-, NO_3^-, ClO_4^-, I^-, SCN^-
cations
NH_4^+, Rb^+, K^+, Na^+, Cs^+, Li^+, Mg^{2+}, Ca^{2+}, Ba^{2+}
increasing chaotropic (salting-in) effect

Figure 8.4.1 The Hofmeister series illustrating the effects of some anions and cations in promoting protein precipitation. Ions with a higher salting-out effect promote binding to hydrophobic interaction chromatography matrices, whereas ions with a higher salting-in effect promote elution from those matrices.

ECU IAST / CENTRAL UNIVERSITY LIBRARY

series, see Melander and Horvath (1977); for more detail on surface-tension salts, see Srinivasan and Ruckenstein (1980), Franks (1988), and Hodder et al. (1989).

Effect of Buffer pH

In published accounts of hydrophobic-interaction chromatography, pH is shown to be an important separation parameter. Generally, as the pH is increased, hydrophobic interaction is decreased. It is possible that increased titration of the charged groups that occurs with increased pH results in a protein that is more hydrophilic. A decrease in pH tends to increase hydrophobic interaction. Thus, proteins that do not bind to a hydrophobic-interaction matrix at neutral pH do bind at acidic pH. It is advisable to check the binding of the protein of interest at several pH values in the course of optimizing a HIC separation.

Effect of Temperature

On the basis of the hypothesis that interaction between hydrophobic moieties on the protein surface and the immobilized hydrophobic ligand is entropy-driven (see Background Information), one would expect that the interaction should increase with increasing temperature. Experimental evidence to this effect has been presented (Hjerten, 1977), but the role of temperature in HIC is evidently complex, because the opposite results have also been observed (Visser and Strating, 1975). The practical importance of this is that one must be aware that a process developed at room temperature may not be reproducible in the cold room (and vice versa).

Elution of Proteins

Elution of compounds bound to an immobilized hydrophobic ligand can be achieved in one of three ways: (1) by a linear or stepwise decrease in the concentration of salt, (2) by addition of some proportion of organic solvent to the elution buffer, or (3) by addition of neutral detergents to the elution buffer.

The most common way to desorb the proteins from the HIC support is to reduce the salt concentration of the buffer (see discussion above under Type and Concentration of Salt in Buffer), or to use water alone as an eluant. An alternative elution scheme for desorption of the bound protein may exploit the fact that low concentrations of water-miscible alcohols, detergents, and salting-in salts (i.e., chaotropic salts that decrease precipitation of hydrophobic compounds; see Fig. 8.4.1) result in the weakening of the protein-ligand interaction. The nonpolar regions of the alcohols or detergents compete with the bound protein for the hydrophobic ligand, resulting in displacement of the protein. Salting-in salts disrupt the structure of the water, decrease the surface tension, and thereby weaken the hydrophobic interaction. These compounds can be used in the elution scheme to affect selectivity during desorption, but there is a risk that the protein will be denatured or inactivated after exposure to them. Detergents can be effective for cleaning HIC media that have very strongly hydrophobic proteins bound to them (see Support Protocol 2).

Preparation of High-Salt Buffers

As discussed above under Type and Concentration of Salt in Buffer, the binding of a protein to an HIC medium is facilitated by high salt concentrations. The sample should thus be in high salt prior to application to the HIC column. This can be done by direct dilution in high-salt solution or by buffer exchange through gel filtration (see *UNIT 8.3*). Before deciding to use gel filtration, it is necessary to ensure that none of the sample components precipitate in the high-salt buffer. This can be done in a small test tube by adding an aliquot of the high-salt buffer to the sample and checking for flocculation.

BRANDEIS UNIVERSITY LIBRARY

As the use of ammonium sulfate in buffers for HIC is very common, preparation of such buffers requires some comment. Because ammonium sulfate can be contaminated with heavy metals, iron in particular, the best grade available (usually called enzyme grade) should be used. For the same reason it may be necessary to include micromolar amounts of EDTA in HIC buffers containing ammonium sulfate. Preparation of a saturated solution takes several hours; therefore it is best to prepare the solution a day before chromatography is to be attempted. Concentrations of ammonium sulfate are expressed in terms of molarity or percent saturation. For use in a saturation table, the sample can be considered to be 0% saturated or 0 M salt.

Scopes (1994) presents two equations for calculating ammonium sulfate concentration. Also useful are the salting-out tables found in general biochemistry references including Segel (1976), which is aimed at students, and Englard (1990). Before buffer preparation, it is important to take into account that addition of ammonium sulfate to water causes an increase in volume; e.g., 761 g of ammonium sulfate is added to one liter of water to make a saturated solution, resulting in a final volume of ~1.5 liters. If the water is heated to between 70°C and 80°C, the ammonium sulfate will go into solution faster (in 30 min to 1 hr). If the solution is heated, it should be cooled before use—e.g., overnight in a refrigerator. In a saturated solution there will be crystals of ammonium sulfate in the bottom of the flask. The pH of a saturated ammonium sulfate solution is ~5; it can be adjusted with concentrated ammonium hydroxide. The aliquot of solution to be used should first be filtered through filter paper. Saturated ammonium sulfate solution may be stored several weeks at 4°C.

NOTE: All glassware used in hydrophobic-interaction chromatography should be clean. Spills of highly concentrated salt solutions should be cleaned up immediately, especially if the salt splashes onto instruments.

BASIC PROTOCOL 1

PACKING A COLUMN WITH AN HIC MATRIX OF ≥90-µm BEADS

This protocol describes preparation and degassing of the HIC gel medium and packing of the column. After these procedures are completed, a packed column will be ready for testing (Basic Protocol 2) and sample application. This protocol and that for high-resolution media (see Alternate Protocol) are generally applicable to all bulk carbohydrate-based media, and can be skipped if a prepacked column is to be used. If non-carbohydrate-based media are to be used, consult the manufacturer's literature for packing instructions.

Materials

Appropriate HIC matrix with bead size ≥90 µm (see Strategic Planning and Support Protocol 1)
Packing solution: distilled H_2O or low-ionic-strength buffer (e.g., 20 mM sodium phosphate, pH 7.0)
20% (v/v) ethanol

Chromatography column with flow adaptors (see Strategic Planning)
Sintered-glass funnel (medium or coarse grade)
Carpenter's level
Pump (see Strategic Planning)

1. Equilibrate all materials to the temperature at which chromatography will be performed.

2a. *To wash the HIC matrix by decantation:* Allow gel to settle, decant off the preservative solution, and add an excess of packing solution. Repeat wash several times.

ECU IASI CENTRAL UNIVERSITY LIBRARY

2b. *To wash the HIC matrix by filtration:* Pour the gel into a sintered-glass funnel attached to a suction flask and vacuum line and allow the preservative solution to filter off. Release the suction, resuspend the gel in an excess of packing solution, and restore the suction to filter off the packing solution. Repeat wash several times.

Gels are shipped in a preservative solution—usually 20% ethanol or a dilute thimerosal or sodium azide solution.

Washing by filtration is a faster method than washing by settling and decantation. A sintered-glass filter must be used, not filter paper in a Buchner funnel.

3. Prepare a slurry consisting of 70% washed, settled gel in packing solution.

The packing solution (water or dilute buffer) provides a low-viscosity liquid phase for packing the gel in the column.

4. Degas the gel slurry 3 to 5 min under vacuum with swirling.

A water aspirator pulls enough vacuum for this degassing.

5. Mount column vertically. Flush the end pieces of the column with 20% ethanol, then flush with packing solution to replace the ethanol. Close outlet, leaving a few centimeters of packing solution in the bottom of the column.

6. Pour the gel slurry into the column with one motion, avoiding introduction of air bubbles.

Pouring the slurry down a glass rod held up against the side of the column wall will minimize the introduction of air into the slurry. In the absence of a glass rod, pouring the gel down the column wall will have the same effect.

7. Immediately fill the remainder of the column with packing solution, mount the top adaptor, and connect the column to the pump. Use a carpenter's level to check that the column is vertical.

It is not necessary to push the adaptor down into the gel at this point, but it is convenient to move it into the column ~1 cm above the settled gel to minimize the need for adjustment after the matrix is packed.

8. Fill the buffer reservoir with packing solution. Open the bottom of the column and set the pump to run at the desired flow rate. Continue passing the packing solution through the column until a constant bed height is reached, then pass an additional 3 bed volumes of solution through at the same flow rate.

Different flow rates are recommended by manufacturers for different gel matrices—e.g., Sepharose 6 Fast Flow matrices are packed at a flow rate of 500 cm/hr, and Sepharose 4 Fast Flow gels at a flow rate of 400 cm/hr. Ideally, these two media should also be packed at constant pressure: 1.5 bar for Sepharose 6 Fast Flow and 1.0 bar for Sepharose 4 Fast Flow. However, constant-pressure packing requires a pressure gauge in the chromatography system and this is not always available. If the recommended flow rate cannot be achieved, the gel should be packed at the maximum flow rate that the pump can deliver.

IMPORTANT NOTE: *Do not exceed 70% to 75% of the packing flow rate in subsequent chromatographic procedures, because if the separation is run at a flow rate approaching that used for packing, there is a risk that the column will continue to pack during sample application and elution, leading to distorted peaks and non-reproducible elution patterns.*

9. Mark the level of the packed bed on the column tube. Close the outlet of the column, then stop the pump. Disconnect the inlet tubing from the pump. Adjust the adaptor to the top of the gel medium and lower it 3 mm below the mark on the column tube. Tighten the adaptor and reconnect the inlet tubing to the pump.

The column is now ready to use in a separation. For examples of protein purifications done by HIC, see Background Information.

BOSTON UNIVERSITY LIBRARY

ALTERNATE PROTOCOL

PACKING A COLUMN WITH AN HIC MATRIX OF ≤34-µm BEADS

This protocol describes the variations in packing procedure for high-resolution HIC matrices. Carry out Basic Protocol 1 with the following additional materials and alternate procedures at the indicated steps.

Additional Materials (also see Basic Protocol 1)

Appropriate HIC matrix with bead size ≤34 µm (see Strategic Planning and Support Protocol 1)
Tween 20
Chromatography column rated at 5 bar, with flow adaptors (see Strategic Planning)
Pressure gauge

3a. Add 250 µl (one drop) Tween 20 per 500 ml of gel slurry.

Tween 20 will decrease the surface tension within the gel solution, making the slurry more homogeneous and easier to swirl and degas.

7a. Pack the column at a flow rate of 30 cm/hr until the bed reaches a constant height (or at least 20 min). Shut off the pump, then lower the adaptor to ~1 cm above the settled gel bed. Turn on the pump and increase the flow rate until a pressure of 5.0 bar is reached. Continue packing at this pressure for 30 to 60 min.

After the high-resolution gel is packed, some resistance may be encountered from the packed bed when attempting to push the adaptor down 3 mm into the bed (see Basic Protocol 1, step 9). It is nevertheless important to do this before using the column in a separation.

BASIC PROTOCOL 2

TESTING THE PACKED BED

Testing the packed column is easy, and is recommended for two reasons. First, it is better to find out whether or not the column is properly packed before the sample is applied. It is not unusual for someone who has never packed a column before to try two or three times before succeeding. Second, testing column performance with a tracer before the sample is applied and the column used and regenerated provides a baseline for comparison after a number of runs. Often, the theoretical plate number and/or asymmetry factor, determined as described below, can be used to predict column failure. Thus, it is recommended that the packed column be tested before it is used and then again before each additional use (or before every other use, or on some other regular schedule). To test a packed column, a low-molecular-weight test substance that has no interaction with the matrix is injected into the column. The number of theoretical plates (N) or the height equivalent to a theoretical plate (H, sometimes called HETP) is then calculated from the elution volume of the test substance. The asymmetry factor (A_s) is also calculated. The small molecular weight assures that the test substance has access to the entire chromatographic bed. 1% (v/v) acetone can be used as a test substance. The acetone sample is applied just as though it were any other chromatographic sample. The sample volume used for this test should be small: 2% of the column volume for 90-µm packings or 0.5% of the column volume for 34-µm packings. However, for evaluating column packing it is appropriate to minimize the volume between the injection point and the detector; thus, short lengths of tubing should be used in the chromatography system for the evaluation step even if longer lengths will be used for the chromatography of an unknown sample later on. The flow rates used for evaluation of the column should be kept low to minimize the zone broadening (*UNIT 8.1*) at the front and rear of the zones. For columns packed with 90-µm matrices, the flow rate should be 15 to 30 cm/hr; for columns packed with 34-µm matrices, the flow rate should be 30 to 60 cm/hr.

ECU IAS/CENTRAL UNIVERSITY LIBRARY

Because acetone absorbs at 280 nm, it is not necessary to change the wavelength setting on the detector to test the packed bed. However, it will be necessary to change the sensitivity of the detector to keep the peak on-scale so that the peak apex can be seen. The variables N, H, and A_s should not be calculated from a peak that has gone off-scale.

The following standard chromatographic equations are used to calculate the number of theoretical plates (N; also see discussion of column efficiency in *UNIT 8.1*) and then to calculate plate height (H):

$$N = 5.54(V_e/W_h)^2$$

and finally $H = L/N$

where V_e is the volume eluted from the start of sample application to the peak maximum, W_h is the peak width measured at half peak height (as traced by the recorder), and L is the length of the packed bed.

Because the plate count (N) is dimensionless, the measurement of V_e and W_h can be taken in distance on the chart paper (mm) or volume of eluant (ml). The units used should be the most convenient for the investigator, but both V_e and W_h should be expressed in the same units for a given calculation. Figure 8.4.2 shows a chromatogram with V_e and W_h marked.

As a general rule, a good value for H is about two to three times the mean bead diameter of the gel being packed. Thus, a good H value for a 90-µm matrix is between 0.018 and 0.027 cm and a good H value for the 34-µm matrix is between 0.0070 and 0.010 cm.

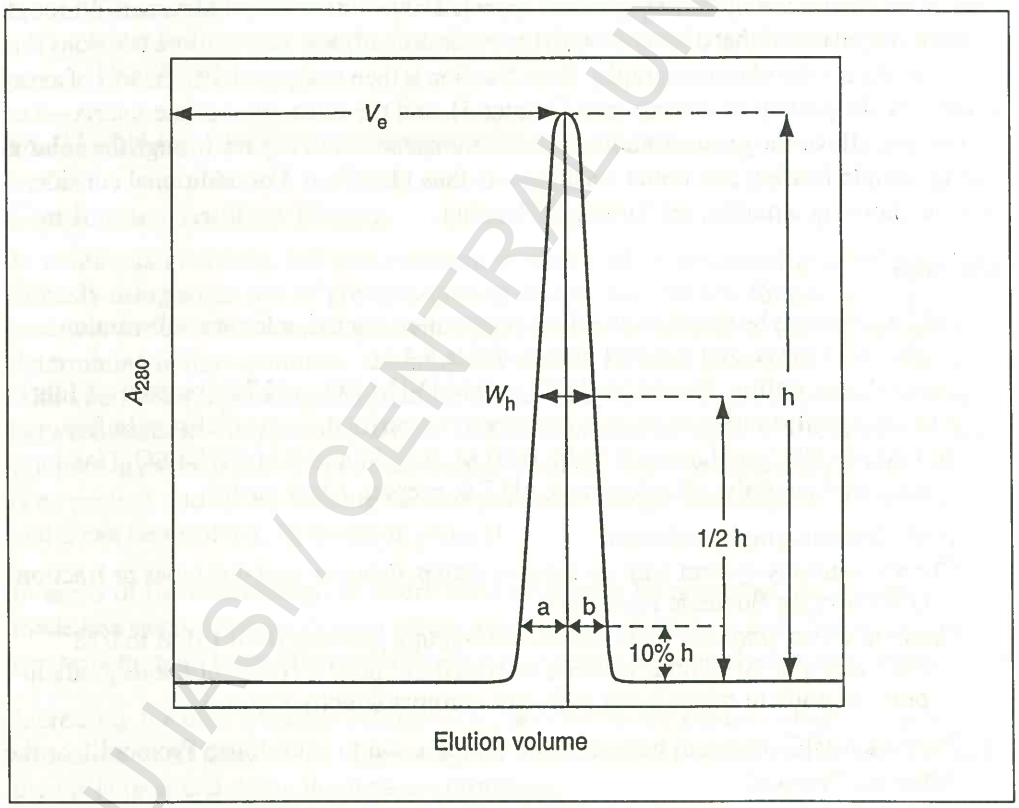


Figure 8.4.2 Chromatogram illustrating parameters used in calculating plate number and asymmetry factor for a column. V_e is the elution volume for the protein whose peak is depicted, h is the height of that peak, W_h is the width of the protein peak at half the peak height, *a* is the width of the leading portion of the peak at 10% of the peak height, and *b* is the width of the tailing portion of the peak at 10% of the peak height.

B.C.U. „M. Eminescu" IASI
CHIMIE
U IASI / CENTRAL UNIVERSITY LIBRARY

Another standard chromatographic data analysis procedure for testing a packed bed is calculation of the asymmetry factor A_s. On the same peak used to measure H on the chart recording, a line is drawn from the peak maximum to the baseline, dividing the peak in two parts lengthwise. Asymmetry is calculated simply by the equation:

$$A_s = b/a$$

where a is the width of the front (leading) portion of the peak measured at 10% peak height and b is the width of the back (tailing) portion of the peak measured at 10% peak height. The chromatogram in Figure 8.4.2 depicts the quantities a and b graphically.

A_s should be as close as possible to 1, but a reasonable value for a short-bed HIC column is between 0.80 and 1.80. An extensive leading edge on a peak ($A_s < 0.80$) is usually an indication the column is packed too tightly, and an extensive trailing edge ($A_s > 1.80$) is an indication the column is packed too loosely. These problems can be solved by repacking the column.

SUPPORT PROTOCOL 1

PILOT EXPERIMENT TO CHOOSE A MATRIX AND DETERMINE BINDING AND ELUTION CONDITIONS FOR HIC

This protocol describes an experiment to identify the appropriate HIC matrix and initial salt concention to bind and elute a target molecule. This experiment is done with very small columns and consumes very little sample. A small quantity of the sample solution dissolved in a high-salt start buffer is applied to several different columns, each packed with a different HIC matrix. Elution is then carried out using a either a descending continuous gradient or a descending step gradient of salt concentration (see Basic Protocol 3 for more discussion of the two gradient types). The results will include a wash-through fraction (i.e, material that did not bind to the column at all) and one or more fractions that will elute during the chromatography. Each fraction is then analyzed by some sort of assay to identify the protein of interest (see Chapter 3), and the most appropriate matrix—i.e., the one that allows the greatest amount of contaminant material to pass through the column during sample loading and initial washing—is thus identified. For additional considerations in choosing a matrix, see Strategic Planning.

Materials

HIC matrices to be tested (e.g., a low-substitution phenyl, a higher-substitution phenyl, a butyl, and an octyl matrix; Table 8.4.1)
General start buffer: 50 mM Na_2HPO_4/1.0 M $(NH_4)_2SO_4$, pH 7.0 (prepare ~1 liter)
5 to 10 mg/ml solution of protein mixture to be purified, in general start buffer
50 mM Na_2HPO_4containing 0.75 M, 0.50 M, 0.25 M and 0 M $(NH_4)_2SO_4$ (for step gradient only; all solutions at pH 7.0; prepare 1 liter each)

1-ml chromatography columns
Chromatography system with syringes or pump, detector, and test tubes or fraction collector (see Strategic Planning)
Gradient mixer (*UNIT 8.2*) set to deliver descending gradient from 1.0 M to 0 M $(NH_4)_2SO_4$ in 10 column volumes of Na_2HPO_4, pH 7.0 (for continuous gradient only; if gradient mixer is not built into chromatography system)

1. Pack each HIC matrix to be tested into a 1-ml column as in Basic Protocol 1 or the Alternate Protocol.

2. Equilibrate each column with at least 10 column volumes of general start buffer.

   The flow rate for equilibration can be fast—e.g., 1 column volume/min. See Critical Parameters for guidelines on column equilibration.

PCU IASI CENTRAL UNIVERSITY LIBRARY

3. Apply 1 ml of protein solution to be purified in start buffer to each column. Perform initial washes in start buffer, and monitor the eluant using a detection scheme appropriate to the protein of interest.

   A slower flow rate is recommended for sample application and elution than for equilibration—e.g., 0.25 column volumes/min.

4. Elute the sample using either a gradient mixer set to deliver a descending gradient from 1.0 M to 0 M $(NH_4)_2SO_4$ in 10 column volumes of Na_2HPO_4, pH 7.0 *or* a step gradient of 10 column volumes each of 0.75 M, 0.50 M, 0.25 M, and 0 M $(NH_4)_2SO_4$ in 50 mM Na_2HPO_4, pH 7.0. Continue to monitor the eluant and construct a chromatogram.

   See Critical Parameters and Troubleshooting for guidelines on interpreting chromatograms obtained from this pilot experiment and for optimizing chromatography conditions.

   The most appropriate matrix is the one that allows the greatest amount of contaminant material to pass through the column during sample application and initial washing. If the protein of interest elutes during sample application or initial washing with start buffer, repeat the procedure with the same gel matrix but increase the salt concentration of the start buffer. Alternatively, more hydrophobic matrices may be investigated. The purification of the protein should be evaluated even where elution occurs in the initial wash, because a considerable amount of contaminating material may be bound to the HIC media and hence removed.

   If the protein of interest does not elute until a 0 M salt concentration has been reached, the salt concentration of the start buffer may be decreased from 1.0 M $(NH_4)_2SO_4$ (e.g., to 0.25 M). Elution may then be done using 50 mM Na_2HPO_4, pH 7.0, or water alone. If the activity of the protein of interest is adversely affected by low salt concentrations, a less hydrophobic matrix that allows elution at a higher salt concentration may be investigated.

ELUTION OF PROTEINS FROM HIC COLUMNS

BASIC PROTOCOL 3

Continuous-Gradient Elution

In continous gradients, salt concentration is increased or decreased gradually and continously using some sort of gradient-mixing device (see *UNIT 8.2*). Simple linear gradients (see *UNIT 8.2* for definitions of gradient types) are the first choice in pilot experiments for determining initial conditions (see Support Protocol 1). After more experience is obtained with a particular separation, the gradient can be made more complex to optimize resolution between specific sample components. This is illustrated in Figure 8.4.3, where the linear gradient in panel A shows very poor resolution of the first two components in the mixture (i.e., peaks 1 and 2). By making the first portion of the gradient slope less steep, peaks 1 and 2 can be resolved, as shown in panel B.

In areas of the chromatogram where resolution must be improved, the gradient can be made less steep, whereas in areas where resolution is adequate or not critical, the gradient can remain more steep. The general effect of gradient slope is illustrated in Figure 8.4.4.

Increasing the total gradient volume—i.e., decreasing the gradient slope—will improve resolution in all parts of the chromatogram. The drawback to this is that it will increase the cycle time and dilute the separated fractions.

BCU ASTON CENTRAL UNIVERSITY LIBRARY

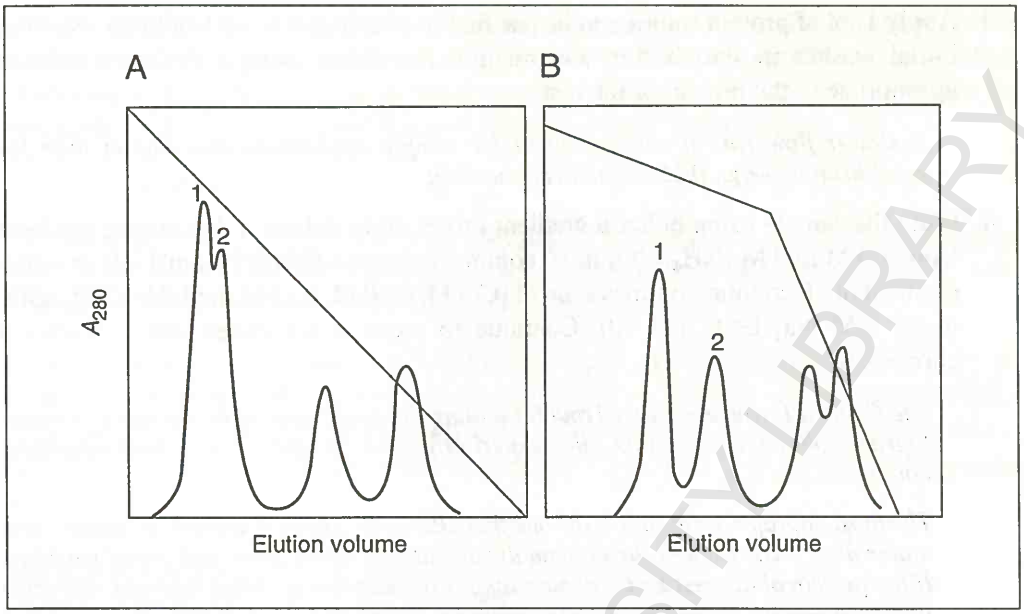

Figure 8.4.3 Chromatograms illustrating use of complex gradient elution to improve resolution. (**A**) A simple linear gradient gives poor resolution of protein peaks 1 and 2. (**B**) A complex gradient where the gradient slope is less steep in the region of peaks 1 and 2 gives better resolution of these two components.

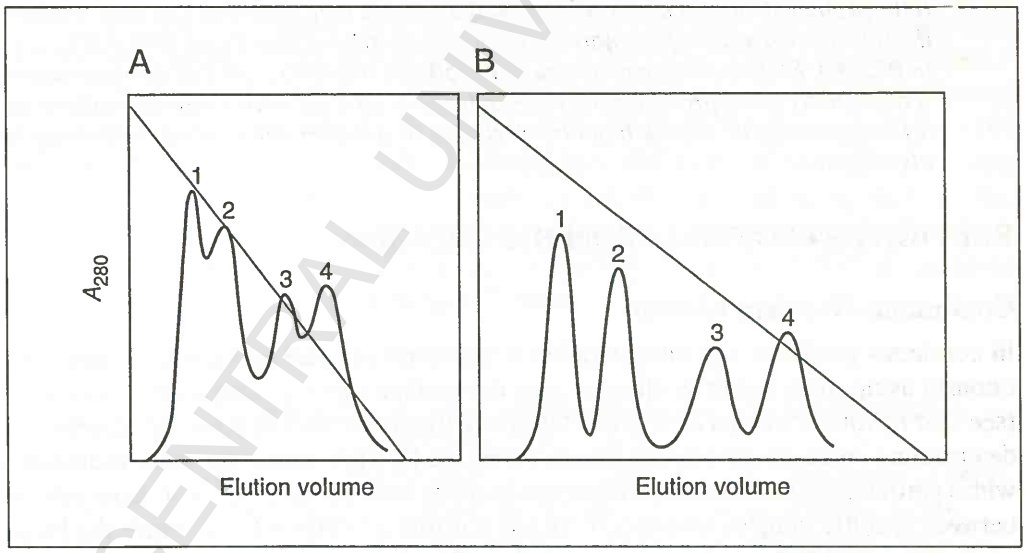

Figure 8.4.4 Chromatograms illustrating the general effect of a change in gradient slope on peak resolution. (**A**) A steep slope gives poor resolution among the four sample components. (**B**) A less steep slope gives better resolution (though the total elution volume is higher, meaning that the eluted sample components will be more dilute and that more buffer is needed for the elution).

Step-Gradient Elution

In step-gradient elution, one or more solutions of a particular discrete concentration are passed through a column. The principle of stepwise elution is to provide maximum resolution in the area of the gradient where the protein of interest elutes. Stepwise elution is preferred for large-scale preparative applications because it is technically simpler and more reproducible than continous-gradient elution. It is also advantageous in small-scale applications because the compound of interest can be eluted in a more concentrated form, provided there is no coelution of a more strongly bound compound. When stepwise elution is used, one must watch out for artifact peaks that can appear if the next step is started too

PCU IASI CENTRAL UNIVERSITY LIBRARY

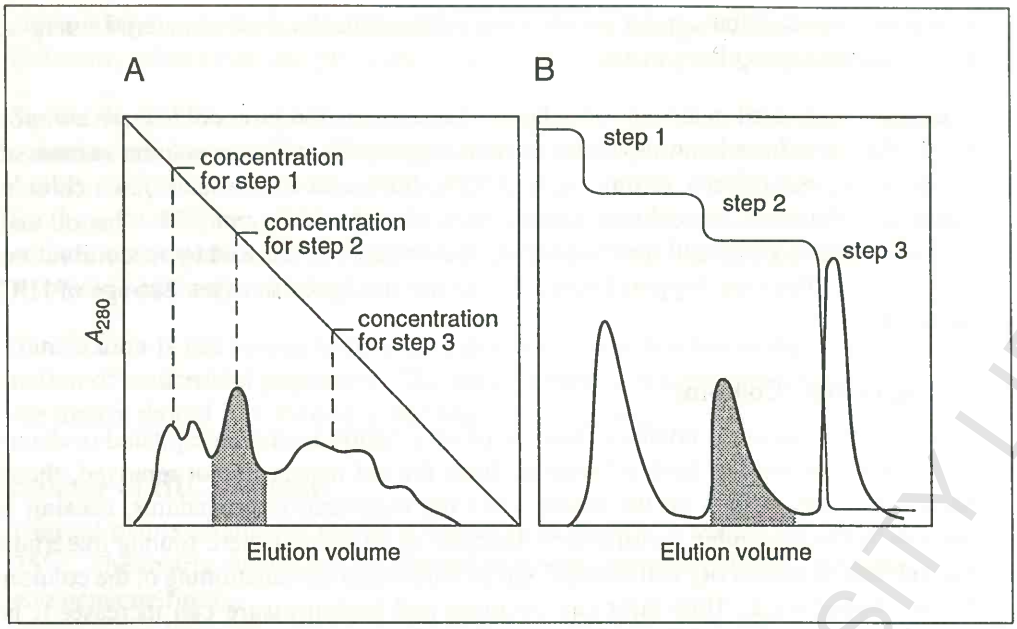

Figure 8.4.5 Chromatograms illustrating use of the results of linear-gradient elution to devise a step-gradient elution scheme. The shaded area represents the target protein peak. (**A**) Elution by linear gradient yields poor resolution among sample components. However, it is possible to note the salt concentration at the points on the gradient where the peaks for the loosely bound contaminants, target protein, and tightly bound contaminants emerge. (**B**) Step-gradient elution with three discrete solutions prepared on the basis of the elution salt concentrations noted in panel A. The target protein peak and the two contaminant peaks are sharply resolved.

early—i.e., during a trailing peak. It is recommended that a stepwise elution scheme be developed after several continuous gradient schemes have been run to characterize sample behavior on the matrix. This development should include three stages. In the first stage a continuous gradient is optimized to elute all the compounds that bind to the gel less tightly than the protein of interest. The elution strength and gradient volume should be high enough to elute all weakly binding contaminants but not high enough to elute the protein of interest. In the second stage the elution strength is increased so that the protein of interest elutes with minimal dilution, but more tightly bound contaminants are not eluting. In the third step the elution strength is increased to elute the most tightly bound contaminants. Once these three regions of the chromatogram are identified, these gradient positions are converted to steps (i.e., solutions representing the concentration of eluant at these points in the chromatogram are prepared and used for step elution). Figure 8.4.5 illustrates this process of switching from a continuous to a step gradient.

REGENERATION, CLEANING, AND STORAGE OF HIC COLUMNS

SUPPORT PROTOCOL 2

Regeneration of HIC Columns

After each use, the matrix must be regenerated to restore its original functionality. There are two general regeneration procedures for HIC columns. The first is to simply wash the column with several column volumes of distilled water (Milli-Q purified or equivalent). The second is to wash the columns with at least two column volumes of 6 M urea or 6 M guanidine hydrochloride and then at least 10 column volumes of start buffer (see Support Protocol 1) or storage solution (see Storage of HIC columns, below). The first procedure is sufficient if the buildup of tightly bound protein contaminants is minimal; the second procedure is recommended for more tightly bound contaminants. Deciding which to use

BOWLING GREEN STATE UNIVERSITY LIBRARY

is situation-dependent, but a quick screen using each, noting if a peak of material emerges, can indicate the appropriate choice.

If detergents were used in the elution scheme, the regeneration protocol is more complicated. In this case the column should be washed sequentially with one column volume of distilled water; one column volume each of 25%, 50%, and 95% ethanol; two column volumes of *n*-butanol; one column volume each of 95%, 50%, and 25% ethanol, and finally one column volume of distilled water. This should be followed by reequilibration with the start buffer (see Support Protocol 1) or the storage buffer (see Storage of HIC columns, below).

Cleaning of HIC Columns

Cleaning of HIC columns involves removal of very tightly bound precipitated or denatured proteins, as well as lipid substances, from the gel matrix. If not removed, these contaminants may remain on the matrix after the regeneration procedures, causing a decline in chromatographic performance. Because of buildup of these fouling materials on the gel, matrix selectivity will change, and in some cases the functioning of the column will also change—e.g., flow rates can decrease and back-pressure can increase. It is preferable to clean the matrix while it is still in the column, a practice referred to as "cleaning in place," so that the column does not have to be unpacked, repacked, and tested again. There is no single recommended protocol for cleaning in place; the procedure must be designed with some knowledge of the contaminants present in the feed stream. In general, however, NaOH is a very effective cleaning agent that can be used for solubilizing both denatured and precipitated protein and lipids.

Removal of precipitated proteins

To remove precipitated proteins, a general recommendation is to wash the column with four column volumes of 0.5 to 1.0 N NaOH at a slow flow rate (e.g., 40 cm/hr), then with two to three column volumes of water. After the water wash, the column can be equilibrated with the start buffer (see Support Protocol 1) or put into the storage buffer (see Storage of HIC Columns, below).

Removal of tightly bound proteins and lipids

There are two general recommendations for the removal of strongly bound hydrophobic proteins, lipids, and lipoproteins. The first is to wash the column with four to ten column volumes of ethanol, starting with 30% ethanol and working up to 70%, then with six to ten column volumes of distilled water (Milli-Q purified or equivalent; this should reduce the alcohol content of the eluate to between 10 and 1 ppm). The 30% to 70% ethanol may be replaced with 30% isopropanol. The second procedure is to wash the gel matrix with one to two column volumes of a 0.5% solution of nonionic detergent (e.g., Triton X-100) in 1 M acetic acid, followed by five column volumes of 70% ethanol to remove the detergent. The ethanol is then washed out with six to ten column volumes of distilled water. After the water wash, the column can be equilibrated with the start buffer or put into the storage buffer.

Sanitization of HIC Columns

Sanitization is the inactivation of microbial populations in the gel matrix. NaOH is very effective for sanitizing the matrix in addition to functioning as a general cleaning reagent. A general sanitizing procedure for HIC columns is to expose the matrix to 0.5 to 1.0 N NaOH for 30 to 60 min. The column should then be washed with at least ten column volumes of start buffer (see Support Protocol 1) if it is to be used right away. The large volume of wash solution is required because a large pH adjustment is being made. If the

PCU IASI CENTRAL UNIVERSITY LIBRARY

column is going to be stored it should be washed with storage buffer (see Storage of HIC Columns, below) until the pH of the effluent equals the original pH of the storage buffer.

Sodium hydroxide is widely accepted as an agent for sanitizing chromatographic media, columns, and systems. For this purpose it is used at higher concentrations (e.g., 0.5 N to 1.0 N). At lower concentrations (e.g., 0.01 N) it is an effective bacteriostatic agent, and for the most common gram-negative contamination a good bactericidal effect is also seen at these concentrations. NaOH also destroys endotoxin on the column and is nontoxic as a contaminant in the end product.

Sanitization is not synonymous with sterilization, which refers to the destructive elimination of a microbial population. The manufacturer's recommendations for autoclaving the matrix should be followed if sterilization is required.

Storage of HIC Columns

Unused matrix should be stored in closed containers at a temperature between 4° and 25°C. The matrix should not be allowed to freeze as this will disrupt the bead structure and generate fines.

Used matrix should be stored in the presence of a suitable bacteriostatic agent—e.g., 0.01 N NaOH or 20% ethanol—at a temperature between 4° and 8°C. Used matrix should also be protected against freezing. Packed columns should be stored under the same conditions. For long-term storage, the matrix should be cleaned (see Cleaning of HIC Columns) before equilibration with the storage buffer. Recycling the storage solution or flushing the column with fresh storage solution at least once a week during long-term storage is an effective method for preventing bacterial growth.

Chromatography matrices from Pharmacia Biotech are supplied in 20% ethanol, and this solution can be used as an alternative to NaOH for storing columns. Other manufacturers ship media in other bacteriostatic solutions, which can also be used as alternative storage buffers.

Other bacteriostatic compounds can be added to the storage buffer, including 0.002% chlorhexidine (which can, however, cause precipitation of sulfate ions if mixed with a high-molarity salt such as that used in start buffers for HIC); 0.5% trichlorobutanol (effective in weakly acidic solutions only), 0.005% thimerosal (effective in weakly acidic solutions); 0.001% to 0.01% phenyl mercuric acetate, borate, or nitrate (effective in weakly alkaline solutions); and 0.02% to 0.05% sodium azide.

COMMENTARY

Background Information

Tiselius (1948) laid down the foundations of what today is called hydrophobic-interaction chromatography (HIC). Since then, a number of theories have been proposed to explain this type of chromatography, but no single one has gained universal acceptance. All of the explanations refer to the interactions of the structure-forming salts (see Strategic Planning, Type and Concentration of Salt in Buffer) and the effects that they exert on other solutes and solvents in a system. Porath (1986) posed a general explanation for HIC based upon salt-promoted adsorption. In an extension of earlier work in which the observations of Tiselius were extended and the behavior of hydrophobic molecules in solution were linked to thermodynamic theory (Porath, 1973), they concluded that the driving force of HIC is the gain in entropy arising from the structural changes in the water surrounding the interacting hydrophobic groups. Hjerten (1977) expressed this idea in terms of the thermodynamic relationship $\Delta G = \Delta H - T\Delta S$. The displacement of water molecules surrounding the hydrophobic ligands on the matrix and the hydrophobic amino acids on the surface of the protein leads to an increase in entropy (ΔS), because more water is returned

BOURNEMOUTH UNIVERSITY LIBRARY

to the bulk solution after a hydrophobic interaction occurs. This leads to a negative value for the ΔG of the system, which implies that hydrophobic interaction is thermodynamically favorable. This also implies that the entropy of water is the driving mechanism for hydrophobic interaction; thus, HIC is unique among the adsorptive separations in that it occurs as a result of its environment.

A second explanation for hydrophobic interaction was proposed by von der Haar (1976) and by Melander and Horvath (1977). According to these authors, hydrophobic interaction results from the increase in surface tension of water arising from dissolved structure-forming salts. A third explanation for hydrophobic interactions was proposed by Srinivasan and Ruckenstein (1980). This hypothesis proposes that hydrophobic interaction is a result of the increase in van der Waals attraction between the protein and the immobilized ligand that results from the increase in the ordered structure of water in the presence of structure-forming salts.

Elution by salt gradient

An example of elution by salt gradient was published by Lau et al. (1987) as part of the purification of acid phosphatase from bovine bones by HIC. The active fractions from previous steps were pooled in 100 mM sodium acetate buffer, pH 6.5, and adjusted to 30% saturation by adding solid ammonium sulfate at 4°C with gentle stirring for ≥2 hr. This enzyme solution was applied to a phenyl HIC column equilibrated with 30% ammonium sulfate in 100 mM sodium acetate buffer, pH 6.5. The chromatography was done at room temperature. The column was eluted with a descending salt gradient starting at 30% ammonium sulfate/100 mM sodium acetate, pH 6.5, and ending with 0% ammonium sulfate/100 mM sodium acetate, pH 6.5. The yield was 92% and the purification was 13-fold. This was the last step in a four-step purification protocol and the purity of the isolated enzyme was determined by SDS-PAGE.

HIC with gradient elution offers an alternative in monoclonal antibody purification, provided that the monoclonal antibody is stable in high salt. As most monoclonal antibody purifications start with an ammonium sulfate precipitation step, the antibody will normally be present either in a high salt–soluble fraction or as a precipitate that can be redissolved and applied to a HIC column. Monoclonal antibody samples containing albumin and transferrin are particularly suitable for HIC because the albumin and transferrin can be eluted as sharp peaks, minimizing contamination of the antibody. This was demonstrated by Sparrman et al. (1986), who used an alkyl Superose matrix. A clarified sample was equilibrated with 0.7 M ammonium sulfate by buffer exchange using gel-filtration chromatography. The column was then equilibrated with several bed volumes of the start buffer, 1.6 M ammonium sulfate. A linear gradient was produced by mixing buffer A (0.1 M phosphate, pH 7.0/2 M ammonium sulfate) and buffer B (0.1 M phosphate alone) starting at 20% buffer B and ending with 80% buffer B. The transferrin eluted at ~40% buffer B, and the albumin eluted at ~45% buffer B. The monoclonal IgG peak eluted at ~55% buffer B and was therefore sharply separated from the contaminating proteins.

Elution by detergents

Addition of detergents to the HIC column is one method for increasing the resolution of elution. However, some detergents can bind very strongly to HIC matrices and are difficult to wash out with common solvents such as ethanol. Detergents should be used with care. The mechanism of detergent action in HIC is that the nonpolar end of the detergent molecule competes with the hydrophobic patches on the protein for the hydrophobic group on the matrix.

An example of detergent elution was published by Hereld et al. (1986), describing the purification of phospholipase C from the protozoan *Trypanosoma brucei*. The enzyme was present in an ammonium sulfate cut prepared from the solubilized membranes of the protozoan. A phenyl column was equilibrated with 25 mM sodium succinate buffer (pH 6.0) containing ammonium sulfate at 50% saturation. The sample (already in ammonium sulfate) was applied to the column and eluted in a descending salt gradient starting with the 50% saturated ammonium sulfate in buffer A and ending with 0% salt (i.e., buffer only). The phospholipase was then eluted by application of buffer containing 1% CHAPS. Most of the protein eluted in a sharp peak immediately after application of the detergent, but there was some trailing in this elution. The yield was 62%, with a 22-fold purification.

Elution by polarity-reducing compounds

The addition of various polarity-reducing compounds to the buffer is another way to increase the resolving power of the elution

PCU IAS/CENTRAL UNIVERSITY LIBRARY

buffer. This can be done only if the protein of interest is stable upon exposure to the compound used. The reagents most commonly used for this purpose are 40% ethylene glycol or 30% isopropanol, dissolved in salt-free buffer. These are used to decrease the polarity of the eluent, resulting in a decrease in binding strength and thus elution of the bound protein from the column.

An example of this technique, using ethylene glycol to elute human pituitary prolactin, was published by Roos et al. (1979). The work was done in the cold, and started with whole organs that were homogenized and extracted at pH 9.8. Between 200 and 400 mg protein was applied to a phenyl column equilibrated with a buffer consisting of 0.2 M glycine adjusted to pH 9.8 with NaOH. Elution was carried out by stepwise reduction of the buffer concentration, first to 0.02 M glycine, pH 9.8, then to 0.002 M glycine, pH 9.8, with 50% (v/v) ethylene glycol added. The last buffer eluted the prolactin. Flow rate for this elution was ~5 cm/hr and the recovery was 95%.

HIC and protein polarity

It has been estimated by Klotz (1970) and Lee and Richards (1971) that 40% to 50% of the surface of a protein is nonpolar. These nonpolar areas are the areas on the protein responsible for binding the protein to hydrophobic matrices in the presence of moderate to high concentrations of salting-out salts. Various hydrophobicity scales for the amino acids have been published; Ericksson (1989) presents several of these in tabular form. There is also a relationship between this salt-promoted interaction with a HIC ligand and the precipitation data for proteins (Melander and Horvath, 1977).

HIC and other chromatographic techniques

HIC is complementary to the other adsorptive techniques, as well as gel filtration, in that it separates on the basis of a very different physicochemical property of the protein than these other methods and can therefore be used in conjunction with them to achieve more complete separation (see *UNIT 8.1*). The physicochemical property exploited by HIC is the presence or absence of the various hydrophobic amino acids in the protein, as distinguished from the property exploited by ion-exchange chromatography, which is the presence or absence of the various charged amino acids. HIC also distinguishes proteins according to the hydrophobic amino acids on the surface of the protein, not those buried inside the folded protein. This distinguishes HIC from reversed-phase chromatography, which also separates on the basis of hydrophobicity, but on the basis of the hydrophobicity of the denatured or unwound sequence. If there is reason to believe it should be possible to exploit the hydrophobicity of the surface of the protein of interest, or to exploit the hydrophobicity of the surface of the contaminants in the sample, then HIC should be included in a separation plan.

Critical Parameters and Troubleshooting

Because the fundamental operating principle of HIC is that hydrophobic interactions are facilitated by high-salt environments, an incomplete equilibration of either the sample or the matrix with the high-salt buffer will have a negative effect on results and reproducibility.

Sample equilibration

The sample must be completely dissolved in the start buffer. This can be done either by buffer exchange through gel-filtration chromatography (*UNIT 8.3*), dialysis (*APPENDIX 3B*), or membrane filtration. Sample solubility should be checked in each salt environment to which the sample will be exposed to during chromatography, to make sure that there will be no precipitation when changing from a high-salt to a no-salt environment.

Column equilibration

The column must be equilibrated in the high-salt environment at the correct pH for sample application. Many chromatographers try short-cuts during column equilibration only to find that they must repeat the run. It is common that at least 10 column volumes of buffer must pass through a column to equilibrate it. The column should be equilibrated at the temperature at which the chromatography will be run. Thus, a column run overnight in the cold room is not equilibrated for a run the next morning at room temperature.

Optimizing resolution

Panels A to F in Figure 8.4.6 show some typical results that may be obtained on different HIC matrices using the methodology of Support Protocol 1. The shaded section of each chromatogram indicates the protein of interest.

Target protein eluted early in the gradient; resolution not satisfactory (Fig. 8.4.6A).

Not much can be gained in this situation by changing the salt concentration of the equili-

PRIVATE/CENTRAL UNIVERSITY LIBRARY

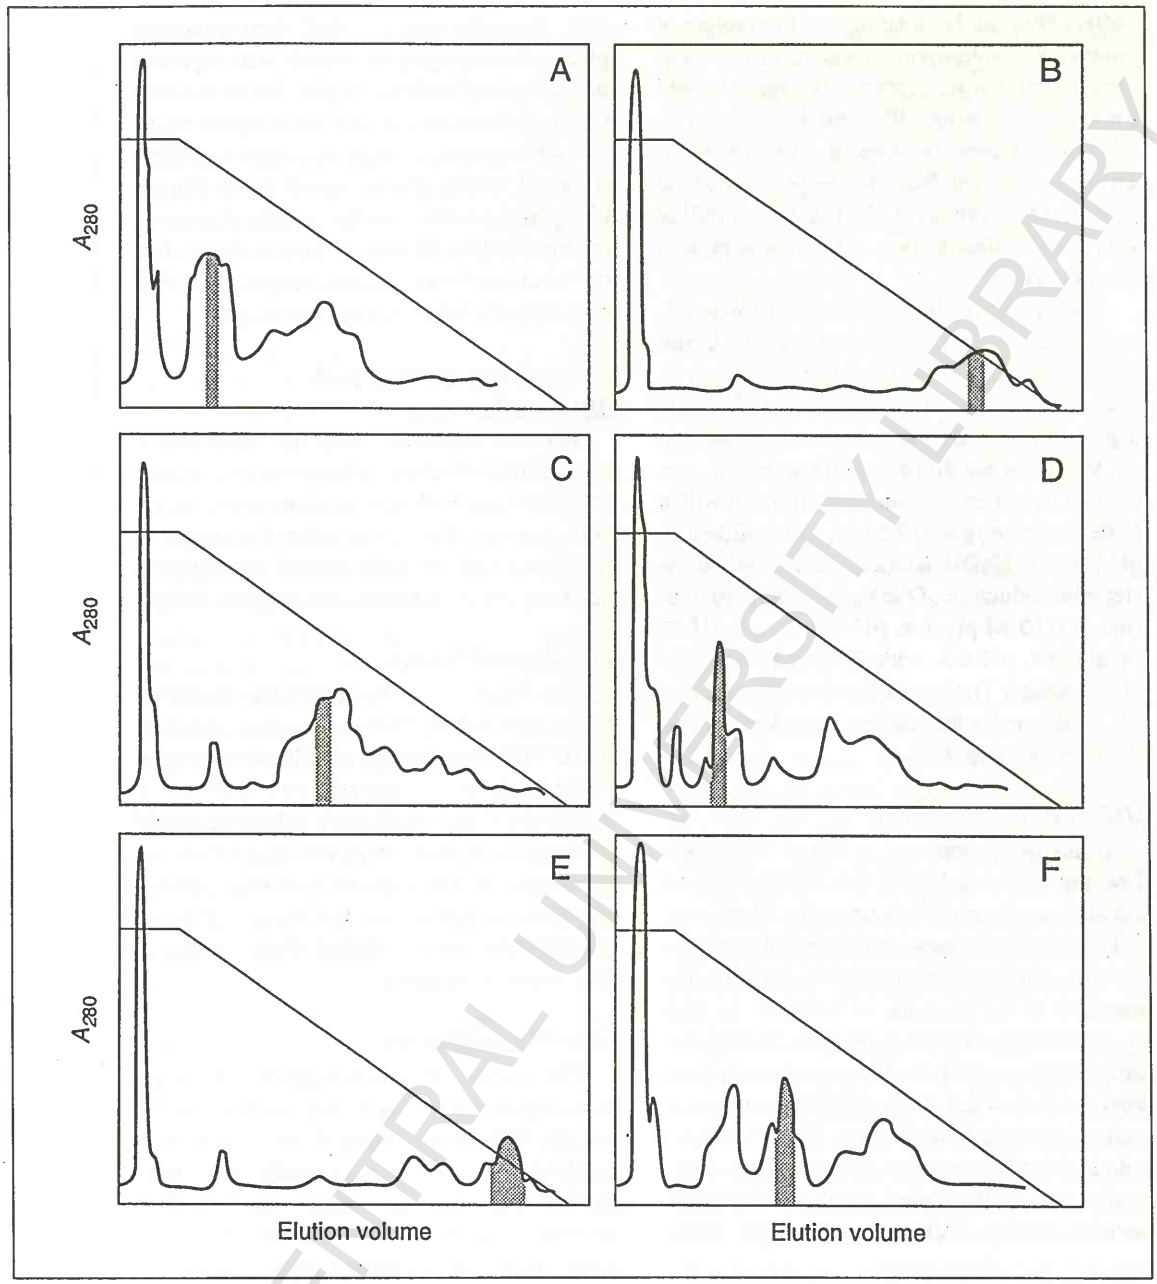

Figure 8.4.6 Chromatograms illustrating various optimal and suboptimal outcomes in HIC. (**A**) Target protein eluted early, resolution not satisfactory. (**B**) Target protein eluted late, resolution not satisfactory. (**C**) Target protein eluted in middle of gradient, resolution not satisfactory. (**D**) Target protein eluted early, resolution satisfactory. (**E**) Target protein eluted late, resolution satisfactory. (**F**) Target protein eluted in middle of gradient, resolution satisfactory (optimal results). These results and techniques for improving upon them are discussed in Critical Parameters and Troubleshooting.

bration buffer. Decreasing the salt concentration will decrease the binding capacity of the protein of interest and might even lead to its elution together with the unbound contaminant fraction. Increasing the salt concentration might lead to adsorption of unwanted impurities and a conseqent decrease in the selectivity of the matrix for the protein of interest.

Changing the pH of the equilibration buffer might result in a stronger binding and higher selectivity for the protein of interest. The effect of pH is variable for different proteins; usually lowering the pH leads to increased binding. Increasing the pH usually leads to a decreased binding of proteins, which in this particular case might result in the elution of the protein of interest together with the unbound fraction.

The appropriate next step in this case would be to try the experiment at a lower and higher

ACU IASTA CENTRAL UNIVERSITY LIBRARY

pH. If no improvement in selectivity is obtained, a matrix with a different ligand or (if available) the same ligand at a higher degree of ligand substitution should be tried.

Target protein eluted near the end of the gradient; resolution not satisfactory (Fig. 8.4.6B).

A decrease in buffer salt concentration will weaken the strength of binding, resulting in earlier elution of the protein of interest. A decrease in salt concentration may also have a positive effect on selectivity because a greater quantity of the less hydrophobic substances will be eluted with the unbound fraction. However, the effect of this approach on the resolution will be marginal, because the contaminants elute very close to the protein of interest—both before and after the target protein peak. Changing the pH of the equilibration buffer may have a positive effect on resolution and should be tried.

The appropriate next step in this separation would be to try the experiment at a lower and higher pH. If no improvement in resolution is obtained, a gel matrix with a different ligand or (if available) the same ligand at a lower degree of ligand substitution should be tried.

Target protein eluted in the middle of the gradient; resolution not satisfactory (Fig. 8.4.6C).

Changing the concentration of the salt in the equilibration buffer will have a limited effect on resolution. However, either an increase or decrease in the pH of the equilibration buffer might have a favorable effect. The appropriate next step in this experiment is to repeat the separation at a higher and lower pH. If no improvement is seen, a gel matrix with a different ligand or (if available) the same ligand at a higher degree of ligand substitution should be tried.

Target protein is eluted early in the gradient; resolution is satisfactory (Fig. 8.4.6D).

The separation shown in panel D is an example of a good choice of matrix for the protein of interest. However, the fact that the protein of interest is eluted very early in the gradient indicates that the binding capacity of the matrix may be low. This may be compensated for, if necessary, by a moderate increase of salt in the equilibration buffer. This may in turn result in a decrease in the selectivity of the adsorbent because some of the unbound proteins might be adsorbed together with the protein of interest. Another negative effect of increased salt concentration may be a decrease in resolution caused by an increase in gradient slope if the total gradient volume or the cycle time is kept constant. Increased salt concentration will also result in increased costs, which may be important in a manufacturing process. Not much can be gained here by changing the pH of the equilibration buffer, as the resolution obtained is satisfactory.

There is no need to try to improve on this separation unless the low binding capacity is a problem. If that is the case and the problems with increased salt concentration mentioned above are encountered, a matrix with a different ligand or (if available) the same ligand at a higher degree of ligand substitution should be tried.

Target protein of interest is eluted near the end of the gradient; resolution is satisfactory (Fig. 8.4.6E).

This also illustrates a good choice of matrix for the protein of interest. Decreasing the concentration of salt in the equilibration buffer will give earlier elution of the protein of interest, reduced cycle time, and decreased cost for salt. A problem in this situation might be that some of the most hydrophobic-contaminating substances are bound so strongly that an organic solvent or chaotropic agent has to be used to clean the column (see Support Protocol 2). Not much can be gained here by changing the pH, because the selectivity is good. If the very strong binding of hydrophobic contaminants poses a problem, a medium with a different ligand or (if available) the same ligand at a lower degree of ligand substitution should be tried.

Target protein elutes in the middle of the gradient; resolution is satisfactory (Fig. 8.4.6F).

The choice of ligand here is good and there is little risk of strong binding of the most hydrophobic contaminants. This panel illustrates an example of good results in hydrophobic-interaction chromatography.

The examples presented in Figure 8.4.6 do not consider two extreme cases that may arise—i.e., that in which the protein of interest is not bound to the column at all, and that in which the protein of interest binds so strongly that it is difficult to elute without the use of denaturing solvents. In both instances a different HIC medium or another chromatographic separation technique should be tried.

PURDUE UNIVERSITY LIBRARY

Although it is assumed for the sake of discussion that the resolution is not satisfactory in some of the chromatograms shown in Figure 8.4.6, the requirements for resolution in any chromatographic step must be stipulated on a case-by-case basis. What seems to be fairly poor resolution at an advanced stage of a separation can often be good enough at an initial capture step where the main objective of the separation is reduction of volume, removal of some critical contaminants, and preparation for further chromatography using a high-resolution matrix.

For more guidelines on troubleshooting chromatographic separations, the Troubleshooting section in *UNIT 8.2* may be consulted.

Anticipated Results

Hydrophobic-interaction chromatography (HIC) is intended for use as one of several chromatographic steps in a protein purification scheme. The product that elutes from a HIC column may not be chemically pure, as HIC will copurify proteins of similar hydrophobicity. Yields will be high (step yields of 60% to 90% are common), and because the conditions of HIC are nondenaturing, activity recovery will be high as well.

Time Considerations

Chromatography using prepacked HIC columns can be run in ~30 min to 4 hr. It will take ~8 hr to pack and equilibrate a column, then load and elute a sample. Cleaning, regeneration, and reequilibration can be carried out overnight. Samples can often be stored overnight in the high-salt start buffers, but the possibility of precipitation should be ruled out first.

Chromatofocusing

Chromatofocusing (CF) is a versatile, high-resolution chromatographic technique suitable for separating proteins on the basis of their isoelectric points. It may be used to purify proteins with isoelectric points in the range of 3 to 11. Proteins elute from a CF column in descending order of isoelectric point. The unique aspect of this technique is the formation of a descending linear pH gradient in situ by elution with a single buffer containing a large number of buffering species (i.e., the CF elution buffer described here, which contains polybuffer)—the same buffering system used in isoelectric focusing (*UNITS 10.2 & 10.4*). This methodology is in contrast to the mixing of a high- and low-pH buffer prior to the column—the technique used to form pH gradients for elution in ion-exchange chromatography (see *UNIT 8.2*).

The Strategic Planning section discusses choice of chromatofocusing medium and buffers, determination of the quantity of medium needed, and preparation of CF buffers. The Basic Protocol provides the procedure for a typical chromatofocusing experiment, Support Protocol 1 describes regeneration of the chromatofocusing column, and Support Protocol 2 presents several methods for separation of the polybuffer from the purified protein. A schematic representation of the steps in a CF experiment is provided in Figure 8.5.1.

STRATEGIC PLANNING

Selecting CF Medium and CF Buffers

The first step in selecting a medium, start buffer, and elution buffer for chromatofocusing (CF) is to determine the appropriate pH gradient range on the basis of the isoelectric point of the target protein. After the pH gradient range has been selected, Tables 8.5.1 and 8.5.2 may be used to select the appropriate CF gel medium and buffers. Finally, after the CF buffers and CF gel medium have been selected, Table 8.5.1 may be used to determine the amount of buffer required and Table 8.5.2 may be used to determine the amount of gel required for the application.

The CF media and buffers listed in Table 8.5.1 are designed to produce a gradient over a maximum interval of 3 pH units or a minimum of 1 pH unit. For initial experiments a pH gradient spanning 3 pH units should be used. Once the chromatographic behavior of the target protein is characterized, narrower gradients can be used to optimize resolution.

If the isoelectric point of the protein is known, the pH range of the CF experiment is chosen so that the target protein will elute after one-third to one-half of the pH gradient. For example, if the isoelectric point of the target is 6.2, a pH range of 4 to 7 or 5 to 8 can be chosen for initial experiments.

If the isoelectric point of the target protein is unknown, it may be determined by isoelectric focusing (*UNIT 10.2*) or by the test tube method for determining starting conditions for ion-exchange chromatography (*UNIT 8.2*). For an example of the latter method, see Figure 8.2.3, Panel A, where the isoelectric point of the protein is between 5.5 and 7.0. Alternatively, because most proteins have an isoelectric point in the range of 4 to 7 (Gianazza and Righetti, 1980), it is usually appropriate to simply select a pH gradient in that range for initial experiments.

Polybuffer 96 and Polybuffer 74 (Pharmacia Biotech) are amphoteric buffers designed for chromatofocusing in the ranges of pH 6 to pH 9 and pH 4 to pH 7, respectively. They contain a large number of buffering species to provide an even buffering capacity, and

choose appropriate CF medium and buffers according to pI of target protein (Strategic Planning and Table 8.5.1)
set up chromatography system (Basic Protocol, step 8)
equilibrate CF medium with CF start buffer and pack into column (Basic Protocol, steps 1-7)
adjust pH of CF start buffer to upper limit of pH gradient (Strategic Planning, Table 8.5.1, and Table 8.5.2)
purge chromatography system with CF start buffer (Basic Protocol, step 8)
attach CF column to system and test for equilibration (Basic Protocol, steps 9-10)
adjust pH of CF elution buffer to lower limit of pH gradient (Strategic Planning)
allow 5-10 ml CF elution buffer to run through CF column (Basic Protocol, step 12)
equilibrate sample with elution buffer if necessary (Basic Protocol, step 11)
apply sample to CF column and begin collecting fractions (Basic Protocol, step 12)
reequilibrate CF column with CF start buffer (Support Protocol 1)
develop pH gradient by elution with CF elution buffer (Basic Protocol, step 13)
regenerate gel (Support Protocol 1)
assay fractions and pool those containing the target protein (Basic Protocol, step 14)
remove polybuffer from protein, if necessary (Support Protocol 2)

Figure 8.5.1 Flow chart for a chromatofocusing experiment.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

are used together with the polybuffer exchange gel PBE 94 or the prepacked Mono P column (both available from Pharmacia Biotech). For chromatofocusing in the range pH 8 to 11, Pharmalyte pH 8 to 10.5 is used in conjunction with the polybuffer exchange gel PBE 118 (both items also available from Pharmacia Biotech). Suitable CF start buffers for different selected pH gradient ranges are indicated in Table 8.5.1. The normal counter-ion for these anion-exchange media is chloride. Monovalent anions other than chloride may be used as counter-ions, but it is critical that these should have a pK_a at least 2 pH units below the lowest point of the gradient chosen (Hutchens, 1989).

As bicarbonate ions and atmospheric carbon dioxide can cause fluctuations in the pH gradient, all buffers must be degassed before use. Atmospheric carbon dioxide may cause a plateau in the region of pH 5.5 to 6.5, depending on the conditions. These effects are most marked with Polybuffer 96 in pH gradients ending at pH 6, and can be avoided by using acetate as the counter-ion (Pharmacia Biotech, 1985). Alternatively, the lower limit for gradients with Polybuffer 96 may be set at pH 6.5. Acetate is not usually recommended as a counter-ion with Polybuffer 74 because of its higher pK_a. Multivalent anions are not recommended as counter-ions.

Determination of Appropriate Quantity of CF Medium

The amount of gel required for a chromatofocusing run depends on the amount of sample, the nature of the sample and contaminants, and the degree of resolution required. For most separations, a bed volume of 20 to 30 ml is sufficient for separation of samples containing from 1 to 200 mg of protein per pH unit covered by the gradient (e.g., 600 mg of protein for a 3-pH-unit gradient). However, the precise amount of gel used will depend on the resolution required from the experiment, a factor that should be considered during optimization.

Preparation of CF Buffers

CF start buffer is prepared as in Table 8.5.1. CF elution buffers are prepared by diluting Polybuffer 96 or 74 or Pharmalyte 8 to 10.5 with distilled water according to the dilution factors listed in Table 8.5.1. The pH of the CF elution buffer should then be adjusted to the lower limit of the selected pH gradient. Approximately 15 V_c of CF start buffer and 15 V_c of CF elution buffer per run are typically required. This should be enough for equilibration (system, column, and sample), separation, and regeneration.

All buffers should be degassed under vacuum or by sonication prior to use. Buffers to be used with the prepacked column Mono P HR 5/20 should be filtered through a 0.45-µm filter membrane prior to use.

SEPARATION OF PROTEINS BY CHROMATOFOCUSING

BASIC PROTOCOL

In this procedure, the CF column is equilibrated in CF start buffer at a pH higher than that of the CF elution buffer. As the lower-pH CF elution buffer moves through the column, the ion-exchange groups of the medium in the column are titrated by the CF elution buffer, forming a descending linear pH gradient in the column. In a case where the isoelectric point (pI) of a protein is below the pH at which the column is equilibrated, the protein will have a net negative charge at the beginning of the experiment and therefore will bind to the anion-exchange medium in the CF column. As the descending pH gradient slowly forms in the column, the pH at the position where the protein is bound will eventually drop below the pI of the protein, and the net charge on the protein will become positive. The positively charged protein will then desorb from the anion-exchange medium and be carried through the column in the mobile phase. As the desorbed and now positively charged protein advances through the column in the mobile phase, it will pass through

[b]Degas all buffers before use.

[c]PBE 94, Mono P, Pharmalyte 8-10.5, Polybuffer 96, and Polybuffer 74 are products of Pharmacia Biotech (see *SUPPLIERS APPENDIX*).

[d]The dilution factor given is not critical; optimal conditions will be found by experience.

[e]Gradient volume will vary with the exact conditions chosen.

[f]Gradients ending at pH 9 are not recommended because pH 9 is above the pH of Pharmalyte pH 8-10.5.

[g]pH adjusted with HCl.

[h]PBE 118 and Pharmalyte 8-10.5 as well as PBE 94 and Polybuffer 96 (all from Pharmacia Biotech) also cover this range.

[i]pH adjusted with acetic acid.

BOUAS / CENTRAL UNIVERSITY LIBRARY

Table 8.5.2 pH Ranges, Loading Capacities, and Flow Rates for Chromatofocusing Gel Media[a]

CF gel medium	pH range	Recommended loading capacity	Recommended flow rate
PBE 118	8-11	10 mg protein/ml gel	50 cm/hr
PBE 94	4-9	10 mg protein/ml gel	50 cm/hr
Mono P HR 5/20	4-9	25 mg protein/column 5 mg protein/peak	0.5-1 ml/min

[a]Recommended flow rates and loading capacities are for initial experiments; see *UNIT 8.2* for optimization procedures. A peristaltic pump is generally adequate for packing and operation of PBE 94 and PBE 118 columns; the Mono P HR 5/20 column is designed for use at higher pressures and should be used with HPLC or FPLC systems.

the gradient, in which the pH in the column is increasing. When the pH in the column finally exceeds the pI of the protein, the net charge of the protein again becomes negative; hence the protein is again adsorbed to the anion-exchange medium. The net effect, as the protein adsorbs and desorbs many times, is a focusing effect which results in zone sharpening, sample concentration, and very high resolution.

Materials

CF gel medium PBE 94 or PBE 118 *or* prepacked CF column Mono P (Pharmacia Biotech; see Strategic Planning, Table 8.5.1, and Table 8.5.2)
CF start buffer (see Strategic Planning and Table 8.5.1)
CF elution buffer (see Strategic Planning and Table 8.5.1)
Protein sample to be purified

Sintered-glass filter funnel, medium porosity
Side-arm flask
Chromatographic system including:
Appropriate chromatographic column
Fluid delivery system with appropriate pump
Sample injection valve
UV monitor suitable for use at 280 nm
pH monitor with flowthrough electrode (optional)
Recorder
Fraction collector

Additional reagents and equipment for checking packed chromatographic bed (*UNIT 8.4*), desalting via gel-filtration chromatography (*UNIT 8.3*), and protein assay (Chapter 3)

Pack the column

1. Pour the appropriate amount of CF gel medium into a sintered-glass funnel attached to a side-arm flask. Using aspiration, pass start buffer through the gel in the funnel until the pH of the effluent is the same as that of the start buffer.

   Equilibration usually requires 10 to 15 bed volumes of start buffer. The gel should be stirred gently from time to time to ensure complete equilibration.

   Steps 1 to 7 are omitted where a prepacked CF column is used. CF columns may also be equilibrated after packing. If a column is used in which the gel medium was not equilibrated before packing, or if a prepacked column is used, the column should be washed with 2 to 3 V_c of 1 M NaCl to remove any bound substances, then with 10 to 15 V_c of CF start buffer until equilibrated. The column has reached equilibrium when

BCU LIBRARY / CENTRAL UNIVERSITY LIBRARY

the pH and conductivity of the eluant match the corresponding values for the CF start buffer. When the column is equilibrated, proceed to step 8.

2. Disperse gel in a small amount of start buffer (~50% of settled bed volume to be packed) to make a slurry. Degas under vacuum.

3. Mount chromatographic column vertically and flush any air bubbles from underneath the bed support nets. The column outlet should be closed at this point.

   See Figure 8.3.1 for an illustration of the chromatographic column. Best results are obtained on long, narrow columns. For high resolution in preparative applications, a bed height ≥30 cm is desirable. A column diameter of 2.5 cm at a 40-cm bed height (V_c = 200 ml) is usually sufficient for separating ≤2000 mg of protein.

4. Place 2 to 3 ml start buffer in the column and pour gel slurry down a glass rod into the column, taking care to avoid introducing air bubbles.

   If the volume of the slurry is greater than that of the column, a packing extension should be used (see Fig. 8.3.1).

5. Open column outlet and allow gel to settle into column. When all of the suspension has run into the column, remove packing extension (if used) and connect top piece (i.e., flow adaptor; see Fig. 8.3.1) to the column, taking care to exclude air bubbles. Connect column to pump.

6. Run start buffer through column at a flow rate of 100 cm/hr until the gel bed has completely settled.

   Equilibration of a column that has already been packed without previous equilibration can be carried out at a lower flow rate. The column has been equilibrated when the pH and conductivity of the eluant match the corresponding values for the start buffer (usually after 10 to 15 bed volumes of start buffer have passed through the column; see annotation to step 1).

7. Check the quality of the column packing (see *UNIT 8.4*).

   A well-packed column is essential to get the full benefits of chromatofocusing—i.e., the achievement of extremely narrow zones (0.02 pH units). Care must be taken in the choice of dye substance for checking beds, as they may be strongly charged. Bovine cytochrome c (pI = 10.5) is recommended as the dye marker for visual inspection of the bed in CF columns. Dilute acetone solutions are appropriate for efficiency tests (see UNIT 8.4).

Prepare the system

8. Set up the chromatography system according to the manufacturer's instructions without the column in-line, but with the UV monitor in-line. Purge the system of air bubbles by washing with CF start buffer. Check for leakage.

9. Install the packed column in the system and continue to equilibrate with start buffer at the flow rate appropriate for the column (see Table 8.5.2).

   Do not exceed 75% of the maximum flow rate used in packing the column (i.e., 75 cm/hr for 100 cm/hr packing flow rate; see step 6).

10. Check that the UV monitor signal is stable and that the recorder is operational. Collect one fraction and measure the pH, which should be the same as that of the CF start buffer. If the pH is not the same, continue to equilibrate the system by running start buffer through the column.

Prepare sample and apply to column

11. Equilibrate protein sample in CF elution buffer or start buffer by desalting via gel-filtration chromatography (*UNIT 8.3*).

BCU IASI (CENTRAL) UNIVERSITY LIBRARY

Although the best way to ensure that the sample will bind to the column is by buffer exchange into start buffer, this step is only necessary when the ionic strength is high (typically >50 mM). Diluting the sample with distilled water can also be used to decrease the ionic strength. Sample pH is not critical if the buffering capacity of the sample is less than that of the start buffer.

The amount of sample to be applied to the CF column depends on the amount of protein present in each zone. As a guideline for initial experiments, 10 mg protein can be applied for every 1 ml CF medium. This quantity will vary according to the number of proteins present in the sample. The volume of sample is unimportant so long as all of the sample is applied before the substance of interest is eluted from the column. The composition of the sample is important: it should not contain large amounts (>0.05 M) of salt.

12. Using a linear flow rate of 50 to 60 cm/hr, run 5 ml CF elution buffer through the equilibrated CF column, then run the sample in CF elution buffer or CF start buffer.

    Running elution buffer through the column before running the sample insures that sample proteins are never exposed to extremes of pH.

    NOTE: *Do not monitor protein at 254 nm, because CF elution buffers absorb at that wavelength.*

13. Still using a linear flow rate of 50 to 60 cm/hr, begin development of the pH gradient by eluting the sample with CF elution buffer. Begin fraction collection, and continue elution with CF elution buffer until the pH of the fractions collected reaches the desired pH (i.e., the pH of the CF elution buffer).

    When exploring conditions for a new separation, collect 20 fractions over the linear pH gradient. Once the separation has been refined, smaller fractions can be collected to optimize resolution; alternatively the peak collection feature of an automated fraction collector may be employed.

    There is a 1.5 to 3.0 V_c delay before the pH gradient begins to elute from the column. The exact delay volume depends on the buffering capacities of the CF column and CF elution buffer.

14. Assay the fractions collected (see Chapter 3) and pool those containing the target protein.

    The Polybuffer 74 or 96 contained in the CF elution buffer does not interfere with most enzyme assays or amino acid analyses (UNIT 3.3). Although CF elution buffer does not interfere with Coomassie blue–based protein assays, it forms a complex with copper ions and interferes with the Lowry protein assay (UNIT 3.4). Where necessary, CF elution buffer may be removed by any of several methods (see Support Protocol 2).

REGENERATION OF THE CF COLUMN

SUPPORT PROTOCOL 1

Additional Materials (also see Basic Protocol)

1 M NaCl

1. Wash column with 2 to 3 V_c of 1 M NaCl to remove bound material.

   Strongly bound material can often be removed with 0.1 M HCl or 0.1 M NaOH, but the gel should be equilibrated to a pH of 4 to 9 as soon as possible after treatment with these acid or alkaline reagents.

2. Equilibrate column with 10 to 15 bed volumes of CF start buffer in preparation for the next chromatographic run.

   If column is being prepared for storage, equilibrate with 2 or 3 column volumes of 20% ethanol instead of start buffer.

BCU ASI / CENTRAL UNIVERSITY LIBRARY

REMOVAL OF POLYBUFFER FROM PROTEIN

There are several methods for separating polybuffer from proteins where it is necessary to do this in preparation for analysis or further purification, including precipitation, hydrophobic interaction chromatography (HIC), gel filtration, and affinity chromatography.

Precipitation

The simplest method for separating protein from polybuffer is precipitation with ammonium sulfate (Scopes, 1994). Solid ammonium sulfate is added to the relevant fractions until a suitable concentration (80% to 100% saturated) is obtained. The sample is then allowed to stand 1 to 2 hr until the protein precipitates. This procedure is usually relatively simple, as the pH of the fraction is at or near the isoelectric point of the protein. Alternatively, the fractions of interest can be placed in dialysis tubing and dialyzed against saturated ammonium sulfate. Precipitation has the advantage of concentrating and stabilizing the sample, and is also inexpensive.

Hydrophobic Interaction Chromatography (HIC)

HIC (*UNIT 8.4*) can be used in conjunction with ammonium sulfate treatment. Ammonium sulfate is added to the fraction of interest obtained from chromatofocusing to a level of 80% saturation, which will favor hydrophobic interactions. This treatment may result in precipitation of the sample protein. If this happens, the purified sample can be harvested by centrifugation.

Gel Filtration

CF elution buffer can be removed from most proteins by gel filtration (*UNIT 8.3*) on a column packed with Superdex 75 prep grade medium (Pharmacia Biotech). If the molecular weight of the protein is <15,000, some difficulties may be encountered in achieving baseline separation in short columns.

Affinity Chromatography

The protein of interest can be easily be separated from CF elution buffer by taking advantage of the biological activity of the protein. The fractions of interest are passed through a column containing a bioselective adsorbent that binds the desired protein, allowing components of the CF elution buffer to elute unretarded. See Chapter 9 for a variety of affinity chromatography techniques.

COMMENTARY

Background Information

Chromatofocusing was first described by Sluyterman and coworkers (Sluyterman and Elgersma, 1978; Sluyterman and Wijdenes, 1978). They proposed that a pH gradient could be produced on an ion exchanger by taking advantage of the buffering action of the charged group of the ion exchange medium. If a buffer that has been initially adjusted to one pH is run through an ion-exchange column that has been initially adjusted to a second pH, a pH gradient is formed, just as if two buffers at different pH were gradually mixed in the mixing chamber of a gradient maker. If such a pH gradient is used to elute proteins bound to the ion exchanger, the proteins elute in order of their isoelectric points. Furthermore, focusing effects occur, resulting in band sharpening, sample concentration, and very high resolution.

The high resolution attainable with CF makes this technique ideal for the intermediate purification and polishing stages of a purification process (*UNIT 8.1*). The combination of CF with techniques that separate proteins based on physiochemical attributes other than charge characteristics—i.e., HIC (*UNIT 8.4*), gel filtration (*UNIT 8.3*), and affinity chromatography (Chapter 9)—is recommended. If the presence of polybuffer in the sample interferes with the intended use of the target protein, an additional polishing step will be required to remove the polybuffer (see Support Protocol 2).

BCU IAS / CENTRAL UNIVERSITY LIBRARY

Critical Parameters and Troubleshooting

The most critical steps in chromatofocusing are: first, selection of the correct pH gradient range for separation, and then proper matching of the buffering capacity of the CF medium to the buffering capacities of the CF start and elution buffers. Monitoring pH and ionic strength of the column effluent during the run is advised for both the interpretation of results and use in troubleshooting. Conductivity and pH monitors equipped with flow cells may be included downstream from the column; these should be calibrated prior to the experiment. If the conductivity and pH are to be measured in the collected fractions, the measurements should be made as soon as possible after collection to avoid variations from uptake of atmospheric gases.

Linear gradients are required for optimal resolution because nonlinear pH gradients give poor resolution in certain areas of the chromatogram. To produce a linear pH gradient, it is necessary that the CF eluant buffer and CF medium have an even buffering capacity over a wide pH range.

A list of potential problems, causes, and solutions for use in troubleshooting are given in Table 8.5.3.

Anticipated Results

Proteins elute from a CF column in descending order of isoelectric point. The pH at which a protein elutes from the CF column is typically less than its isoelectric point. Recovery from CF in terms of total protein is usually >80%. It is not unusual to notice fluctuations in the pH gradient during the delay in gradient formation (see Basic Protocol, step 14 annotation) or during the elution of concentrated proteins. A

Table 8.5.3 Troubleshooting Guide for Chromatofocusing

Problem	Possible cause	Solution
Protein does not bind to column	Column is incorrectly equilibrated	Check that pH at bottom of column matches that of start buffer
	Start pH is too low	Choose a start buffer with a higher pH
	Ionic strength of eluant is too high	Use buffer composition recommended in Table 8.5.1
	Ionic strength of sample is too high	Remove salt in sample by gel filtration in elution or start buffer (Basic Protocol, step 11)
	Column is contaminated with protein	Regenerate correctly and wash thoroughly before reuse (Support Protocol 1)
Protein binds to but does not elute from column	Eluant composition is incorrect	Check pH of eluant
	pH of eluant is too high	Try a lower pH range
Gradient does not reach desired pH	Eluant composition is incorrect	Check eluant pH; prepare fresh eluant if necessary
	Eluant contains CO_2	Degas all buffers prior to use
Gradient fluctuates	Incorrect counter-ion was used	Use recommended counter-ions (Strategic Planning)
	CO_2 is present	Degas all buffers prior to use; in alkaline regions, degas water before making up eluant
Bands are skewed	Bed net is blocked	Remove bed net; clean or replace with a new net
	Column was poorly packed	Check packing with cytochrome *c* (*UNIT 8.4*); repack bed if necessary.

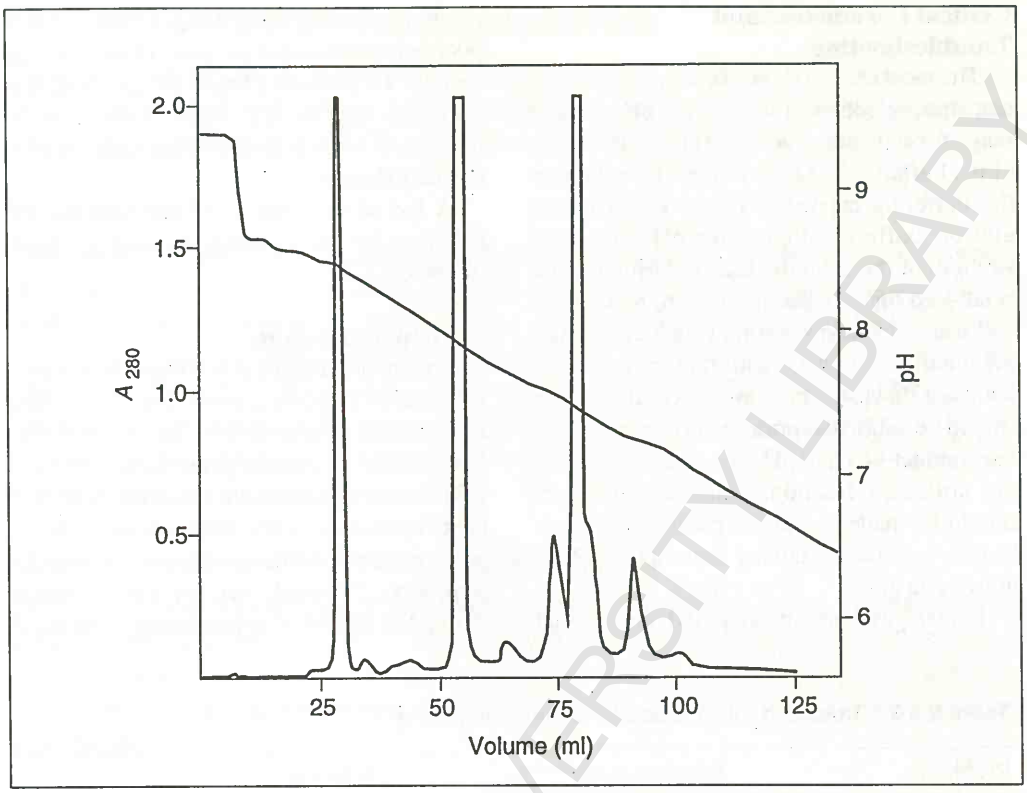

Figure 8.5.2 Chromatogram depicting separation by chromatofocusing with PBE 94 of a model mixture of proteins in the range of pH 9 to 7. An SR 10/50 column (Pharmacia Biotech) with a bed height of 18 cm was used. The sample consisted of 5 ml elution buffer containing 2 mg sperm whale myoglobin, 2 mg horse myoglobin, and 2 mg carboxyhemoglobin. The start buffer consisted of 0.025 M ethanolamine, pH 9.5, and the elution buffer consisted of 0.0075 mmol/pH unit/ml Polybuffer 96, pH 7. A flow rate of 15 cm/hr was used. (Courtesy of Pharmacia Biotech.)

typical chromatogram depicting the separation of a mixture of protein standards by CF is presented in Figure 8.5.2.

Time Considerations

The time required for CF experiments depends primarily on the length of the column, the flow rate, and the volume of sample to be applied; 3 to 4 hr per run is common, excluding the time required for column packing. Separation times using the Mono P HR 15/20 are <1 hr. As with any chromatographic separation, the most time-consuming aspect is normally the analysis of the fractions collected. Increasing resolution with narrow gradients, achieved by optimizing the CF separation, will help reduce the number of fractions to be collected.

Hydroxylapatite Chromatography

Hydroxylapatite (also called hydroxyapatite), a form of calcium phosphate, can be used as a matrix for the chromatography of both proteins and nucleic acids. Molecular separation is not completely dependent on any single property of the molecule such as molecular weight, size, or isoelectric point; the complex interactions between the matrix and the sample confer unique separative properties on hydroxylapatite. It may be used early in purification schedules to fractionate crude mixtures or later on to separate components that have not been well resolved by other steps, such as affinity chromatography or gel filtration.

Two basic protocols are set out in this unit. The first (see Basic Protocol 1) describes standard low-pressure chromatography of a protein mixture using a hydroxylapatite column prepared in the laboratory; the second (see Basic Protocol 2) describes an HPLC method, applicable to proteins and nucleic acids, that uses a commercially available column. Alternate protocols describe column chromatography using a step gradient (see Alternate Protocol 1) or batch binding and step-gradient elution (see Alternate Protocol 2).

STRATEGIC PLANNING

Selecting a Matrix

Choosing the most suitable form of hydroxylapatite matrix for the application is crucial for success. Hydroxylapatite is available in powder form, as a hydrated gel, in a ceramic form, and prepacked into a variety of columns (Table 8.6.1). Most suppliers provide excellent instruction leaflets and/or technical bulletins, and are pleased to offer advice concerning their products. (Also see Critical Parameters.)

Selecting a Column

The optimal size of a hydroxylapatite column is determined by the amount of material to be processed. The binding capacity of the matrix is usually supplied by the manufacturer, and is used to calculate the approximate quantity required. The resin bed should not be too long in relation to its width to allow use of a reasonable flow rate and to minimize broadening of the eluted peaks (see *UNIT 8.1*). A bed height-to-width ratio between 5:1 and 12:1 is suggested. The best type of column to use is one with two adjustable end pieces, so the volume of the bed can be varied as required (see Figure 8.3.1 for illustrations of typical chromatography equipment; also see Critical Parameters).

LOW-PRESSURE CHROMATOGRAPHY FOR PROTEIN PURIFICATION

BASIC PROTOCOL 1

Low-pressure chromatography is frequently used for laboratory-scale purifications (i.e., a few milligrams to a few grams). By choosing a suitably sized column, small or large fractionations can be accommodated.

The procedure described here uses a closed-column pumped system. The matrix is prepared, the column is packed, the sample is chromatographed, and the eluted proteins are visualized by in-line UV detection. Variations on this procedure might include the use of prepacked columns and the detection of eluted proteins by dye binding (*UNIT 3.4*), functional assay, or PAGE (Chapter 10).

Hydroxylapatite can be obtained commercially or, if desired, can be prepared in the laboratory (Atkinson et al., 1973). If the technical literature supplied with the product suggests steps additional to or different from those described in this protocol, always follow the manufacturer's recommendations.

Materials

Hydroxylapatite matrix (see Table 8.6.1)
Loading buffer: 10 mM sodium phosphate, pH 6.8 (*APPENDIX 2E*)
Protein sample to be purified
Gradient solutions: 0.01 and 0.4 M sodium phosphate, pH 6.8 (*APPENDIX 2E*)
Loading buffer (see above) with 0.02% sodium azide

Side-arm flask and vacuum source
Glass chromatography column (see Strategic Planning) with two adaptors or removable end piece and one adaptor (Fig. 8.3.1), tubing, and optional packing reservoir (e.g., Pharmacia Biotech C or XK series)

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Tubing clamps
Peristaltic pump
Buffer reservoirs
Fraction collector
UV monitor with 280-nm filter, connected to a chart recorder
Gradient mixer

Prepare gel

1. Calculate the amount of hydroxylapatite matrix required based on protein-binding capacity.

Capacity of the matrix is usually supplied by the manufacturer

If matrix is supplied dry

2a. Degas a sufficient volume of loading buffer in a side-arm flask under vacuum. Add one part matrix to six parts loading buffer and resuspend by swirling gently.

Do not use a magnetic stirrer as this will damage the hydroxylapatite crystals.

3a. Allow the slurry to settle for a minimum of 20 min, then decant the fines, which are in the cloudy solution above the settled matrix.

4a. Add a volume of loading buffer approximately equal to the volume of the settled bed and mix gently by swirling. Allow matrix to settle.

5a. If the matrix settles to give a sharp dividing line between the bed and clear buffer above, swirl gently to resuspend and proceed to packing of the column (step 6). If the supernatant buffer is still cloudy, repeat steps 3a and 4a, then proceed to step 6.

If matrix is supplied hydrated

2b. Resuspend the matrix (in its own storage buffer as supplied by the manufacturer) by swirling gently.

3b. Pour a sufficient volume of the suspension into a beaker and allow to settle for a minimum of 20 min. Decant the fines.

4b. If the buffer in which the matrix was shipped is different from the loading buffer (10 mM sodium phosphate) add a volume of loading buffer approximately equal to that of the matrix, mix by swirling gently, allow to settle for a minimum of 20 min, then decant.

5b. Add a volume of loading buffer approximately equal to that of the matrix and swirl gently to resuspend. Proceed to packing of the column.

Pack column

6. Examine the column to check that it is clean and undamaged and that sinters, support nets, and O rings are present and intact.

7. Insert bottom adaptor if used, or screw in the end piece. Mount column in a laboratory stand with clamps to ensure that it is vertical. If the volume of the resin slurry is greater than that of the column, fit a packing reservoir (Fig. 8.3.1).

8. Pour a small volume of loading buffer into the column and check that it flows freely through the bottom sinter. Clamp off the outlet tubing with a tubing clamp, leaving ~2 cm of buffer above the sinter.

9. Swirl the hydroxylapatite slurry (step 5a or 5b) gently to resuspend, then pour it all into the column at once and allow 2 to 3 cm to settle under gravity. Release the tubing clamp and allow the rest of the bed to pack under gravity flow.

10. Attach a peristaltic pump to the bottom outlet and pump 5 bed volumes of loading buffer through the column to equilibrate.

PCI LIBRARY / CENTRAL UNIVERSITY LIBRARY

As a rough guide, a standard general-purpose matrix such as Bio-Gel HT (see Table 8.6.1) may be used at a linear flow rate of 75 cm/hr. Fine-particle DNA columns should be run at ~1/10 this rate. Macroporous material—e.g., Macro-Prep Ceramic (Table 8.6.1) can tolerate flow rates up to 5000 cm/hr. The linear flow rate (cm/hr) is equal to the volumetric flow rate (cm^3/hr) divided by the column cross-sectional area (cm^2).

The column should be equilibrated at a flow rate 25% to 50% higher than that anticipated for the separation to ensure that there is no further compaction of the bed during the run.

If the manufacturer recommends a maximum flow rate, this should never be exceeded.

11. Insert the top adaptor, lower it onto the column bed, and tighten.

    Buffer will emerge from the tubing, which should remain filled to prevent air from being drawn into the column.

12. Place the tubing from the top adaptor into a reservoir of loading buffer clamped to the support stand at the same level as the top of the column.

13. Pump a further 5 bed volumes of loading buffer through the column.

    If the bed shrinks so that there is a gap between the top adaptor and the surface of the bed, carefully loosen the top adaptor, lower it onto the bed and retighten. The column is now ready and may be used at once or stored for several weeks at 4°C.

Prepare sample

14. If necessary, free sample of particulate matter by centrifuging or passing it through a 0.45-µm filter.

15. Adjust sample to the same pH and a similar salt concentration as the loading buffer.

    If only the pH of the sample is different from that of the loading buffer, this can be carefully adjusted by adding 10 mM sodium dihydrogen phosphate (to decrease pH) or 10 mM disodium hydrogen phosphate (to increase pH). If the salt concentration is too high, the sample should be dialyzed against an appropriate buffer. Buffer exchange may also be effected by use of a desalting column (UNIT 8.3) or a membrane concentration device (UNIT 4.4). The sample may also be diluted with low-ionic-strength buffer.

Chromatograph sample and regenerate column

16. If the column has been stored for some time, pump a little loading buffer through it and check the bed for air bubbles or cracks and the tubing connections for leaks.

17. Transfer the top adaptor tubing from the buffer reservoir to the sample and pump the sample onto the column, collecting fractions with a fraction collector and monitoring the A_{280} using a UV monitor with a 280-nm filter, connected to a chart recorder.

    Take care not to introduce air into the column.

18. Wash the column with loading buffer until the A_{280} returns to baseline, collecting the flowthrough and wash fraction, as these contain the material which does not bind to the matrix.

19. Degas appropriate volumes of 0.01 and 0.4 M sodium phosphate, pH 6.8, as in step 2a. Connect gradient mixer to column and place the two gradient solutions in the respective reservoirs. Elute the bound material using a linear gradient from 0.01 to 0.4 M sodium phosphate with a gradient volume 6 to 10 times the bed volume. Elute any material still bound by washing with 0.4 M sodium phosphate, pH 6.8. Collect 20 to 40 fractions of a size appropriate to the volume of the gradient until all bound material has been eluted (as judged by the A_{280} of the eluant).

20. Regenerate column by washing with 5 bed volumes of loading buffer, then wash with 2 bed volumes of loading buffer containing 0.02% sodium azide. Store column at 4°C.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

CAUTION: *Sodium azide is toxic and potentially explosive. Avoid contact with metals and acids and do not lyophilize solutions containing azide. See* APPENDIX 2A *for additional guidelines on the handling and disposal of sodium azide.*

If the manufacturer recommends a different procedure for column regeneration, this should be followed.

Figure 8.6.1 and Table 8.6.2 show results for low-pressure chromatography.

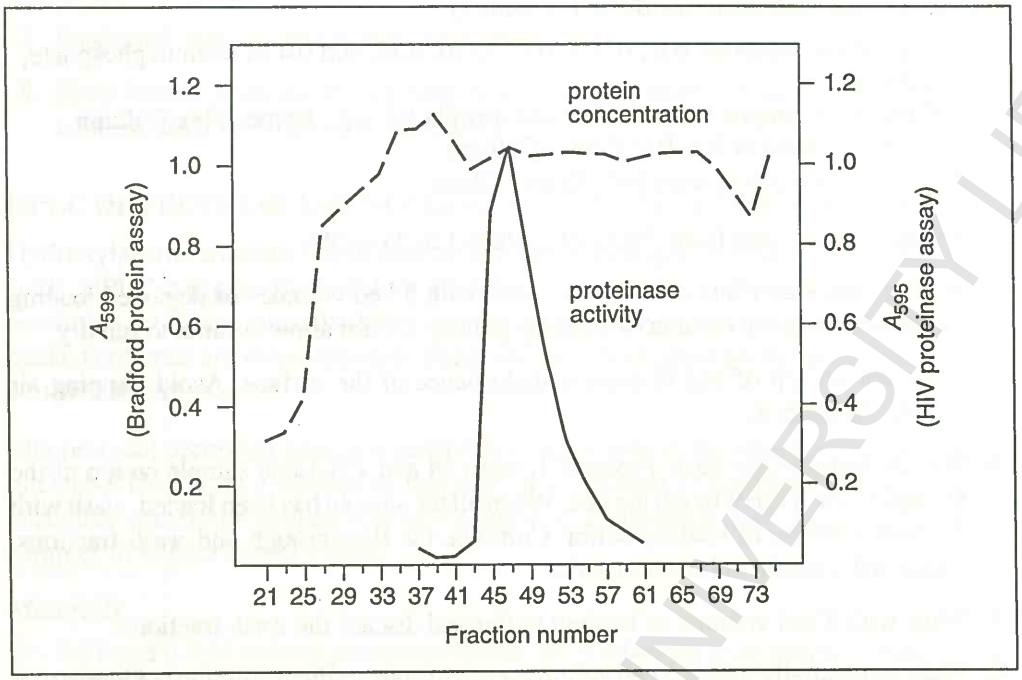

Figure 8.6.1 Chromatogram illustrating purification of HIV-2 proteinase on a hydroxylapatite column (A.V. Broadhurst and A.J. Ritchie, unpub. observ.). 139 g recombinant *E. coli* expressing HIV-2 proteinase were lysed by lysozyme digestion and sonication. The soluble fraction was treated with 1% streptomycin sulfate to precipitate nucleic acids. The supernatant was brought to 25% saturation with solid ammonium sulfate and the pellet was discarded. The ammonium sulfate was increased to 40% saturation and the pellet containing the proteinase was dialyzed against 10 mM sodium phosphate, pH 6.8, containing 0.0125% Tween 20. This fraction was applied to a 4.5 × 19–cm Bio-Rad HT hydroxylapatite column, bed volume 300 ml, at a linear flow rate of 10 cm/hr. The column was washed with 250 ml 10 mM sodium phosphate (pH 6.8)/0.0125% Tween followed by 250 ml 25 mM sodium phosphate (pH 6.8)/0.0125% Tween 20. Bound proteins were eluted with a 600 ml gradient of 25 to 250 mM sodium phosphate, (pH 6.8)/0.0125% Tween. The fractions were assayed for protein by the Bradford method (the dotted plot and the *y* axis on the left; Bradford, 1976; also see *UNIT 3.4*) and for proteinase activity using a colorimetric assay (the solid plot and the *y* axis on the right; Broadhurst et al., 1991).

Table 8.6.2 Typical Purification Scheme for HIV-2 Proteinase Incorporating Hydroxylapatite Chromatography[a]

Purification stage	Total proteinase activity (U)	Specific activity (U/mg)
Crude *E.coli* lysate	79,120	13.9
40% ammonium sulfate pellet	54,590	48.2
Pooled peak fractions from hydroxylapatite column	31,995	194
Pooled concentrated fractions from G-75 gel-filtration column	18,333	561

[a]1 U is arbitrarily defined as the amount of enzyme required to release 1 µmol product/min at 37° in a colorimetric assay (Broadhurst et al., 1991).

BCU LIBRARY CRANFIELD UNIVERSITY LIBRARY

ALTERNATE PROTOCOL 1

SIMPLE COLUMN CHROMATOGRAPHY FOR PROTEIN PURIFICATION USING HYDROXYLAPATITE

If only basic equipment is available, simplified methodology in which the pump is replaced by a gravity column may be applied successfully. The method described below is also useful for quick trial runs to assess the suitability of hydroxylapatite for particular applications.

Additional Materials (also see Basic Protocol 1)

Step gradient solutions: e.g., 0.025, 0.05, 0.10, 0.25, and 0.4 M sodium phosphate, pH 6.8
Column with integral bottom sinter and airtight lid: e.g., Kontes Flex-Column (Kontes Glass) or Bio-Rad Econo-Column
Frit to place on top of resin bed (Kontes Glass)

1. Prepare matrix. (see Basic Protocol 1, steps 1 to 5a or 5b).
2. Pour matrix slurry into column and wash with 5 bed volumes of degassed loading buffer, allowing the column to drain by gravity. Do not allow column to run dry.
3. Place frit on top of bed to prevent disturbance of the surface. Avoid trapping air bubbles beneath it.
4. Prepare sample (see Basic Protocol 1, steps 14 and 15). Load sample on top of the frit and allow it run through the bed. When all the sample has been loaded, wash with 1.5 bed volumes of loading buffer. Combine the flowthrough and wash fractions, which will contain unbound material.
5. Wash with 8 bed volumes of loading buffer and discard the wash fractions.
6. Wash sequentially with 2.5 bed volumes each of step gradient solutions of increasing concentration—e.g., 0.025, 0.05, 0.10, 0.25, and 0.4 M sodium phosphate, pH 6.8 (degassed before use; see Basic Protocol 1, step 2a). Collect each wash separately.

ALTERNATE PROTOCOL 2

BATCH PROCESSING FOR PROTEIN PURIFICATION USING HYDROXYLAPATITE

If hydroxylapatite is to be used with very crude material early in the purification schedule, or if the volume to be processed is very large, this batch separation procedure may be appropriate. Batch processing does not require sophisticated equipment; it can be done quickly and is useful for trial runs.

Materials (also see Basic Protocol 1)

Step gradient solutions: e.g., 0.025, 0.05, 0.10, 0.25, and 0.4 M sodium phosphate, pH 6.8
Sintered-glass funnel
Side-arm flask and vacuum source

NOTE: Degassing of buffers is not essential for batch processing.

1. Prepare matrix (see Basic Protocol 1, steps 1 to 5a or 5b).
2. Carefully remove all supernatant buffer from the settled matrix by decantation.
3. Prepare sample (see Basic Protocol 1, steps 14 and 15).

If the sample volume is small, add sufficient 10 mM sodium phosphate, pH 6.8, to make it approximately twice the bed volume.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

4. Mix the sample with the hydroxylapatite matrix by gentle swirling. Leave for 15 min.
5. Pour slurry into sintered-glass funnel and apply a very gentle vacuum until the buffer just reaches the top of the matrix.

   IMPORTANT NOTE: *Do not allow the matrix to dry out.*
6. Wash matrix in funnel with a small amount of loading buffer. Collect and combine the flowthrough and wash fractions.
7. Wash well with loading buffer and discard wash.
8. Elute bound proteins by washing with a step gradient of increasing phosphate concentration (see Alternate Protocol 1, step 6).

HPLC OF PROTEINS AND NUCLEIC ACIDS USING HYDROXYLAPATITE

BASIC PROTOCOL 2

Hydroxylapatite columns can be used for the chromatography of both proteins and nucleic acids. HPLC is especially useful for analytical applications, as the technique offers high resolution, excellent reproducibility, and fast analysis times. For occasional users, ready-packed columns are recommended. These are usually of good quality and are tested and certified before sale.

The protocol described here is a general one applicable to the separation of proteins or nucleic acids. Using a method of this type, it is possible to quantitate the amount of a particular protein or nucleic acid in a sample by comparison with a range of standard samples of known concentration.

Materials

0.01 and 0.4 M sodium phosphate buffer, pH 6.8 (*APPENDIX 2E*; prepare using boiled H_2O)
Protein or nucleic acid standard solutions
Protein or nucleic acid test samples
0.2 M sodium hydroxide
0.01 M sodium phosphate, pH 6.8 (*APPENDIX 2E*) with 0.02% (w/v) sodium azide
0.45-µm filters (for buffers)
0.22-µm filters (for samples)
~7.5-mm × 7.5-cm HPLC column packed with suitable grade of hydroxylapatite (Table 8.6.1)
Guard column recommended for HPLC column used
HPLC apparatus equipped with pumps, gradient mixer, autosampler or injection loop, integrator, and UV monitor

Prepare buffers and sample

1. Filter 0.01 and 0.4 M sodium phosphate buffers through a 0.45-µm filter. Degas in side-arm flasks under vacuum before use.
2. Filter sample through a 0.22-µm filter.

   If sample is very turbid it may be necessary to centrifuge it first to avoid blocking the filter.

Prepare column and chromatograph samples

3. Follow any instructions supplied by the manufacturer relating to preparation of column and assembly of HPLC system.
4. Equilibrate column with 0.01 M sodium phosphate buffer, pH 6.8, prepared as in step 1.

BOJASI CENTRAL UNIVERSITY LIBRARY

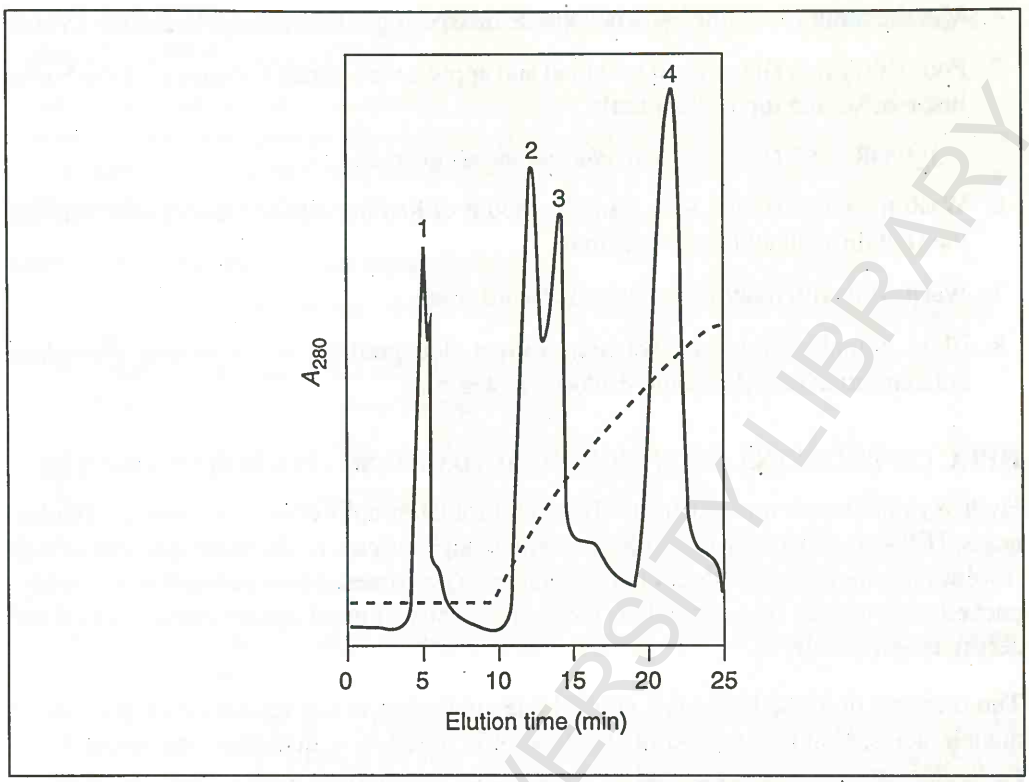

Figure 8.6.2 Chromatogram illustrating purification of monoclonal antibody from mouse ascites fluid. A Bio-Rad Bio-Gel HPHT column with guard column was used and 0.5 ml mouse ascites fluid was applied. The column was eluted with a linear gradient of 0.01 to 0.30 M sodium phosphate, pH 6.8 at a flow rate of 1.0 ml/min. Peak 1 contains low-molecular-weight material, peak 2 contains albumin and serum protease, peak 3 contains other serum (ascites) proteins, and peak 4 contains essentially pure IgG. The linear gradient is traced via the conductance (dotted line). Adapted from Bio-Rad Technical Bulletin US/EG 1115.

5. Program the HPLC to inject 20 µl of sample and set the UV monitor to 260 nm for nucleic acids or 280 nm for proteins. Place 0.01 and 0.4 M sodium phosphate buffers, pH 6.8, in the appropriate reservoirs of the gradient mixer and run a 30-min linear gradient from 0.01 to 0.4 M sodium phosphate at a flow rate of 1 ml/min.
6. Run a standard through the column to to check its performance using the parameters in step 5. Collect 1-ml fractions.
7. Run the standard at a range of concentrations to generate a standard curve.
8. Run the test samples.
9. Use the integrated peak areas of the standards and test samples to calculate the concentration of the protein/nucleic acid of interest in the samples.

See Figure 8.6.2 for representative results.

Regenerate and store column

10. At the end of each sample batch, inject 1 column volume of 0.2 M sodium hydroxide to remove any strongly bound material. Wash extensively with 0.4 M sodium phosphate.
11. Store column at room temperature in 0.01 M sodium phosphate, pH 6.8 containing 0.02% sodium azide.

CAUTION: *Sodium azide is toxic and potentially explosive. Avoid contact with metals and acids and do not lyophilize solutions containing azide. See APPENDIX 2A for additional guidelines on the handling and disposal of sodium azide.*

BCU IASI CENTRAL UNIVERSITY LIBRARY

COMMENTARY

Background Information

Calcium phosphate gels have been used for chromatography for many years. The material originally used was unsatisfactory with respect to flow rate, stability, and elution characteristics, and fell out of favor as newer matrices such as HA Ultrogel and Macro-Prep Ceramic became available. In the 1950s, Tiselius and co-workers described a process for preparing hydroxylapatite, a crystalline form of calcium phosphate, and demonstrated its usefulness for protein separation (Tiselius et al., 1956). Material prepared by this method demonstrated superior flow rates and has been commercially available for many years. Recently, some new forms of hydroxylapatite with spherical particles have been developed, and these have demonstrated even better flow rates as well as enough mechanical strength to be used in high-pressure systems. These technological advances, combined with hydroxylapatite's unique mode of separation, make this medium a useful addition to the chromatographer's repertoire.

Protein binding to hydroxylapatite is mediated through interactions between the amino and carboxyl groups of the protein and the Ca^{2+} and PO_4^{3-} groups of the hydroxylapatite crystal lattice. Basic proteins are thought to bind via electrostatic interactions between their amino groups and the surface PO_4^{3-} groups, the positive charge rather than the chemical nature of the group being the important factor (Gorbunoff, 1984b). Acidic and neutral proteins bind to the Ca^{2+} sites via their carboxyl groups; this interaction encompasses both electrostatic interactions and specific effects (Gorbunoff, 1984b). As a general principle, basic proteins with an isoelectric point (pI) of 8 can be eluted by increasing the concentration of the phosphate buffer, and they are also displaced by very low concentrations of Mg^{2+} or Ca^{2+} ions and moderate concentrations of NaCl (Gorbunoff, 1984a). Acidic or neutral proteins can be eluted by increasing the phosphate concentration, but not by adding Mg^{2+} or Ca^{2+} ions or NaCl. Increasing the pH of the elution buffer promotes desorption of proteins irrespective of pI (Gorbunoff, 1984a).

There are many proteins whose interactions with hydroxylapatite are not as easily predicted on the basis of pI alone—e.g., β-lactoglobulin, ovomucoid, trypsinogen (Gorbunoff and Timasheff, 1984), phosphoproteins (Bernardi et al., 1972), and metalloproteins (Atkinson et al., 1973). Tertiary structure is also important for binding, and proteins with floppy or unstructured regions such as the glycoprotein ovomucoid, or those that have been denatured, show reduced affinity for hydroxylapatite (Gorbunoff, 1984a). The distribution of surface charge may also play a part (Gorbunoff, 1984b).

Nucleic acids bind to hydroxylapatite by interaction of the charged phosphate backbone with the Ca^{2+} ions at the crystal face. Double-stranded DNAs bind more tightly than single-stranded DNAs, possibly because their planar nature maximizes the interaction. (Martinson, 1973). Small double- and single-stranded DNAs appear to separate by size. tRNAs can also be separated, and secondary and tertiary structures may be important in this context (Kawasaki et al., 1986).

Hydroxylapatite chromatography is performed using mild conditions at moderate pH and salt concentration, which favors the preservation of biological activity. The matrix has low nonspecific binding, and small molecules such as amino acids do not bind well. It is chemically stable at pHs between 6 and 11 and can be used with denaturing agents, detergents, and reducing agents such as dithiothreitol. EDTA and chelating buffers such as PIPES should be avoided as these bind the calcium.

The unique mode of separation of hydroxylapatite, combined with the improved handling characteristics of the newer forms available, make it a useful adjunct to the more commonly used techniques such as ion-exchange and hydrophobic-interaction chromatography. Hydroxylapatite has proved useful in the separation of IgG idiotypes that cannot easily be separated by other techniques (Juarez-Salinas et al., 1986), as well as for the isolation of immunoglobulins from ascites fluid and tissue culture media (Smith et al., 1984). Another application may be the secondary purification step for recombinant proteins with N-terminal affinity tags such as maltose-binding protein (MBP), glutathione-S-transferase (GST), or 6His. When these proteins have been isolated by affinity chromatography, any breakdown products produced by C-terminal degradation and any premature termination fragments will also bind to the resin, as they are tagged. These contaminants can be difficult to remove by gel filtration or ion-exchange chromatography as they may differ very little in size or charge from the protein of interest; hence hydroxylapatite chromatography may assist in the separation.

B.C.U. „M. EMINESCU" IAȘI
CHI IE

As an example, during the preparation of human cytomegalovirus proteinase for crystallographic studies, protein that had been purified using Mimetic Green and Q Sepharose and that appeared to be homogeneous on PAGE, separated into two peaks on a hydroxylapatite column (A.V. Broadhurst, unpub. observ.).

The ability of hydroxylapatite to bind and separate nucleic acids can be advantageous during chromatography of proteins derived from recombinant *E. coli.* Crude extracts contain large quantities of DNA, which can bind to proteins or ion-exchange resins and contaminate the product. Hydroxylapatite can be used to remove nucleic acids during the purification.

Critical Parameters

Selecting format

Careful consideration must be given to choosing the most appropriate chromatographic format for the application. If hydroxylapatite is to be used with very crude material early in the purification schedule, or if the volume to be processed is very large, a batch separation (see Alternate Protocol 2) may be suitable. Batch processing does not require sophisticated equipment; it can be done quickly and is useful for trial runs.

Low-pressure chromatography (see Basic Protocol 1 and Alternate Protocol 1) can be used to prepare milligram to gram quantities of protein. Semiautomated or fully automated systems are available, but satisfactory results can be obtained with quite basic equipment. This type of chromatography is used primarily for preparative rather than analytical purposes.

HPLC (see Basic Protocol 2), although it can be scaled up for preparative use, is particularly suitable for analytical applications. Its main advantages are high resolution, reproducibility, and rapid throughput.

Selecting matrix

Various grades and types of hydroxylapatite are commercially available (see Table 8.6.1). In general, hydroxylapatite with a small particle size will be suitable for analytical applications, giving excellent resolution but operating at low flow rates. Material with a larger particle size can be used at higher flow rates but with some loss of resolution. Hydroxylapatite can be difficult to work with as its crystalline structure is fragile and easily damaged, but some of the newer types (TSKgel HA-1000 from TosoHaas and MacroPrep ceramic hydroxylapatite from Bio-Rad) are purported to be more robust and are suitable for use with-high pressure systems.

There are several types of ready-prepared columns available commercially. These are designed for particular applications such as HPLC or low-pressure chromatography; some are of particular utility for the separation of proteins and others for separation of nucleic acids.

Selecting buffers

Sodium or potassium phosphate buffers at near-neutral pH are used for the majority of hydroxylapatite applications. Low phosphate concentration and low pH increase protein binding; high phosphate concentration and high pH promote desorption. In this context, low and high pH refer to the range 6 to 8, over which phosphate is an effective buffer. Potassium phosphate is more soluble than sodium phosphate at lower temperatures and is recommended for cold-room use.

The protein-binding capacity of hydroxylapatite is maximal at pH 6.6 to 7 and decreases sharply above pH 7 (Atkinson et al., 1973). The matrix itself is chemically stable over a pH range of 6 to 11, but dissolves below pH 5.5. Buffers other than phosphate have been employed—e.g., MOPS with a phosphate gradient (de Gunzberg et al., 1984)—but should be used with caution as they may damage the matrix. 10 mM Tris·Cl can be used, but may cause some deterioration over time. Chelating buffers such as PIPES must be avoided. Buffer pH should always be within the range over which the sample protein is known to be stable.

Various buffer additives can be employed. Glycerol, added to stabilize proteins, can be used at a concentration of 10% to 15%; it increases buffer viscosity so that a reduction in flow rate may be necessary. Reducing agents such as dithiothreitol and 2-mercaptoethanol, as well as nonionic detergents such as Triton X-100 and Tween 20, are compatible with hydroxylapatite. SDS has been used, but can reduce nonspecific binding and alter elution characteristics; it is also rather insoluble at 4°C and therefore is probably best avoided. Chelating agents such as EDTA are contraindicated as they bind to the calcium ions of hydroxylapatite and will rapidly destroy the column.

Troubleshooting

Many of the problems encountered during hydroxylapatite chromatography are common to all types of column chromatography, but a few are unique owing to the crystalline mineral nature of the matrix.

Column bed drying out or becoming filled with bubbles

Drying out of the bed is usually caused by the system not being airtight. Ensure that all O rings and seals are present and in good condition. It may help to have the buffer reservoir slightly higher than the top of the column. Drying out can also occur if the top sinter or the top of the bed becomes clogged, causing the pump to create a vacuum in the bed. This might be alleviated by reducing the flow rate; if this does not work, remove the top sinter, wash it, and replace. If the problem persists it may be necessary to modify the sample preparation.

Bubbles that appear in the gel are usually caused by inadequate degassing of the buffers. Dissolved gases will be released under reduced pressure or if the buffers/column are moved from a colder to a warmer environment. Degas all buffers (unless they contain volatile solvents) under vacuum before use. Bubbles may also appear if high concentrations of detergent are included in the buffers; this can be minimized by avoiding shaking or vigorous stirring of the buffers and using a moderate flow rate.

Inadequate or decreasing flow rate

This problem may be caused by packing the bed at too high a flow rate, causing it to become compressed. Manufacturers' recommended flow rates should never be exceeded; this is particularly important with hydroxylapatite because of its inherently fragile nature.

The presence of fines (resulting from inadequate removal before packing the bed) or degraded material can also cause poor flow rates. Ensure that the matrix is prepared as recommended; hydroxylapatite is easily damaged by rough treatment such as stirring with magnetic stirring bars and should be resuspended only by gentle swirling.

If hydroxylapatite columns are stored for long periods the top of the bed may become hard and crusted, causing reduced flow rate. This results from the reaction of the calcium ions with carbonate from water used to prepare the buffers. Boiled, degassed water should be used. The hard, crusted material can be removed and replaced with a little fresh hydroxylapatite slurry.

If the flow rate achievable is not high enough to allow the experiment to be performed in a reasonable time, consider whether a matrix with a larger particle size would be more suitable, or whether a batch process might be preferable.

If the flow rate is constant during the preliminary washing and equilibration of the column but decreases during sample loading, the problem may lie with the sample itself. It is important that particulate matter be removed from the sample before loading or it will block the sinter or the top of the gel bed. The sinter can be removed, washed, and replaced as an interim measure, but improved sample preparation is the cure. Crude extracts of recombinant *E. coli*, which are increasingly used as the starting point for protein purification, can be problematic. Even if the extract is clarified by centrifugation, it may be extremely viscous due to the high DNA content. It is often possible to reduce the viscosity enough to achieve a reasonable flow rate by diluting one part sample with three parts buffer before loading. If this fails, try precipitating the nucleic acids with 0.01% aqueous polyethyleneimine or 1% streptomycin sulfate, or treat the sample with DNase. *UNIT 4.5* contains additional guidelines on clarification of samples and nucleic acid removal.

Protein not bound to column

If the protein of interest is only partially bound, with significant amounts appearing in the flowthrough, the binding capacity of the column may have been exceeded. Try increasing the ratio of matrix to total protein.

If the protein is not bound using 10 mM sodium phosphate, pH 6.8, try reducing the molarity of the sodium phosphate. Concentrations as low as 1 mM can be used, although the buffering capacity will be small at this concentration. If the protein is stable at lower pH, the pH of the loading buffer can be decreased to 6 to facilitate binding. Do not reduce the pH below 5.8, as the hydroxylapatite matrix will dissolve at lower pH.

Adding 0.005 mM $CaCl_2$ to the buffer will increase binding of acidic proteins. $CaCl_2$ should only be used with low molarities of phosphate (<200 mM) or calcium phosphate will precipitate out of solution.

Even if none of the above modifications are successful, hydroxylapatite chromatography might still be a useful initial step if a significant amount of contaminating material is removed by binding to the matrix.

Poor separation of proteins on gradient and problems with eluting bound protein

If there are protein peaks that do not separate completely, try increasing the volume of the gradient. Do not exceed more than ~12 bed

BOSTON BIOMEDICAL RESEARCH INSTITUTE LIBRARY

volumes as there will be no benefit from this.

If all the bound material elutes very early on in the gradient, try using a narrower gradient—e.g.,10 mM to 150 mM sodium phosphate, pH 6.8.

If most of the proteins elute near the end of the gradient, try using a higher loading concentration of sodium phosphate—e.g., 50 to 100 mM.

The molarity of the elution buffer can be increased. If phosphate concentrations >0.4 M are required for complete elution and the chromatography is to be done at 4C, use potassium phosphate buffer instead of sodium phosphate, as it is more soluble. Desorption of proteins can also be achieved by increasing the pH of the buffer.

Basic proteins can be eluted with Ca^{2+} at concentrations of ~0.003 M. This cannot be done in phosphate buffer as calcium phosphate will precipitate out. Wash the column with 1 mM NaCl, then with 0.003 M $CaCl_2$ in 1 mM NaCl.

Anticipated Results

High recoveries can be expected with hydroxylapatite; near-quantitative yields have been reported with 90% to 95% being common. Retention of activity is usually excellent because of the mild conditions employed (Kato et al., 1987). Depending on the nature of the sample to be chromatographed, >20-fold purification is achievable.

Time Considerations

Small columns can be prepared and a chromatographic run carried out in a working day. Larger columns take longer to run and therefore will need to be prepared in advance.

CHAPTER 9
Affinity Purification

INTRODUCTION

Affinity chromatography in the context of this chapter refers to a variety of techniques that exploit the fact that proteins can act as ligands for a variety of ligand-binding proteins (e.g., antibodies, enzymes, and lectins) or are themselves ligand-binding proteins (i.e., act as receptors). Because receptor-ligand interactions are very specific and receptor and/or ligand sites are often unique to the protein of interest, exploitation of this methodology often yields pure or nearly pure proteins with a minimal number of purification steps.

Some receptor or ligand sites, such as antigenic epitopes and the active sites of enzymes, are limited to the protein of interest and, once discerned, provide a powerful approach for purification of the protein. Other receptor or ligand sites, such as those with the ability to interact with certain dyes or lectins, respectively, are less specific, but nevertheless provide approaches for isolating particular proteins from complex mixtures of proteins. Receptor and/or ligand-binding sites present in a protein, such as reactivity with a particular substrate or monoclonal antibody, are often known prior to the initial biochemical characterization of the protein. This knowledge saves time and facilitates development of the purification procedure. In other cases, such as for dye binding or lectin reactivity, it is often necessary to perform pilot studies to determine the feasibility of using a particular affinity chromatography method. Because each protein contains multiple receptor and/or ligand-binding sites, the combination of several different affinity chromatography steps in a purification scheme can often be utilized to obtain pure proteins.

Receptor and ligand-binding sites are usually natural properties of proteins; however, it has become popular in the case of recombinant proteins to engineer particular binding sites, such as metal-binding sites, as extensions from either the N- or C-terminus into the recombinant protein of interest. Such alterations of the natural protein greatly facilitate their purification. If structural alteration of the recombinant protein by the ligand-binding site is undesirable, protease cleavage sites can be positioned adjacent to the ligand-binding site so that this protein extension can be removed after it has been used for affinity purification (e.g., as when a polyhistidine Ni^{2+} binding site is removed by thrombin cleavage).

Essentially all forms of affinity chromatography involve the following steps:

1. Choice of appropriate ligand.
2. Immobilization of the ligand onto a support matrix.
3. Loading of the protein mixture of interest onto the matrix.
4. Removal of nonspecifically bound proteins.
5. Elution of the protein of interest in a purified form.

This chapter presents an eclectic collection of affinity purification protocols that have proven extremely useful in protein purification.

Lectin affinity chromatography, described in *UNIT 9.1*, is frequently utilized in glycoprotein purification schemes. In this approach a protein is bound to an immobilized lectin through its sugar chain, unbound protein is washed away, and the bound protein is eluted. Sugar side chains present in glycoproteins are usually of sufficient complexity that they present the possibility of reacting with a number of different lectins in a fashion useful for purification. Suitable lectins are tabulated in this unit. However, the potential resolving power of this large battery of lectins is limited by the facts that (1) most or many glycoproteins in a crude mixture of proteins share identical or near-identical sugar side chains and (2) lectin specificities are often not absolute. Nonetheless, when appropriately applied, lectin affinity purification usually yields a significant enrichment of the glycoprotein of interest. The basic and alternate protocols describe the use of concanavalin A (Con A) or wheat germ agglutinin (WGA) for preparative glycoprotein purification. These lectins are commonly used because of their general applicability and availability. Others can be readily substituted using the procedures described.

Dye affinity chromatography, described in *UNIT 9.2*, is a protein purification procedure based on the high affinity of immobilized dyes for binding sites on many proteins. It is a rapid and versatile method that is especially applicable for obtaining 10- to 100-fold purification of the desired protein from crude extracts. The dye ligand can be selected either to remove unwanted proteins (negative chromatography) or to bind to the protein of interest (positive chromatography); these two types of chromatography can also be coupled in series (tandem chromatography). Support protocols are provided to guide selection of appropriate dyes and support matrices.

Affinity purification of proteins can also be accomplished by their interaction with natural ligands, as described in *UNIT 9.3*. These ligands may be macromolecules such as proteins and nucleic acids, or low-molecular-weight compounds such as substrates, inhibitors, cofactors, etc. Because such interactions tend to be specific for particular proteins or groups of proteins, high degrees of purification can be obtained in a single step. Because of this specificity, the protocols in *UNIT 9.3* do not detail a specific purification scheme, but deal instead with choices of column matrices and methods of coupling potential ligands to these matrices.

UNIT 9.4 describes a method for the facile purification of recombinant proteins by metal-chelate affinity chromatography (MCAC). Proteins engineered to have six consecutive histidine residues on either the amino or carboxyl terminus can be purified in native or denatured forms using a resin containing nickel ions (Ni^{2+}). Techniques for creating a fusion protein consisting of the protein of interest with a histidine tail are outlined in a Strategic Planning section. The protocols describe expression of the histidine-tailed fusion proteins and their purification in native form by MCAC, as well as the purification of the fusion protein under denaturing conditions and the subsequent renaturation procedure (by either dialysis or solid-phase renaturation). In addition, analysis of the purified product and regeneration of the resin is presented.

UNIT 9.5 describes the isolation of soluble or membrane-bound protein antigens by immunoaffinity chromatography. By this technique, purifications of 10,000-fold or more can often be achieved in one step. Immunoaffinity columns most often employ monoclonal antibodies covalently attached to a solid-phase matrix; polyclonal antibodies have been used successfully, but they usually lack the specificity required for a single-step protein purification. The amount of protein that can be purified is solely dependent on the amount and affinity of the antibody employed. In addition to describing the overall procedure, this unit provides alternate conditions of elution and a method for attaching the antibody to the support matrix.

BCU IASRI CENTRAL UNIVERSITY LIBRARY

Many biological processes, such as recombination, replication, and transcription, involve the action of sequence-specific DNA-binding proteins. Affinity chromatography (as described in *UNIT 9.6*) is a very effective means of purifying a protein based on its sequence-specific DNA-binding properties, and is relatively straightforward if proper care is taken. The affinity chromatography procedure that is described in this unit uses DNA encoding specific recognition sites for the desired protein that has been covalently linked to a solid support. Researchers in the past have purified proteins based on the proteins' ability to bind DNA, only to be disappointed to find that the DNA-binding activity of their highly purified products was not sequence-specific. This situation can be avoided by carefully performing all of the preliminary steps and experimental controls described in this unit. Figure 9.6.1 provides a summary diagram of the entire chromatography procedure. With this procedure, a high degree of purification can be achieved using a DNA affinity column.

A similar degree of purification can be accomplished using biotinylated DNA fragments that contain the desired protein binding site and streptavidin-coated column matrices (*UNIT 9.7*). This purification scheme, outlined in Figure 9.7.1, utilizes the tight and nearly irreversible binding that occurs between biotin and streptavidin to fish out specific DNA binding proteins from crude cellular or nuclear lysates. After washing, the protein of interest is eluted with high-salt buffer. This protocol is relatively easy to optimize by following the success of the isolation using gel mobility-shift assays; it is also economical, as a single type of column matrix is compatible with any biotinylated DNA probe.

In summary, affinity chromatography at its best is the most powerful technique for protein purification available, because its high selectivity can, in principle, permit purification of a desired protein from a crude mixture of proteins in a single step. Moreover, the technique usually offers simultaneous concentration of the desired protein.

John E. Coligan

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Lectin Affinity Chromatography

Lectin affinity chromatography is the most frequently used specific purification procedure for glycoproteins. A protein is bound to an immobilized lectin through its sugar chain, the unbound protein is washed away, and the bound protein is eluted. Numerous plant lectins have been identified and in many cases their sugar specificity is known. This sugar specificity is the basis for the separation and structural analysis of many individual oligosaccharides and glycopeptides (Chapter 12) and for the identification of lectin-binding glycoproteins. Glycoproteins often contain multiple chains of a given sugar type; the resulting multiple interactions with the immobilized lectin may make it difficult to elute some of the proteins from the lectin column. The presence of multiple low-affinity sugar chains can still produce substantial interaction with a lectin-containing column even though individual sugar chains may have a low affinity. Thus, only limited information on the structure of a sugar chain can be obtained from the binding of a protein to a lectin column. These qualifications by no means belittle the usefulness of lectin affinity chromatography for glycoprotein purification; lectin affinity chromatography may be used to partially purify glycoproteins and to provide limited qualitative information about the nature of their carbohydrate components. Other preparative purification steps, such as ammonium salt precipitation and gel-filtration and ion-exchange chromatographies (*UNIT 8.2 & UNIT 8.3*), are usually done prior to using lectins, but this is not necessary.

Many different lectins are commercially available in an immobilized form suitable for glycoprotein purification, but some can be rather expensive. Con A–Sepharose is the most commonly used lectin for glycoprotein purification. It is relatively inexpensive, stable, and able to bind to many different glycans. Bound proteins can be eluted with α-methyl-D-mannoside (αMM). Wheat germ agglutinin (WGA) is the next most popular lectin for the same reasons although it is somewhat more expensive.

Many other lectins can be used to purify glycoproteins. A broad range of immobilized lectins is available from E-Y Labs, Vector, Sigma, and Pharmacia Biotech (*SUPPLIERS APPENDIX*). Most are also available in free form, if desired. However, this array of lectins is never used for routine protein purification. First, their higher price, shorter track records, and, in some cases, requirement for exotic sugars to elute bound proteins make them less popular for routine use. Second, the time and cost of screening and optimizing conditions for so many lectins would be prohibitive. Third, many have very similar specificities. Fourth, even using a battery of lectins to purify a protein would not yield a single species, since other proteins with similar sugar chains would copurify. Although these other lectins are less frequently used, the principles of Con A–Sepharose and WGA–agarose lectin affinity chromatography apply to them as well.

The names, sugar specificity, elution conditions, and general types of sugar chains that bind to 25 different lectins are given in Table 9.1.1. This table is not comprehensive (there are at least twice as many lectins commercially available), but those listed are the most commonly used. The list is intended as a guide to possible alternatives, and an attempt has been made to group lectins of similar specificities together. However, specificities are not always hard and fast, and the comments in the table are not always sacrosanct. Some lectin–ligand binding requirements are well characterized, but many of the "rules" for lectin sugar specificity are based on screening simple sugars to inhibit lectin binding. These competitors can mimic only limited features of the binding of a lectin to its natural ligand. For instance, both pea and lentil lectins bind only sugar chains with α-fucose residues in the core region of N-linked chains, and yet mannose, not fucose, is used to elute bound proteins. Cummings (1994) provides an excellent perspective on the use of lectins.

Table 9.1.1 Lectins Useful for Glycoprotein Purification

Acronym (organism and source)	Metal ions required	Sugar specificity[b]	Elution conditions	Useful for binding
Con A (*Canavalia ensiformis;* jack bean seeds)	Ca^{2+}, Mn^{2+}	α-Man > α-Glc	0.1–0.5 M α-MeMan	High-Man, hybrid, and biantennary N-linked chains
LCA or **LCH** (*Lens culinarus;* lentil seeds)	Ca^{2+}, Mn^{2+}	α-Man > α-Glc	0.1–0.5 M α-MeMan	Bi- and triantennary N-linked chains with Fucα1-6 in core region
PSA (*Pisum sativum;* peas)	Ca^{2+}, Mn^{2+}	α-Man	0.1–0.5 M α-MeMan	Similar to LCA/LCH
WGA (*Triticum vulgaris;* wheat germ)	Ca^{2+}, Mn^{2+}	β-GlcNAc	0.1–0.5 M GlcNAc	GlcNAc- and Sia-terminated chains, or clusters of *O*-GlcNAc; succinylated form selectively binds GlcNAc>Sia
RCA (*Ricinus communis;* castor bean)				
RCA-I[a]	—	β-Gal β-GalNAc	0.1–0.5 M Gal or lactose	Galβ1-4 on N-linked chains; can also bind β-GalNAc
RCA-II[a]	—	β-Gal	0.1–0.5 M Gal	β-GalNAc-terminated chains.
PHA (*Phaseolus vulgaris;* red kidney bean)				
E_4PHA	—	GalNAc	0.1–0.5 M GalNAc	Gal-terminated N-linked chains with "bisecting" GlcNAcβ1-4
L_4PHA	—	GalNAc	0.1–0.5 M GalNAc	Tri- and tetrabranched N-linked chains
GSL-1, BSL-1 [*Griffonia (Bandeiraea);* Simplicifolia seeds]	Mg^{2+}, Ca^{2+}	α-Gal α-GalNac	0.1–0.5 M melibiose	Chains terminated by α-Gal residues
DSA (*Datura stramonium;* Jimsonweed seeds)	—	Galβ1-4GlcNAc	0.1–0.5 M GlcNAc or 20 mM *N,N′,N″*-chitotriose	Proteins with poly-*N*-acetyllactosamine-containing chains; highly heterodispersed glycoproteins often contain variable lengths of this repeat
LEL (*Lycopersicon esculentum;* tomato meat)	—	β-GlcNAc	0.1–0.5 M β-GlcNAc or 20 mM chitobiose or chitotriose	Similar to DSA; prefers longer poly-*N*-acetyllactosamines than DSA
STL (*Solanum tuberosum;* potato tubers)	—	β-GlcNAc	0.1–0.5 M GlcNAc or 20 mM chitobiose or chitotriose	Proteins with poly-*N*-acetyllactosamines
MAL (*Maackia amurensis;* seeds)	—	Siaα2-3Galβ1-4 GlcNAc	0.5 M lactose	α2-3-linked Sia to Gal in N-linked sugar chains; underlying sugars and peptide contribute to binding

Table 9.1.1 Lectins Useful for Glycoprotein Purification, continued

Acronym (organism and source)	Metal ions required	Sugar specificity[b]	Elution conditions	Useful for binding
EBL or **SNA** (*Sambucus nigra;* elderberry bark)	—	Siaα2-6Gal or GalNAc	0.1–0.5 lactose	α2-6-linked Sia in N and O sugar chains
LFA (*Limax flavus;* garden slug)	—	Neu5Ac	10 mM Sia	Sia-terminated chains irrespective of linkage
GNL (*Galanthus nivalis;* snowdrop bulbs)	—	α1-3Man	0.5 M α-MeMan	High-Man-type chains, but not to Glc
UEA-I (*Ulex europaeus;* furze gorse seeds)	—	α-L-Fuc	0.1–0.5 M L-Fuc or methyl-α-L-Fuc	Sugar chains with terminal α-Fuc, especially in α1-2 linkage, but much less with α1-3 or α1-6 linkages
AAA (*Anguilla anguilla;* freshwater eel)	—	α-L-Fuc	0.1–0.5 M L-Fuc	Similar to UEA-I but more broadly binds any fucosylated oligosaccharide
Lotus (*Lotus tetragonolobus;* asparagus pea)	—	α-L-Fuc	0.1–0.5 M L-Fuc	Outer-branch α-Fuc residues; does not bind when Fuc is linked to chitobiose core of N-linked chains
HPA (*Helix promatia;* albumin gland of edible snail)	—	α-GalNAc	0.1–0.5 M GalNAc	Proteins with terminal α-GalNAc or GalNAcα-*O*-Ser/Thr (Tn antigen)
Jackalin (*Artocarpus integrifolia;* jackfruit seeds)	—	α-Gal	0.1–0.2 M melibiose	Proteins with only a single O-linked chain with T antigen Galβ1-3GalNAcα-*O*-Ser/Thr can bind; not inhibited by lactose; Sia in chain does not interfere with binding
VVL or **VVA** (*Vicia villosa;* hairy vetch seeds)	—	GalNAc	0.1–0.5 M GalNAc	Proteins with Tn antigen, GalNAcα-*O*-Ser/Thr
SBA (*Glycine max;* soybean)	—	GalNAc or Gal	0.1–0.5 M GalNAc	α- or β-linked GalNAc
PNA (*Arachis hypogaea;* peanut)	—	Galβ1-3GalNAc	0.1–0.5 M lactose	Proteins with T antigen, but does not bind if sugar chain is sialylated
DBA (*Dolicholos biflorus;* horse gram seeds)	—	Terminal α-GalNAc	0.1–0.5 M GalNAc	Terminal α-GalNAc (specific for blood group A), not those in the core of O-linked chains
LBA (*Phaseolus lunatus;* lima bean)	Mn^{2+}, Ca^{2+}	Terminal α-GalNAc	0.1–0.5 M GalNAc	Proteins with blood group A structure GalNAcα1-3(Fucα1-2)Gal–

[a]*CAUTION:* Both RCA-I and RCA-II are extremely toxic, with lethal doses of 1 molecule/cell.

[b]Abbreviations: Fuc, L-fucos; Gal, D-galactose; GalNAc, *N*-acetyl-D-galactosamine; Glc, D-glucose; GlcNAc, *N*-acetyl-D-glucosamine; Man, D-mannose; Neu5Ac, *N*-acetyl-D-neuraminic acid; Sia, sialic acid.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

In general, these immobilized lectins can be used in two ways. First is as an affinity step for routine purification. If a novel protein may be glycosylated, using several lectins that bind very different types of sugar structures (N-linked vs. O-linked) will probably give reasonable purification. It will also give some indication of the type of sugar chains on the protein. Both Vector and E-Y Labs sell kits with six or seven different lectins for this purpose. The second and more systematic approach is useful for better-characterized glycoproteins. Here, the lectins are chosen to resolve potentially different glycoforms that may have different biological activities. An excellent example of this second type of analysis is given by Li and Jourdian (1991).

The Basic and Alternate Protocols describe the use of lectins for preparative glycoprotein purification. Con A–Sepharose and WGA–agarose were chosen for convenience and availability. The Support Protocol describes a small-scale pilot procedure to test for lectin binding and to determine elution conditions. There are many variations on the basic procedure in the literature, but all use the same principles: bind the protein to immobilized lectin through its sugar chain, wash away unbound protein, and elute bound protein with a simple sugar that resembles the sugar ligand of the bound protein. Because many proteins have sugar chains that can bind to a specific lectin, this procedure seldom yields a pure protein.

BASIC PROTOCOL

CON A–SEPHAROSE AFFINITY CHROMATOGRAPHY

Con A–Sepharose chromatography is used to partially purify glycoproteins that contain terminal mannose or glucose residues. The steps presented below give typical conditions for this type of chromatography, although a variety of approaches have been utilized. In this protocol, bound glycoproteins are eluted with α-methyl-D-mannoside (αMM) after the column is first washed to remove unbound and weakly bound proteins. Before proceeding, it is advisable to conduct a pilot study to test the protein of interest for lectin binding and elution conditions (see Support Protocol). In order to purify the protein effectively, a specific assay for detecting the protein of interest (i.e., activity or antibody-binding assay) must be available.

Materials

10 mg/ml Con A–Sepharose (Pharmacia Biotech or Sigma)
Column buffer (see recipe)
0.5 M αMM in column buffer
Protein sample in column buffer

1.5 × 30–cm glass or disposable chromatographic column
Glass wool

NOTE: Carry out this procedure at room temperature if the protein to be isolated will tolerate this condition. If not, carry it out in a cold room, and prechill all solutions to maintain temperature.

1. Gently resuspend 50 ml settled Con A–Sepharose (10 mg lectin/ml packed resin) in 50 ml column buffer to make a slurry. Degas the slurry.

   This volume of lectin beads should be sufficient to bind ~100 mg glycoprotein. If a 1.5 × 30–cm column is not available, either the dimensions of the column or the total amount of resin can be modified. A 1.0 × 30–cm column will bind ~50 mg total glycoprotein. If the amount of glycoprotein in the sample is substantially less than 50 to 100 mg, decrease the volume of the column accordingly. The ratio of input protein to lectin does not seem to matter as long as the column is not overloaded.

BCU IASTOCENTRAL UNIVERSITY LIBRARY

2. Pack a glass wool plug over a sintered glass or polypropylene frit at the bottom of the column and pour the degassed slurry into the column.

   The glass wool prevents the beads from clogging the frit and slowing the flow rate. Alternatively, BioGel P2 or Sephadex G10 can be used in place of the glass wool.

3. Continue packing the column until the desired level is reached (for a 50-ml volume this is ~28 cm). Wash the gel with 2 to 3 column volumes of column buffer to remove any loosely bound or degraded Con A.

4. Wash with 2 to 3 column volumes of 0.5 M αMM in column buffer or the highest concentration of αMM that will be used.

5. Wash the column with >5 column volumes of column buffer *without* αMM to reequilibrate.

   It is important to prewash the column with the eluting sugar and then to reequilibrate the column to remove any materials that may have previously bound to the column. Check completeness of washing by phenol–sulfuric acid assay (Manzi, 1993). Estimate the amount of residual sugar using αMM as a standard. An acceptable level is <0.1 mM or ~20 μg/ml.

6. Slowly load the protein sample on the column to permit binding without disturbing the surface.

   A flow rate of ~1 ml/min (~0.5 ml/min/cm^2 of area) is desirable.

7. Wash the column with column buffer and monitor the flowthrough and subsequent wash fractions by measuring the A_{280} until it approaches baseline value.

   If the A_{280} does not rapidly return to baseline, it may indicate weak interaction of some proteins with the lectin, or overloading of the column.

8. Using an appropriate specific assay, check flowthrough and wash fractions for the presence of the protein of interest (e.g., enzyme activity or antibody binding).

   To check the lectin-binding properties, see Support Protocol. To determine whether the column was overloaded, add a small amount of the flowthrough (1%) to a small volume of beads as described in the Support Protocol. If the sample is bound to the beads as determined by the appropriate assay, overloading of the original column is indicated. In this case, reapply the flowthrough with excess glycoprotein to the larger column after the bound proteins of the first run have been eluted with αMM and the column reequilibrated.

9. Elute the column with 0.5 M αMM in column buffer. Monitor fractions for A_{280} and for activity (using specific assay) and pool peak-activity fractions.

   Very broad peaks may result during elution with the sugar if the protein dissociates very slowly. When this happens, sample recovery can be improved by filling the column with 0.5 M αMM in column buffer and allowing the column to stand for a few hours. This allows dissociation of the bound material; when the flow is started again, it should give a very sharp peak. Other possible remedies include warming a cold column to room temperature in the presence of αMM, increasing the concentration of αMM to 1 M, or increasing the NaCl concentration to 1 M. A combination of these approaches may be needed to elute a tightly bound protein.

10. Regenerate the column by washing it with 10 vol column buffer or until the αMM concentration is <20 μg/ml.

    The column may now be used for another run or stored indefinitely at 4°C in column buffer containing 0.02% (w/v) NaN_3. Reequilibrate in column buffer before using again.

BOWLING GREEN STATE UNIVERSITY LIBRARY

PILOT STUDY TO DETERMINE LECTIN BINDING AND ELUTION CONDITIONS

If the target protein can be detected easily, test a small sample to establish binding and elution conditions before applying the entire sample to a large column. The easiest approach is to mix a small amount of sample with a measured amount of Con A–Sepharose beads in a series of microcentrifuge tubes. If the material in the sample binds, elute it from the washed beads with various amounts of competing αMM to determine when the activated material is eluted into the supernatant. This shows whether binding occurs and what concentration of competing sugar (or other conditions) will be required to elute it from the column. An abbreviated version of this procedure can be done with a single sample to determine if the protein binds and if it can be eluted with only one concentration (0.75 M) of αMM. It is important to keep the temperature constant, because changes can affect binding and dissociation of the ligands.

Additional Materials (also see Basic Protocol)

Sepharose 4B (Pharmacia Biotech) or other beaded gel to fill space in the tubes
αMM: 0, 0.1, 0.2, 0.4, 0.8, 1.0, and 1.5 M concentrations, in column buffer

1. Prepare a 50% slurry of Con A–Sepharose in column buffer. Cut ~2 to 3 mm off the small end of a 1000-µl pipet tip. Resuspend the slurry immediately before each pipetting, and use the truncated tip to dispense 200 µl of slurry into a series of seven microcentrifuge tubes. Add an equal volume of 50% slurry of Sepharose 4B to one tube (to serve as no-lectin control). Allow gel to settle to see if the dispensing was reasonably accurate.

   Gel material is needed in the controls to account for the volume changes caused by adding the gel. Other nonionic beaded gels, such as Sephadex (Pharmacia Biotech) or Bio-Gel (Bio-Rad) may be substituted.

2. Add the protein sample in 50 µl column buffer and allow 15 min for binding (shake the tube occasionally). Microcentrifuge the gel beads 1 min at 1000 × *g* to sediment. Remove the supernatant and save for analysis (step 6).

3. Use an appropriate assay specific for the protein of interest to determine if it binds to Con A–Sepharose and not to control beads.

4. Wash gel beads by adding 1.4 ml column buffer, microcentrifuging 1 min at 1000 × *g*, and removing supernatant (save for analysis). Repeat wash twice more.

5. Resuspend gel beads in 200 µl of buffer containing 0, 0.1, 0.2, 0.4, 0.8, 1.0, or 1.5 M αMM for each of the seven tubes containing Con A–Sepharose. Add the same volume of column buffer or 1.5 M αMM in column buffer to the control.

6. Incubate 15 min and centrifuge the gel beads 1 min at 1000 × *g*. Remove supernatant. Analyze the supernatant (along with those from steps 2 and 4) using the appropriate detection assay to determine if the protein has been eluted and at what concentration of competing sugar this occurred.

   Increasing the concentration of αMM should elute the target protein from the Con A–Sepharose. If it is not eluted, longer incubation (10 hr) in the presence of αMM or higher temperature may be needed. Although the entire procedure can be done in the cold, binding is tighter at low temperature, and this may make elution more difficult. Once the conditions are established for a particular sample or a lectin, scaling up the preparation for the basic protocol is normally routine.

BCU IASI CENTRAL UNIVERSITY LIBRARY

WHEAT GERM AGGLUTININ (WGA)–AGAROSE AFFINITY CHROMATOGRAPHY

ALTERNATE PROTOCOL

WGA-agarose chromatography is used to purify proteins that contain terminal *N*-acetyl-D-glucosamine (GlcNAc) or sialic acid residues. A protein sample is applied to the column, the column is washed to remove unbound and weakly bound proteins, and bound glycoproteins are eluted with GlcNAc. The advice for purification of glycoproteins on Con A–Sepharose columns applies to columns containing immobilized WGA. Test the binding of the target protein to the lectin using a pilot study like that for Con A–Sepharose (see Support Protocol) before running a large column, substituting GlcNAc for the αMM.

Additional Materials (also see Basic Protocol)

5 mg/ml wheat germ agglutinin (WGA)–agarose (E-Y Labs, Pharmacia Biotech, or Sigma)
PBS (*APPENDIX 2E*)
0.1 M *N*-acetyl-D-glucosamine (GlcNAc) in PBS
Protein sample in PBS
1.0 × 10–cm glass or disposable column (or other column whose length is 10 times its diameter)

1. Resuspend 1 vol WGA–agarose in 2 to 3 vol PBS to make a slurry.

   One milliliter of gel should be enough to bind 1 to 2 mg glycoprotein. To be safe, assume ~5% to 10% of total cell lysate can bind. If target protein requires detergent to solubilize it, WGA is still active in 25 mM Tris·Cl (pH 7.5)/1% Lubrol PX/0.1% sodium deoxycholate. Triton X-100 or Nonidet P-40 (~2% to 3% v/v final) may also be used.

2. Place a glass wool plug over the frit at the bottom of a column whose length is 10 times its diameter. Pour the slurry into the column. Wash the column with ~2 column volumes of PBS to remove any unbound or degraded WGA, then wash with 1 column volume PBS containing 0.1 M GlcNAc. Finally, wash with 5 column volumes PBS.

   The length of the column should be ~10 times its diameter so that weakly bound proteins can be eluted by prolonged PBS wash in the absence of any competing sugar. This will separate them from proteins that do not interact, and differs from using Con A–Sepharose, where continued buffer wash in the absence of αMM does not usually elute weakly bound protein. The choice of these column dimensions for WGA and for most other lectins is based on the successful fractionation of individual glycopeptides by serial lectin affinity chromatography.

   A plug of BioGel P2 or Sephadex G10 can be used in place of the glass wool.

3. Add protein sample in ~0.1 column volumes at a flow rate of ~2 ml/cm^2 per hour, and wash the column with PBS until the A_{280} returns to baseline.

   A small sample volume makes it easier to detect proteins that do not bind to the column and elute promptly as a sharp peak in the flowthrough. Proteins that bind weakly to the column are gradually washed off by continued elution with PBS alone; these proteins would "smear" as a trailing peak. If a preliminary test run shows that the target protein binds strongly to the lectin, and if the column is not overloaded, the sample can be added to the column in a larger volume. The flow rate can be varied. Sometimes the protein of interest can be absorbed to the lectin by gently mixing the two components for several hours before pouring the loaded gel into the column. The protein can then be eluted after washing as determined by the pilot study.

4. Elute the column with 2 to 3 column volumes of 0.1 M GlcNAc in PBS, and assay the fractions for the protein of interest.

   Generally, 0.1 M GlcNAc is sufficient to elute the protein. If this does not work, try a higher concentration (e.g., up to 0.25 M GlcNAc), temporarily turn off the column, or

BOSTON COLLEGE UNIVERSITY LIBRARY

raise the temperature to elute the sample, as with Con A–Sepharose. Adding 0.5 M NaCl to the GlcNAc-containing elution buffer can sometimes improve recovery. A pilot study to determine elution conditions, similar to that described for Con A–Sepharose (see Support Protocol), is highly recommended.

5. Regenerate the column by washing with ≥10 column volumes of PBS or until reducing sugar content is below 20 µg/ml. The column can be reused immediately or stored at 4°C in column buffer containing 0.02% (w/v) NaN_3.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Column buffer

0.01 M Tris·Cl, pH 7.5
0.15 M NaCl
1 mM $CaCl_2$
1 mM $MnCl_2$
Store indefinitely at room temperature

Prepare $MnCl_2$ within a day or two of use and add it to the buffer only after the pH has been adjusted. The final concentration of metal ions can be decreased 10-fold or more if needed.

If detergents are required to solubilize the protein, either Triton X-100 or Nonidet P-40 at ≤2% has a negligible effect on lectins. Do not use glucoside-based detergents because they may interfere with binding.

COMMENTARY

Background Information

See the introductions to *UNIT 12.1* and this unit for discussions concerning properties of glycoproteins that relate to their purification.

Critical Parameters

As with most protein purification procedures, successful lectin affinity chromotography is empirical, so few parameters are written in stone. However, in using lectins, it is important to first determine the binding and elution conditions in a pilot study. Blindly loading a sample onto a column and then trying different elution conditions may give very low yields, either because the protein becomes inactivated or because it cannot be eluted under those particular conditions. It is usually easy to bind the protein to the column, but elution may be more difficult. There are numerous ways to elute tightly bound protein: increase the concentration of sugar in the buffer used for elution, increase temperature, increase NaCl concentration, or stop the column flow for an extended period during the elution with sugar. A combination of these approaches may be needed.

These modifications may cause a protein to elute differently from the same column. Thus, it may be useful to perform two consecutive runs with different elution conditions to separate the protein of interest from different contaminants. Ketcham and Kornfeld (1992) describe the purification of a rare glycosyltransferase using WGA, whereby the lectin affinity chromatography step yielded a 160-fold purification. In addition, environmental carbohydrate contamination may contribute significantly to the total quantity of carbohydrate in a preparation. Follow the suggestions given within the protocols to minimize this effect.

A few general points to remember. Most lectin–sugar binding relies on hydrophobic interactions, so moderate (0.2 M) to high (0.6 M) salt concentrations do not prevent binding. A high salt concentration also reduces nonspecific protein binding. Similarly, tightly bound proteins may be eluted by including 50% ethylene glycol with the sugar. The strength of lectin binding can be significantly affected by the density of lectins on the beads. Usually 3 to 5 mg/ml will bind most proteins, but binding individual free sugar chains may require a higher concentration. Most useful lectins are supplied already bound to beads. If you must couple your own, CNBr-activated Sepharose 4B or Affi-Gel 10 (Bio-Rad) are good supports. Be sure to include any required metal ion and 0.2 M of the eluting sugar during the coupling.

BCU IAS / CENTRAL UNIVERSITY LIBRARY

This will help generate the active conformation and prevent coupling the lectin through the sugar-binding site. Also, keep the soluble lectin concentration below 10 mg/ml during coupling or some may precipitate. Finally, do not couple free *Ricinus communis* II (RCA-II) from castor beans in your own lab because it is deadly: the LD_{50} in mice is 0.8 μg/100 g body weight. For all lectin column runs avoid high concentrations (>1%) of nonionic detergents or any SDS.

Anticipated Results

Lectins can give 2- to >100-fold purifications of glycoproteins and nearly quantitative yields, depending upon the source of the sample and the elution conditions. If the protein of interest is reasonably stable at high salt concentrations and room temperature, specific elution conditions can likely be found that will produce good yields.

Time Considerations

Initial determination of the binding and elution conditions can easily be done in 1 day, assuming the detection assay for the target protein is simple and fast. The amount of time needed to conduct a single run once the elution conditions are known can vary depending upon the size of the sample and the column, and whether elution requires long-term incubation in the presence of the sugar. Even assuming the extremes of sample size and elution conditions, a single run should be completed in 2 to 3 days.

Dye Affinity Chromatography

Dye affinity chromatography is a protein purification procedure based on the high affinity of immobilized dyes for the binding sites on many proteins. It is a rapid, inexpensive, and versatile method that is applicable to the purification of crude cellular extracts.

There are three types of dye affinity chromatography—negative chromatography, positive chromatography, and tandem chromatography. Negative chromatography (Basic Protocol 2) is the simplest of the three procedures. Some of the undesired proteins are retained by the immobilized dye while the remaining proteins, including the desired protein, flow through the column. This results in a modest-fold purification. Negative chromatography is particularly convenient for the rapid removal of degradative enzymes such as proteases and nucleases, and for the removal of very abundant proteins, such as serum albumin. A different immobilized dye is used for positive chromatography (Basic Protocol 3 and Alternate Protocol 2). This immobilized dye retains the desired protein as well as some undesired proteins. The desired protein is then selectively eluted using either a nonspecific reagent, such as a neutral salt, or a specific reagent, such as a substrate, cofactor, or competitive inhibitor. Although positive chromatography requires more investigator involvement, it results in a greater-fold purification than obtained using negative chromatography, and is more commonly used. In some cases, a desired protein can be purified to homogeneity from a crude cellular extract using positive chromatography.

In tandem chromatography (Basic Protocol 4), the most elaborate of the three procedures, negative chromatography and positive chromatography are coupled sequentially. The protein mixture first passes through a column containing the immobilized dye chosen for negative chromatography. The desired protein flows through this column and immediately enters another column containing the immobilized dye chosen for positive chromatography. The desired protein, which is retained by the latter column, is then eluted using either batch or gradient elution. Tandem chromatography is particularly useful for situations in which the immobilized dye used for positive chromatography binds too many undesired proteins, making selective elution of the desired protein difficult.

Use of dye affinity chromatography for protein purification requires selection of one or more immobilized dyes. In addition, positive chromatography requires selection of an elution reagent and its effective concentration. These selections can be made using chromatography, as outlined in Basic Protocol 1, or using centrifugation, as outlined in Alternate Protocol 1, depending on the inclination of the investigator. Immobilized dyes can be purchased as dry powders or suspensions or already poured into miniature columns in kit form. Free dyes also can be purchased and easily immobilized by the investigator (Support Protocol). Alternate Protocol 1 facilitates selection because many samples can be processed simultaneously, but is more expensive because more immobilized dye is required.

SELECTION OF COMPONENTS USING CHROMATOGRAPHY

BASIC PROTOCOL 1

The immobilized dye for negative or positive chromatography and the eluant for positive chromatography can be selected using a chromatographic procedure. A small volume of the protein mixture to be purified is applied to a series of miniature columns, each containing a different immobilized dye. The flowthrough and washes from each column are pooled and analyzed for total protein and for desired protein. The immobilized dye column whose pooled flowthrough and washes contain the least amount of undesired protein and the greatest amount of desired protein is appropriate for negative chromatography. Conversely, the immobilized dye column whose pooled liquid contains the greatest

Copyright © 1995 by John Wiley & Sons, Inc.

BYU/CENTRAL UNIVERSITY LIBRARY

amount of undesired protein and the least amount of desired protein is appropriate for positive chromatography.

The immobilized dye column chosen for positive chromatography is used to select the elution reagent and its effective concentration. The column is washed with small volumes of a potential elution reagent, with the concentration of the reagent increased in small increments in each successive wash. The flowthrough for each wash is then analyzed for both total protein and desired protein. Additional potential elution reagents are examined following application of a fresh aliquot of the protein mixture to be purified. The concentration of elution reagent that provides the greatest-fold purification, recovery of desired protein, and economy of use is selected to be the elution solvent. A specific elution reagent will generally provide a greater increase in fold purification than a nonspecific elution reagent, but the specific elution reagent may cost more.

Materials

Protein mixture to be purified
Appropriate application solvent (see step 1)
Series of immobilized dyes (Table 9.2.1 and Support Protocol)
Concentrated solution of an appropriate elution reagent (see step 11)
Plastic disposable filtration unit with pore size ≤0.45 μm
Small plastic disposable chromatography tubes with bed volume at least 1 ml

[a]Screening kits containing between 5 and 40 immobilized dyes in miniature chromatography columns can be purchased from Affinity Chromatography, Amicon, Wako Pure Chemical, and Sigma. Alternatively, free reactive dyes such as those listed in Table 9.3.2 can be purchased, immobilized, and prepared for chromatography as described in the Support Protocol.

[b]Supplier names and addresses are provided in *SUPPLIERS APPENDIX*.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Prepare protein sample for application to column

1. Prepare the crude protein mixture. If it is a solid, dissolve it in the application solvent. If the protein mixture to be purified is a suspension or a solution, dialyze it for several hours against the application solvent.

   A generic application solvent is 50 mM Tris·Cl buffer, pH 7.5, at room temperature. The identity of the buffer, its pH, and the temperature of the application solvent may be varied to maintain the integrity of the desired protein without compromising the chromatography. However, addition of reagents that increase the ionic strength of the application solvent above 50 mM may diminish retention of all proteins by the immobilized dye columns. Addition of millimolar concentrations of one or more specific reagents that bind to the desired protein to maintain its integrity may diminish the retention of the desired protein by the immobilized dye columns.

2. Clarify the protein mixture, if necessary, either by centrifugation or filtration.

   Filtration should be performed using a plastic disposable filtration unit having a pore size of ≤0.45 μm.

3. Determine the amount of total protein and the amount of desired protein in 1 ml of the protein mixture.

Prepare assortment of immobilized dye columns

4. Pour a sufficient volume of each immobilized dye suspension into a different chromatography tube to form a bed volume of 1 ml in each tube.

   Most commercial screening kits of immobilized dyes are supplied as chromatographic columns having bed volumes ranging from 0.1 to 2.5 ml; these may be used without alteration. The optimal bed volume for a particular situation depends on the total volume of the crude protein mixture available to the investigator; the greater this total volume, the more that can be used. The volume of available crude protein mixture is the principal reason the bed volumes of individual columns in the commercial kits range from 0.1 to 2.5 ml.

   If one or more of the immobilized dyes are available in powdered form, suspend about 0.5 g of each powdered immobilized dye in application solvent for at least 30 min with gentle stirring prior to pouring the columns.

5. Wash each immobilized dye column with 2 bed volumes of chromatographic application solvent. Let the column run dry and discard the washes.

Perform chromatography and assess column performance

6. Apply the same volume of protein mixture to each immobilized dye column and collect the flowthrough in a container.

   The volume of protein mixture added should contain between 5 and 40 mg of total protein per milliliter of bed volume and sufficient desired protein (1% of total protein) for convenient analysis. The flowthrough can be collected in a disposable tube of sufficient volume to contain the application volume and 2 bed volumes of wash.

7. Wash each immobilized dye column with 2 bed volumes of application solvent and collect the flowthrough in the same container used in step 6.

8. Measure the concentrations of the total protein and the desired protein in the combined flowthrough from each column.

9. Compare the amount of total and desired protein in the combined flowthrough from each column.

   The immobilized dye whose combined flowthrough contains the least amount of total protein and the greatest amount of desired protein is most appropriate for negative chromatography (see Basic Protocol 2). The immobilized dye whose combined

BCU MSU ET TRAU UNIVERSITY LIBRARY

flowthrough contains the greatest amount of total protein and the least amount of desired protein is most appropriate for positive chromatography (see Basic Protocol 3 or Alternate Protocol 2).

If positive chromatography is to be performed, continue to use only the immobilized dye column selected for positive chromatography. This column should still retain the desired protein.

Elute desired protein from positive chromatography column

10. Wash the immobilized dye column whose flowthrough contained the least amount of desired protein (i.e., the column selected for positive chromatography) with 2 bed volumes of application solvent containing the lowest concentration of the elution reagent selected for testing. Collect the flowthrough in a separate container.

    A typical nonspecific elution reagent is NaCl, beginning with a lowest concentration of 0.1 M. A typical specific elution reagent is a substrate, cofactor, inhibitor, effector, or ligand, beginning with a lowest concentration of 1 μM. The specific elution reagents chosen for testing should represent a good compromise between availability, economy, and high affinity for the desired protein.

11. Measure the total protein and the total desired protein in the flowthrough.

12. Increase the concentration of the elution reagent in the application solvent by increments and repeat steps 10 and 11.

    A representative increment for a nonspecific elution reagent is 0.2 M and that for a specific elution reagent is an order of magnitude.

    The application solvent containing the lowest concentration of a reagent that elutes at least 80% of the desired protein retained by the immobilized dye column is defined as the elution solvent.

    If alternative elution reagents are to be investigated for reasons of economy or availability, proceed with steps 13 to 15.

Repeat elution using alternative elution solvent (optional)

13. Wash the immobilized dye column selected for positive chromatography with 2 bed volumes of 2 M NaCl followed by 2 bed volumes of application solvent and discard the flowthrough.

14. Reapply a volume of the protein mixture as described in step 6 and wash with two column volumes of application solvent. Discard the flowthrough.

15. Repeat steps 10 to 12 using alternative elution reagent.

ALTERNATE PROTOCOL 1

SELECTION OF COMPONENTS USING CENTRIFUGATION

The immobilized dye for negative or for positive chromatography and the eluant for positive chromatography can also be selected using a centrifugation procedure instead of the chromatography procedure described in Basic Protocol 1. A different immobilized dye is placed in a series of microcentrifuge tubes. The supernatant solution is discarded from each tube and replaced with a small volume of the protein mixture. The contents of each tube are mixed and centrifuged and the supernatants analyzed for the amount of total protein and desired protein. The immobilized dye whose supernatant contains the least amount of total protein and the greatest amount of desired protein is most appropriate for negative chromatography. Conversely, the immobilized dye whose supernatant contains the greatest amount of total protein and the least amount of desired protein is appropriate for positive chromatography. To select an elution reagent for positive chromatography, the same amount of the immobilized dye selected for positive chromatography is added to a series of microcentrifuge tubes. The protein mixture is added to each tube and the

BCU IASH CENTRAL UNIVERSITY LIBRARY

supernatant discarded. A different concentration of a potential elution reagent is added to each tube, mixed, and centrifuged, and each supernatant analyzed for the amount of total protein and desired protein present. Any number of different potential specific and nonspecific elution reagents can be evaluated in this manner. The concentration of elution reagent that provides the greatest-fold purification, recovery of desired protein, and economy of use is selected. The centrifugation procedure allows an investigator to select an elution solvent more expeditiously than does the chromatography procedure because many samples can be processed simultaneously. However, a larger amount of each immobilized dye is required. For a list of materials, also see Basic Protocol 1.

Prepare the protein sample and set up immobilized dye series

1. Prepare protein sample for application to column (Basic Protocol 1, steps 1 to 3).
2. Add a sufficient volume of an immobilized dye suspension to a capped graduated 1.5-ml disposable plastic microcentrifuge tube to bring the solid/liquid boundary to the 0.4-ml mark. Repeat for each available suspension of immobilized dye. Cap each tube and centrifuge at full speed for 1 to 2 min and discard the supernatant.

   If one or more of the immobilized dyes are available in powdered form, suspend about 0.5 g of each powdered dye in application solvent for at least 30 min with gentle stirring prior to adding to the microcentrifuge tubes.

3. Add 1 ml application solvent to each microcentrifuge tube. Cap each microcentrifuge tube and mix its contents by inversion, shaking, or vortexing. Let stand for 30 min to swell the immobilized dye matrix.
4. Centrifuge each tube 1 to 2 min at full speed and discard the supernatant.
5. Add 1 ml application solvent to each tube. Cap each microcentrifuge tube and mix its contents by inversion, shaking, or vortexing. Centrifuge each tube 1 to 2 min at full speed and discard the supernatant.

Apply protein sample to immobilized dye tubes

6. Add the same volume of the protein mixture to each tube.

   The volume of protein mixture should contain between 2.5 and 20 mg of total protein and sufficient desired protein for convenient measurement.

7. Cap each microcentrifuge tube and mix its contents by inversion, shaking, or vortexing. Centrifuge each tube 1 to 2 min at full speed.
8. Measure the amount of total protein and desired protein in each supernatant.

   The immobilized dye whose supernatant contains the least amount of total protein and the greatest amount of desired protein is most appropriate for negative chromatography (see Basic Protocol 2). The immobilized dye whose supernatant contains the greatest amount of total protein and the least amount of desired protein is most appropriate for positive chromatography (see Basic Protocol 3 or Alternate Protocol 2).

Test application solvents for positive chromatography

9. If positive chromatography is to be performed, add a sufficient volume of the immobilized dye suspension selected for positive chromatography to a series of graduated microcentrifuge tubes to bring the solid/liquid boundary in each tube to the 0.4-ml mark.
10. Repeat steps 3 to 6.
11. Construct a series of application solvents each containing concentration of the elution reagent to be tested.

BOU-ASIT-ENTRA- UNIVERSITY LIBRARY

A typical nonspecific elution reagent is NaCl, beginning with a lowest concentration of 0.1 M and increasing in 0.2 M increments. A typical specific elution reagent is a substrate, cofactor, inhibitor, effector, or ligand having a lowest concentration of 1 μM and increasing in order of magnitude increments.

12. Add 1 ml of each application solvent containing the elution reagent to a different centrifuge tube containing immobilized dye. Cap the microcentrifuge tube and mix the contents by inversion, shaking, or vortexing. Centrifuge each tube 1 to 2 min at full speed.

13. Measure the concentration of total protein and of desired protein in each supernatant.

    The application solvent containing the lowest concentration of a reagent that elutes at least 80% of the desired protein retained by the immobilized dye column and that represents a good choice with regard to cost and availability is defined as the elution solvent.

14. Repeat steps 11 to 13 to test additional elution reagents or to refine the concentration of the selected elution reagent, if desired.

BASIC PROTOCOL 2

NEGATIVE CHROMATOGRAPHY

A protein mixture is applied to an immobilized dye column selected for negative chromatography and the column is washed with application solvent. Many of the undesired proteins are retained by the column while the desired protein as well as some of the undesired proteins flow through the column. The concentrations of the total protein and total desired protein in the combined flowthrough are measured. These values should reflect a yield of >80% of desired protein and a modest-fold purification. Negative chromatography is the simplest to execute but, because the desired protein as well as some undesired proteins are not retained and appear in the column flowthrough, it is the least likely to dramatically increase the fold purification of a desired protein. However, it is particularly convenient for the rapid removal of troublesome contaminating proteins such as proteases, nucleases, or serum albumin.

Materials

Protein mixture to be purified
Application solvent, with and without 2 M NaCl
Immobilized dye selected for negative chromatography (see Basic Protocol 1 or Alternate Protocol 1)
0.02% (w/v) sodium azide

Empty chromatographic column with height/diameter ratio ≤5 (sintered glass funnel can suffice)

1. Prepare the protein mixture for chromatography (see Basic Protocol 1, steps 1 to 3).

2. Divide the total protein concentration (in milligrams) to be purified by 5 to estimate the bed volume (in milliliters) of the immobilized dye needed. Add suspension of the immobilized dye to the chromatographic column until that bed volume is acquired.

   Division is by 5 because it is conservatively estimated that each milliliter of column bed volume can retain 5 mg of protein.

   Immobilized dyes may be purchased either as suspensions or as dry powders from commercial sources (see Table 9.2.1). The suspensions are easier to use because they are already swollen; therefore they are the form of choice. If the powdered form of the immobilized dye is used, it should be suspended in an application solvent for about an hour with gentle stirring prior to pouring the column.

BCU IASI CENTRAL UNIVERSITY LIBRARY

3. Wash the column with application solvent until no further dye is eluted.

   The volume of application solution required for washing depends upon the storage of the column. The column matrix slowly but steadily hydrolyzes, generating soluble matrix fragments still containing covalently attached dye molecules. The longer the storage time and the higher the temperature, the greater the amount of solubilized dye. The volume of wash is determined by the investigator; when colored dye stops appearing in the wash, the column is ready for chromatography. This may require 1 or 20 column volumes.

   The presence of the colored dye can be detected in the washing either by visual inspection or by spectrophotometric measurement at an appropriate wavelength.

4. Apply the entire protein mixture to be purified to the immobilized dye column using a flow rate of at least 1 ml/min. Collect the flowthrough liquid in a single container.

   The flow rate is dictated by the size of the column and the density of its packing. A fast flow rate reduces experimental time. Equilibration of protein with immobilized dye is rapid; there is little advantage in using flow rates less than 1 ml/min.

5. Wash the column with 1 column volume of application solvent. Collect the flow-through liquid in the same container as in step 4.

6. Measure the concentration of total protein and total desired protein in the combined flowthrough liquids.

   These values should reflect a good yield, >80% of desired protein, and a modest-fold purification. If the fold purification is less than expected from the results observed using Basic Protocol 1 or Alternate Protocol 1, add more immobilized dye to the column and reapply the combined flowthrough liquids.

7. Wash the column with 1 column volume of application solvent containing 2 M NaCl to displace the retained protein.

   Protein displacement can be ascertained by monitoring the amount of protein in the wash effluent.

8. Prepare the column for storage by washing with 2 column volumes of 0.02% sodium azide and storing the poured column at 4°C.

POSITIVE CHROMATOGRAPHY USING BATCH ELUTION

BASIC PROTOCOL 3

A protein mixture is passed through an immobilized dye column selected for positive chromatography. This immobilized dye retains the desired protein and some of the undesired proteins. The desired protein is then selectively eluted using either a nonspecific or a specific elution reagent (a higher-fold purification will likely be obtained using the specific eluant), and the concentrations of total protein and desired protein in each fraction are measured. This protocol for positive chromatography utilizes batch elution, which is simpler to execute than Alternate Protocol 2 utilizing gradient elution (the latter may yield a higher-fold purification than batch elution but requires more effort to set up).

Materials

Protein mixture to be purified
Appropriate application solvent
Immobilized dye and elution solvent selected for positive chromatography (see Basic Protocol 1 or Alternate Protocol 1)
Empty chromatographic column with height/diameter ratio >5
Fraction collector

1. Prepare protein sample and immobilized dye column (see Basic Protocol 2, steps 1 to 5) using the immobilized dye selected for positive chromatography.

BOSTON COLLEGE CENTRAL UNIVERSITY LIBRARY

2. Measure the concentration of the total protein and the desired protein in the flow-through liquids. If the majority of the desired protein is retained by the column, discard the flowthrough liquid. If a significant amount of desired protein is not retained, add more immobilized dye to the column and reapply the flowthrough liquid.

   Typically, at least 70% and, if possible, 90% or more of the desired protein is retained.

3. Wash the column with the elution solvent selected for positive chromatography using a flow rate of at least 1 ml/min. Collect the flowthrough in a fraction collector in constant-volume fractions, typically 1 ml.

4. Measure the concentration of total protein and desired protein in each fraction.

5. Pool fractions containing the desired protein.

   The specific activity of the desired protein in the fractions can be used to determine which fractions to include in the pool. Typically pool all tubes containing at least 10% of the total amount of desired protein applied to the column.

6. Wash and store the column (see Basic Protocol 2, steps 7 and 8).

ALTERNATE PROTOCOL 2

POSITIVE CHROMATOGRAPHY USING GRADIENT ELUTION

A protein mixture is passed through an immobilized dye column selected for positive chromatography. This immobilized dye retains the desired protein and some of the undesired proteins. The desired protein is selectively eluted using a linear gradient constructed from the elution solvent selected for positive chromatography, and the concentrations of total protein and desired protein in each fraction are measured. This protocol is more elaborate to set up and operate, but sometimes generates a greater-fold purification than obtained using the batch elution system of Basic Protocol 3.

***Additional Materials** (also see Basic Protocol 3)*

Empty chromatographic column having a height/diameter ratio of >5
A coated magnet and magnetic stirrer
Linear gradient maker (commercial or constructed from two beakers of the same size connected by a siphon)

1. Prepare protein sample and immobilized dye column (see Basic Protocol 3, steps 1 and 2).

   All solutions should be carefully introduced so that the column packing is minimally disturbed.

2. Place a volume of the elution solvent selected for positive chromatography in the nonmixing reservoir of the linear gradient maker. This volume is typically equal to the column volume.

   The nonmixing reservoir is the reservoir more distant from the column. Its contents flow into the mixing reservoir prior to introduction onto the column.

3. Place 10% of the volume of elution solvent used in step 2 in the mixing reservoir of the gradient maker. Add application solvent to make up the remaining 90% of the volume.

   This procedure will generate an order-of-magnitude gradient terminating in the eluant concentration employed in batch elution.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

4. Place a magnetic stir bar in the mixing reservoir. Place the mixing reservoir on a magnetic stirrer. Position the nonmixing reservoir so that the bottom of this vessel is adjacent to and coplanar with the bottom of the mixing reservoir.
5. Provide for liquid flow between the two reservoirs and between the mixing reservoir and the column.
6. Gently mix the liquid in the mixing reservoir. Initiate liquid flow between the two reservoirs and between the mixing reservoir and the column. Use a flow rate of 1 ml/min and collect 1-ml fractions.

   Resolution of desired and undesired proteins may be improved by narrowing the concentration range of the specific or nonspecific elution reagent, by increasing the total volume of the elution solutions, or by decreasing the flow rate of the elution solutions.
7. Measure the protein concentrations, pool the appropriate fractions, and wash the column (see Basic Protocol 3, steps 4 to 6).

B. C. U. „M. Eminescu" IAŞI
CHIMIE

TANDEM CHROMATOGRAPHY

BASIC PROTOCOL 4

In tandem chromatography, columns for negative and positive immobilized dye chromatography are sequentially linked. The protein mixture is first passed through the column containing the immobilized dye chosen for negative chromatography, which preferentially removes undesired protein. The effluent from this column is immediately passed over a second column containing the immobilized dye chosen for positive chromatography, which retains the desired protein. The desired protein is then selectively eluted from the second column using either batch or gradient elution and the elution solvent selected for positive chromatography.

Materials

Protein mixture to be purified
Appropriate application solvent
Immobilized dyes selected for negative and for positive chromatography (Basic Protocol 1 or Alternate Protocol 1)
Selected elution solvent
2 M NaCl
0.02% (w/v) sodium azide

Empty chromatographic column with height/diameter ratio >5 (two columns are required if positive chromatography is to be performed using batch elution)
Empty chromatographic column with height/diameter ratio ≥5 (if positive chromatography is to be performed using gradient elution)
Linear gradient maker (for gradient elution)
Fraction collector
Pipettors and disposable tips

Prepare the protein sample and columns

1. Prepare the protein mixture for chromatography (see Basic Protocol 1, steps 1 to 3).
2. Prepare the negative and positive columns (see Basic Protocol 2, steps 2 and 3).

   The immobilized dye selected for negative chromatography is placed in a column with a height/diameter ratio ≤5. The immobilized dye selected for positive chromatography is placed in another identical column (if batch elution is to be employed) or in a column with a height/diameter ratio ≥5 (if gradient elution is to be employed).

BCU IASI / CENTRAL UNIVERSITY LIBRARY

3. Position the negative column immediately above the positive column. Connect the two columns so that the effluent of the upper column flows directly on top of the lower column.

Pass sample through columns

4. Apply the protein mixture to the upper negative column. Collect the flowthrough liquid from the lower positive column in a single container.
5. Wash the tandem columns with 1 collective column volume of application solvent. Add the flowthrough from the washing to the container in step 4.
6. Measure the concentration of desired protein in the collective flowthrough to ascertain that the desired protein has been retained.
7. Uncouple the upper negative column and set it aside.

Recover the protein

8. Wash the positive column with 2 column volumes of application solvent.
9. Subject the positive column to either batch or gradient elution using the elution solvent selected for positive chromatography. Perform and process batch elution (see Basic Protocol 3, steps 3 to 5) or gradient elution (see Alternate Protocol 2, steps 2 to 6).
10. Wash and store each column (see Basic Protocol 2, steps 7 and 8).

SUPPORT PROTOCOL

IMMOBILIZATION OF REACTIVE DYES

Reactive dyes must be covalently attached to an insoluble porous matrix ("immobilized") to be used in a chromatographic protocol for protein purification. A reactive dye is a visible chromophore that has a good chemical leaving group, as illustrated in Figure 9.2.1. Immobilization of a reactive dye is a simple procedure that can be performed in the laboratory to generate immobilized dyes that cannot be purchased or to save the cost of commercial immobilization. Table 9.2.2 lists a selection of dyes that can be purchased at modest cost. Each of these dyes can be immobilized by reacting it with a chromatographic matrix in aqueous solvents using moderate conditions. The nature of the covalent attachment is illustrated in Figure 9.2.1B. This protocol is scaled for preparation of an immobilized dye column having a bed volume of 100 ml.

Materials

Reactive dye (Table 9.2.2)
Concentrated solution of KCl
Reactive chromatographic matrix: e.g., Sepharose CL-4B or CL-6B (Pharmacia Biotech) or other cross-linked agarose
4 M and 1 M NaCl
10 M NaOH
2 M NH_4Cl

Large sintered glass funnel
Plastic disposable filter with pore size of 0.45 μm

1. Remove any salt, buffer, or surfactant from the reactive dye sample by precipitation of the dye as the potassium salt from aqueous solution and filtration of the precipitate using a sintered glass funnel mounted on a filter flask. Place several grams of the dye in a beaker and add water to make a concentrated solution of the dye. Add concentrated solution of KCl dropwise to precipitate the dye from the solution. Pass the dye

BCU IASI - CENTRAL UNIVERSITY LIBRARY

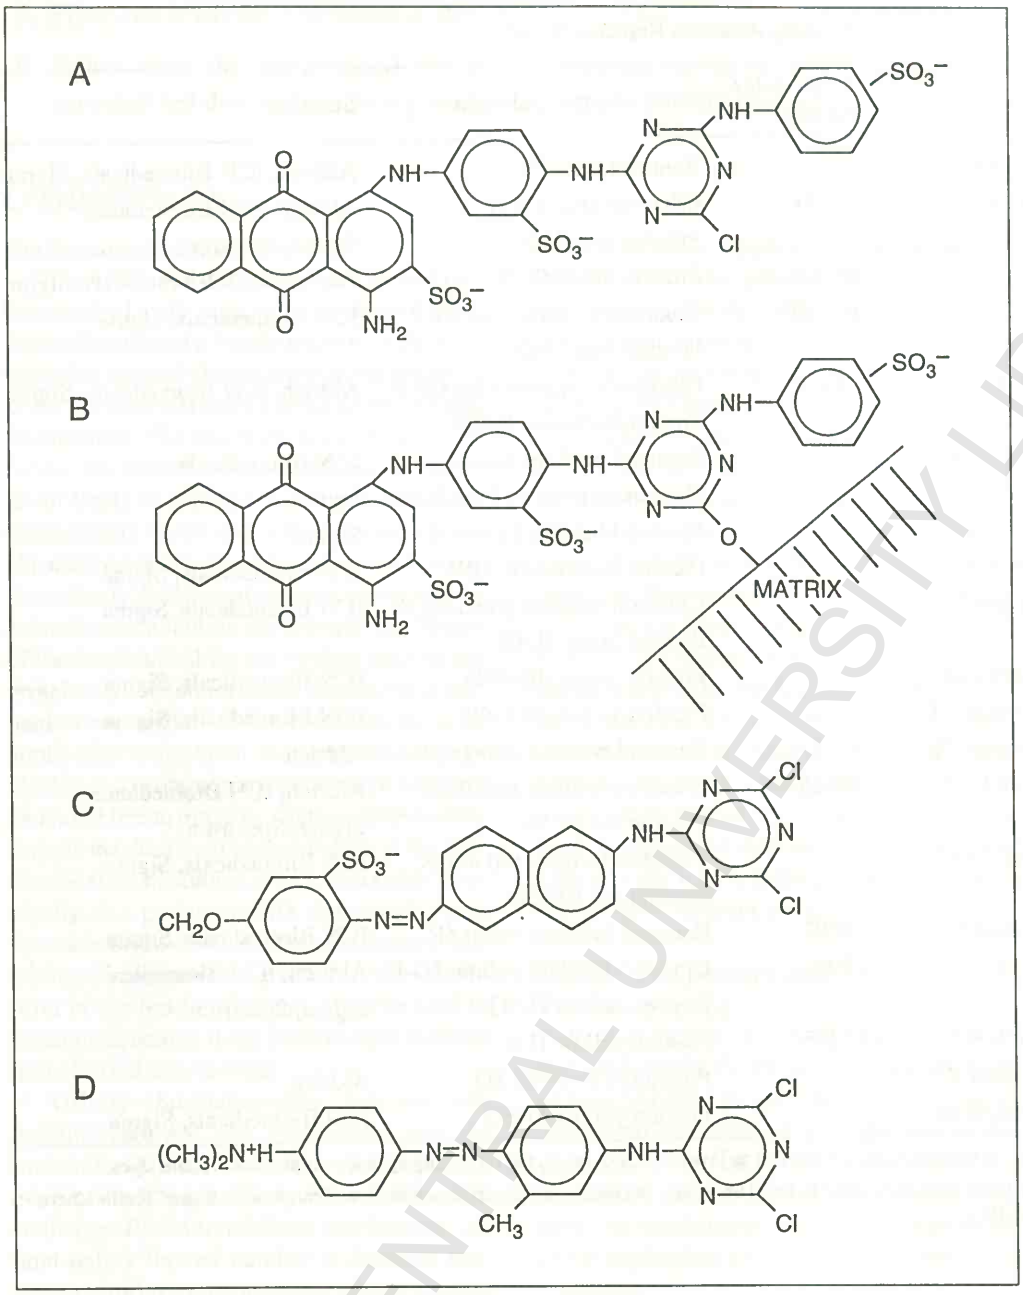

Figure 9.2.1 Structures of some reactive dyes. The dyes are arranged so that their triazine rings, the rightmost rings in structures **C** and **D**, have a common position. (**A**) Reactive blue 2, color index 61211, a reactive monochlorotriazine dye, also designated as Cibacron blue 3G-A and Procion blue H-B. (**B**) Immobilized reactive blue 2, also designated as Affi-Gel blue gel, Blue Sepharose CL-6B, Cibacron blue 3G-A-agarose, and DyeMatrex blue A gel. (**C**) Reactive red 8, color index 17908, a reactive dichlorotriazine dye, also designated as Procion scarlet MX-G. (**D**) A positively charged reactive dye.

suspension through a plastic disposable filter with a pore size of 0.45 µm, wash the filtered precipitate with ~100 ml of water, and air dry the washed precipitate.

The most common reactive dyes—e.g., Procion (ICI) and Cibacron (Ciba-Geigy) dyes—have a sulfonated chromophore linked to a chlorotriazine group by an aminoether bridge.

2. Suspend 80 g chromatographic matrix in 280 ml water.
3. Dissolve 1.2 g reactive dye in 80 ml water and add it to the matrix suspension.

BCIT LIBRARY CENTRAL UNIVERSITY LIBRARY

[a]Dichlorotriazine reactive dyes are denoted as Procion MX dyes; all the remaining dyes are monochlorotriazine dyes.

[b]Numbers are taken from the Colour Index, The Society of Dyers and Colourists and the American Association of Textile Chemists and Colorists (1971).

4. Add 40 ml of 4 M NaCl to the matrix suspension.
5. If a monochlorotriazine reactive dye is used, add 4 ml of 10 M NaOH to the matrix suspension and gently stir it with a magnetic stirrer and stir bar for 72 hr at ambient temperature or 16 hr at 55° to 60°C. If a dichlorotriazine reactive dye is used, add 0.5 ml of 10 M NaOH and gently stir the matrix suspension with a magnetic stirrer and stir bar for 4 hr at ambient temperature.
6. Filter the suspension using the sintered glass funnel and wash the solid material on the filter with copious quantities of water, then 1 M NaCl, and then water again until the filtrate is clear.
7. Suspend the material on the filter in 2 M NH_4Cl, pH 8.5, and gently stir with a magnetic stirrer and stir bar for 4 hr at ambient temperature.

   This step eliminates any remaining chloro groups.

BCU IASI CENTRAL UNIVERSITY LIBRARY

8. Filter and wash the suspension as described in step 6.
9. Either store the immobilized dye as a suspension in water at 4°C or dry the immobilized dye on a sintered glass filter and store as a dry powder.

COMMENTARY

Background Information

The surfaces of all proteins bind at least one biochemical with high affinity. Accordingly, immobilization of a biochemical on a chromatographic support should result in the retention of all proteins that have a binding site for that biochemical. The biochemical can exist in two forms: the mobile biochemical, which moves about freely in solution, and the immobilized biochemical, which is covalently attached to a chromatographic support and cannot move about freely. In chromatography, a competition exists between mobile and immobilized forms of the biochemical for the binding sites on the proteins. If the immobilized form is the dominant concentration of the biochemical, as in application to a column, the protein exists principally as a protein/immobilized dye complex and is not free to move in solution. If the mobile form is the dominant concentration of the biochemical, as in elution, the protein exists principally as a protein/mobile dye complex and moves freely in solution. Elution solutions containing a concentration gradient of the mobile form of the biochemical can often be used to distinguish among those proteins that bind the immobilized biochemical.

Affinity chromatography, however, can present problems. The biochemical must be immobilized in such a manner that the protein can bind it with high affinity, often a substantial challenge. Each immobilized biochemical can bind only a limited number of different proteins, requiring construction of a large number of different affinity columns for purification of a series of proteins. Further, the degradative enzymes present in crude cellular extracts often cleave immobilized biochemicals into useless remnants, necessitating either the frequent replacement of affinity columns or the postponement of their use until the end of a purification scheme. Such postponement compromises the selective power of affinity chromatography, which should, in principle, purify a protein to homogeneity in a single step.

Fortunately, immobilized dye affinity chromatography circumvents these problems. A single reactive dye can effectively bind a large number of different biochemicals. A reactive dye is sufficiently complex that immobilization does not reduce its affinity. An immobilized reactive dye is not degraded by enzymes commonly found in crude protein mixtures, as the chemistry of the dye is quite distinct from that of typical biochemicals.

An immobilized dye functions as a stable general affinity molecule that can be made selective by the nature and concentration of the mobile biochemical chosen as the elution reagent. A single immobilized dye, variously known as Cibacron blue (F)3G-A, Procion blue H-B, reactive blue 2, blue dextran, Affi-Gel blue, or DyeMatrex blue A, has contributed significantly to the purification of over 60 different proteins. Some of these proteins have been purified to homogeneity from a crude bacterial extract in a single step providing a several-thousand-fold purification with >80% yield. Immobilized dyes as a group have contributed significantly to the purification of several hundred different proteins.

Critical Parameters and Troubleshooting

Several aspects of dye affinity chromatography are critical. Foremost is the ionic strength of the application solvent. Because application solvents of ionic strength >50 mM weaken the electrostatic interactions that contribute to the binding of desired proteins by immobilized dyes, the concentrations of ionic components in the application solvent should be kept to a minimum.

Second is the presence of nonionic detergents in the application solvent. Nonionic detergents are frequently used to solubilize intrinsic protein located in subcellular organelles such as membranes. These nonionic detergents form micelles that encapsulate immobilized dyes, making them inaccessible to proteins. Addition of a modest concentration of a negatively charged detergent, such as SDS or deoxycholate, to an application solvent containing a nonionic detergent results in the formation of mixed micelles. The negatively charged immobilized dyes repel the negatively charged mixed micelles in solvents of modest ionic strength, preserving the accessibility of

BAYLOR COLLEGE OF MEDICINE LIBRARY

immobilized dyes to desired proteins (Robinson et al., 1980). The nonionic and ionic detergents should have a concentration ratio of ~5:1.

Third is the sign of the electrostatic charges on immobilized dyes. Most reactive dyes are negatively charged; this is normally an advantage, as most protein binding sites contain positively charged amino acid residues designed to bind negatively charged biochemicals, such as cAMP, glucose 6-phosphate, or oligo(dAT). However, some biochemicals have a positive charge; the proteins to which they bind must then contain negatively charged residues. These binding proteins are electrostatically repelled by negatively charged immobilized dyes in solvents of modest ionic strength. The immobilized form of a positively charged dye (Fig. 9.2.1D) retains proteins having binding sites for positively charged biochemicals, such as trypsin, thrombin, and carboxypeptidase (Clonis et al., 1987). This immobilized dye is particularly useful in removing contaminating proteases from cellular extracts by negative chromatography.

The two primary problems encountered in immobilized dye affinity chromatography are the inability to retain a desired protein and the inability to elute a desired protein that has been retained. The inability to retain a desired protein may result from a number of situations. If a fresh immobilized dye column is being used, the following may pertain:

The ionic strength of the protein mixture may be too high. Either dilute the protein mixture with distilled water or dialyze it against a low ionic strength application solvent, such as 50 mM Tris·Cl devoid of neutral salts.

The concentration in the protein mixture of the biochemical that binds to the desired protein may be too high. Either dilute the mixture with distilled water or, if the biochemical is sufficiently small, dialyze the mixture against a low ionic strength application solvent.

Retention of the desired protein may necessitate the presence of a metallic cation, such as Mg^{2+} or Zn^{2+}. Add a minimal concentration of one or more likely metallic cations to the application solvent.

A nonionic detergent may be present in the protein mixture. Add a sufficient amount of a negatively charged detergent, such as SDS or deoxycholate, to the crude protein mixture to maintain the accessibility of the immobilized dye. However, note that SDS, even in low concentrations, denatures many proteins.

The immobilized dye may have a relatively weak affinity for the desired protein. Add more immobilized dye to the column or screen a series of alternative immobilized dyes for one having a stronger affinity for the desired protein.

The desired protein is designed to bind only positively charged biochemicals. Purchase or synthesize an immobilized dye having a net positive charge.

The desired protein may be among a small group of proteins that is not retained by any immobilized dye. Negative chromatography can then be used to great advantage, particularly a series of negative columns in tandem.

If an old immobilized dye column is being used, the following may pertain:

Insufficient immobilized dye may be accessible. After repeated use of an immobilized dye column the dye may become bound with proteins, detergents, and other components in cellular extracts that are not removed by washing with 2 M NaCl. An immobilized dye column should be periodically washed with several column volumes of one or more of the following solutions to displace these dye-bound components: a strong denaturant such as 8 M urea, 6 M guanidine·HCl, or 1% SDS; a potent lyotropic reagent such as 3 M KSCN; a strong base such as 0.5 M NaOH; or a mixed solvent such as chloroform/methanol.

Insufficient immobilized dye may be present. If an immobilized dye column has been used extensively or stored in solution, the glycosidic bonds linking the sugars in the agarose matrix will be hydrolyzed. Such hydrolysis results in loss of the immobilized dye. A new immobilized dye column is strongly colored. A depleted immobilized dye column is lightly colored and should be replaced.

The inability to elute a desired protein that has been retained on an immobilized dye column presents a different problem, in that the affinity is too strong rather than too weak. Suggestions for weakening the affinity include the following:

Performing the chromatography at a different pH. Most proteins exhibit a pH optimum for binding a biochemical. This pH optimum results in part from changes in the ionic character of some of the amino acid side chains in the protein that are directly involved in binding. Changes in pH that weaken the affinity of biochemicals are likely to weaken the affinity for the immobilized dye as well. Use Basic Protocol 1 to determine the effect of pH on the elution of the desired protein. Note, however, that pH values outside the range 4 to 11 may result in irreversible inactivation.

PCU IASTRI PATNA UNIVERSITY LIBRARY

Performing the chromatography at a different temperature. The binding of a biochemical by a protein involves a combination of weak noncovalent bonds including hydrogen bonding, hydrophobic interactions, and electrostatic interactions. Changes in temperature weaken some of these bonds and strengthen others. Accordingly, changing the temperature may weaken the affinity of the immobilized dye for the desired protein. Note, however, that the temperature should not be increased above 50°C to prevent thermal inactivation of the desired protein.

Increasing the potency of the elution solvent. Nonspecific elution solvents promote elution by weakening the electrostatic and hydrophobic contributions to affinity. The electrostatic contributions will usually be minimized in a 0.2 M solution of any neutral salt. However, minimization of the hydrophobic contributions requires higher concentrations and judicious choice of the neutral salt. The lyotropic or Hofmeister series reflects the relative potency of neutral salts. A 3 M solution of the neutral salt KSCN is among the most potent for weakening hydrophobic interactions (Robinson et al., 1981).

Specific elution solvents, by contrast, weaken affinity by competing with the immobilized dye for the desired protein. The higher the concentration of the biochemical and the stronger its affinity for the desired protein, the greater its effectiveness as an eluant. Accordingly, the concentration of a specific elution solvent should be increased in an effort to elute the desired protein. Clearly, a limiting concentration will be set by the solubility, availability, and cost of the specific eluant. Alternatively, other biochemicals known to bind to the desired protein as substrates, coenzymes, cofactors, competitive inhibitors, and allosteric effectors may be surveyed for their efficacy as elution reagents.

Adding a chelation agent. Metallic cations often function as obligatory cofactors in the binding of biochemicals to proteins. Accordingly, the affinity of the desired protein for the immobilized dye may be weakened by the presence of a chelation agent such as 0.1 M EDTA or EGTA.

Combining specific elution reagents. Immobilized dyes are sufficiently large that a single dye molecule may occupy adjacent biochemical binding sites on a protein: e.g., a dye may occupy the substrate site and the coenzyme site on an enzyme surface. Alternatively, two different immobilized dye molecules may simultaneously bind to two remote sites on the same protein molecule: e.g., different immobilized dye molecules may simultaneously bind to the substrate site and to the allosteric site on an enzyme. In each of these situations, the elution of a desired protein can be accomplished using a combination of specific elution reagents.

Adding a protein denaturant such as 6 M guanidine·HCl. Most proteins can be eluted from an immobilized dye column using a denaturant that unfolds protein binding sites. Because most retained proteins have already been eluted, addition of a denaturant should result in a substantial-fold purification, provided the desired protein is denatured reversibly. Such reversibility is commonly achieved by dilution or dialysis of the column eluate with application solvent.

Lowering the density of the immobilized dye. Many desired proteins are oligomers containing two or more identical binding sites. If the chromatographic matrix contains a high density of accessible immobilized dye molecules, it is likely that two or more immobilized dye molecules will simultaneously bind to a single desired oligomeric protein (Hogg and Winzor, 1985). Such multiple binding makes elution more difficult. Diluting an immobilized dye matrix with an unmodified matrix will not decrease the density of the immobilized dyes on each chromatographic bead. The only remedy is to obtain the same immobilized dye from an alternative supplier, hoping to obtain a less dense sample, or to immobilize the dye in the laboratory using the Support Protocol.

Selecting an alternative immobilized dye that has a weaker affinity for the desired protein. Such weakening should facilitate improved results in positive chromatography.

Anticipated Results

The yield of the desired protein following immobilized dye chromatography is commonly >80%. Random differences in yield occur depending upon how completely the desired protein is retained (positive chromatography) or not retained (negative chromatography) and how completely the retained protein is eluted. Lesser yields are usually the result of proteolysis either before or during chromatography. Proteolysis may generate remnants of the desired protein that have weaker affinities for an immobilized dye. Such remnants elute prior to the elution of the dominant unproteolyzed desired protein and would not be included in the pooled fractions. Good yields of

EXPASY CENTRAL WEBSITE LIBRARY

desired proteins result in part from the speed of affinity chromatography, the temperature, the stabilization provided to the desired protein from binding an immobilized dye, and the respectful treatment of a crude protein mixture by an experienced investigator.

The fold purification achieved by immobilized dye chromatography is largely controlled by the relative population of the desired protein in a protein mixture. If 10% of the mixture is the desired protein, then a 10-fold purification step is maximal. If <0.1% of the mixture is the desired protein, then a >1000-fold purification step is feasible and has been observed. However, in most instances 10- to 100-fold purifications are observed.

Time Considerations

The preliminary survey can be completed in a few hours or a day, depending on its breadth. Once a protocol is selected, negative chromatography should be completed in 1 hr and positive chromatography in a few hours. These time estimates greatly depend on the volume of the solutions to be processed and the flow rates employed.

Affinity Purification of Natural Ligands

Immobilization of proteins, nucleic acids, and other "bioligands" is not simple. The proper bioligand needs to be selected for the specific application of the product. This decision influences all others: the matrix is chosen and activated by the method that is most appropriate for this specific application and the ligand is coupled under conditions dictated by the activation method and the nature of the ligand (e.g., is it a labile protein or a sturdy enzyme cofactor?). There are many matrices and activation and coupling methods, and new ones are constantly being developed. The most frequently used are hydrophilic matrices, which exhibit the necessary low nonspecific binding, and coupling systems that react primarily with nucleophilic residues, such as lysyl amine groups in proteins. Orientation of the resulting biomolecule is extremely important, although these effects have been only superficially investigated. Immobilized IgG is only twofold more efficient when immobilized solely by the Fc portion (Murayama et al., 1978; Doman et al., 1990; Hermanson et al., 1992), whereas the interactions of large proteins that bind macromolecular ligands (lysozyme is a good example) are changed by several orders of magnitude depending on the orientation of the molecule (Fig. 9.3.1). For this reason, it is fortunate that both cationic (e.g., fluoromethyl pyridinium) and hydrophobic (e.g., Emphaze, tosyl agarose) activation methods are available.

The choice of matrix and the stability of the bound ligand determine the choice of activation and coupling methods. Preactivated matrices are available but are very costly. Therefore they are best used when small amounts of ligand are to be immobilized for "test" columns and methods development. Larger projects and large-scale applications require ligand activation in the laboratory. Because of their frequent use in the past, agarose gel is often the matrix of choice and cyanogen bromide is often the activation and coupling agent of choice. However, depending on the procedure, neither may be optimal and before beginning a project it is best to explore the range of matrices and methods carefully, particularly if later industrial level scale-up with regulatory implications is anticipated. An overview of the major activation chemistries is given in Tables 9.3.1 and 9.3.2. Of the many activation systems available, three of the most frequently used are

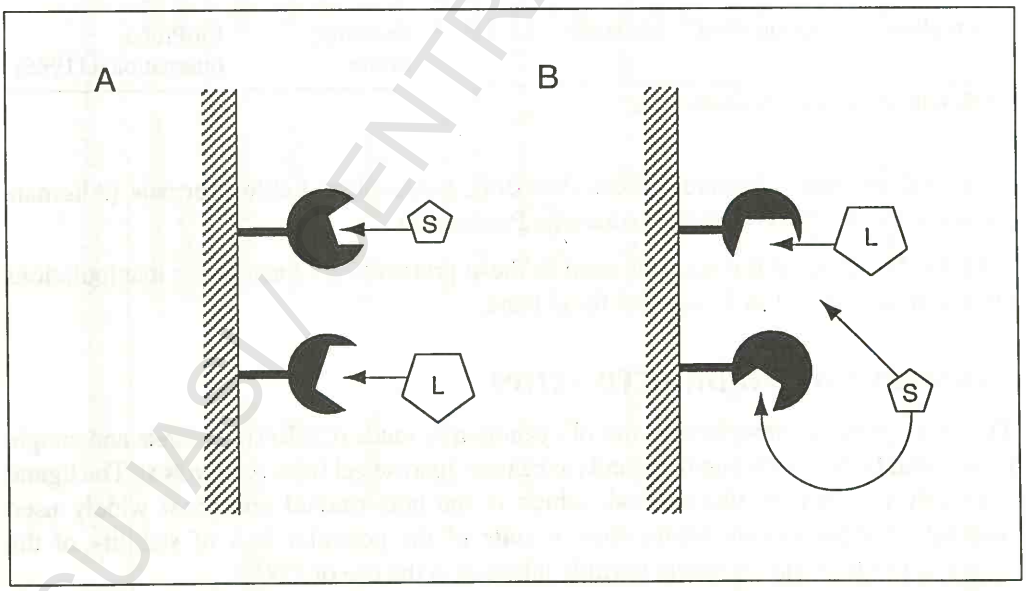

Figure 9.3.1 Binding of small (S) versus large (L) substrates to an oriented (A) and randomly (B) immobilized enzyme. described: cyanogen bromide (Basic Protocol), *p*-nitrophenyl chloroformate (Alternate Protocol 1), and tresyl chloride (Alternate Protocol 2).

CAUTION: Many of the reagents used in these protocols are hazardous; manipulations should be performed in a chemical fume hood.

BASIC PROTOCOL

CYANOGEN BROMIDE ACTIVATION

This basic protocol describes the use of cyanogen bromide (CNBr) to activate and couple proteins and other nucleophilic ligands to beaded agarose gel (also see *UNIT 9.5*). The ligand is readily coupled by this method, which is the best studied and most widely used technique for protein immobilization in spite of the potential lack of stability of the resulting product and the safety hazards inherent in the use of CNBr.

CAUTION: CNBr is very toxic, releases toxic vapor, and is reported to create explosive side products upon storage; therefore, it should always be used in a hood and handled with appropriate CNBr- and solvent-resistant gloves. Only a fresh bottle of CNBr should be

BCU/ASI/CENTRAL UNIVERSITY LIBRARY

employed and it should be opened in the hood. Because of the problems involved in handling CNBr, it is best to dissolve a complete bottle in a defined amount of anhydrous acetonitrile. Short-term storage of this solution (several weeks) at 0°C is possible, but prolonged storage is not recommended.

Materials

Agarose gel (e.g., Sepharose CL-4B)
2 M and 5 M potassium phosphate, pH 12.1
2 M sodium carbonate
2 g/ml CNBr in anhydrous acetonitrile (see recipe)
1 M NaOH
0.2 M sodium bicarbonate, pH 9.0
Sample to be coupled: typically 1 to 10 mg/ml protein, 10 to 200 mg/ml small ligand, or 0.1 to 10 mg/ml nucleic acid
0.1 M potassium phosphate, pH 7.0
Solvent- and CNBr-resistant gloves

1. Wash the agarose gel well with deionized water to remove any preservatives present, then exchange it into 2 M potassium phosphate, pH 12.1, or 2 M sodium carbonate by washing it with 5 vol of the buffer.

   Both buffers work equally well (March et al., 1974). Normally, after washing, the agarose gel is suction filtered with suction maintained until the surface of the agarose gel just barely "cracks." This agarose gel is weighed to obtain the "wet weight" measurement. Although this is a technique-driven procedure and the results vary from person to person, it is the most convenient and widely used method of measuring agarose gel. Other methods, e.g., "dry weight," may be more accurate, but are highly impractical. In most instances, the agarose gel weight is not a critical factor and the person-to-person variation in "wet weight" is not significant.

2. Working in the hood, add 10 g wet weight washed agarose gel at 0°C to 10 ml of ice-cold 5 M potassium phosphate, pH 12.1, or 2 M sodium carbonate, depending on which was used in step 1. Slowly add 1 ml of a 2 g/ml solution of CNBr in anhydrous acetonitrile, with constant stirring and monitoring of the temperature.

   The temperature of the reaction should not exceed 10°C. This can be controlled by the rate of addition of the CNBr solution, by the use of an ice-ethanol bath around the reactor vessel, and/or by adding pieces of ice to the reaction mixture as needed.

   The amount of activation can be varied by increasing or decreasing the volume of CNBr solution. It is preferable to do several test experiments with the total system than to rely on formulas to predict activation levels, even though several such formulas exist (Porath, 1974).

   The author usually uses the weight given by the manufacturer to make up the solution, since any resulting inaccuracy is relatively unimportant. Because the reaction is much more dependent on small changes in temperature, pH, addition rate, etc., than on the precise CNBr concentration, weighing the CNBr is not worth the danger and time involved. All subsequent reactions using CNBr must be done in the hood and wearing appropriate gloves. Excess reagent should be destroyed carefully according to the Material Safety Data Sheet instructions.

3. After the required amount of CNBr is added, keep the mixture under 5°C with stirring for 5 min. Pour the mixture into a suction filtrate apparatus in the hood and filter the agarose gel from the excess reaction mixture.

4. Immediately wash the agarose gel with 5 to 10 vol ice-cold water.

   Destroy the contents of the filter flask, which contains excess CNBr, by slowly adding—in the hood—a 5-fold molar excess relative to the total initial CNBr used, of

PCU IASI / CENTRAL UNIVERSITY LIBRARY

1 M NaOH. Keep the reaction mixture cold by adding pieces of ice. The mixture should be kept in the hood until all CNBr is destroyed.

5. Add an ice-cold solution of protein (1 to 10 mg/ml), small ligand (10 to 200 mg/ml), or nucleic acid (0.1 to 10 mg/ml) in 10 ml of 0.2 M sodium bicarbonate buffer, pH 9.0, to the activated agarose gel.

   Although it is possible to store CNBr-activated agarose gel and activated agarose gel in dehydrated form (i.e., the commercially available CNBr-activated agarose gel) the only practical plan in the laboratory is to couple it to proteins or other biomolecules immediately after preparation (Kohn and Wilchek, 1983b).

6. Place the agarose gel/ligand/buffer solution in a sealed bottle and rotate slowly, end over end, overnight. Collect the agarose gel by suction filtration and wash with 100 ml of 0.1 M potassium phosphate buffer, pH 7.0.

   The temperature depends on ligand lability; for small molecules it is usually 25°C; for proteins it is 4°C. The agarose gel/ligand can be stored, but conditions and length of storage depend on the ligand.

ACTIVATION WITH *p*-NITROPHENYL CHLOROFORMATE

ALTERNATE PROTOCOL 1

Because some materials coupled to CNBr-activated agarose gel lack stability, other activation methods are frequently employed. This alternate protocol describes the use of *p*-nitrophenyl chloroformate in activating agarose gel to produce a stable activated agarose gel that, when coupled to protein or nucleophilic ligands, produces reasonably strong, nonionic coupling bonds to the bound ligand.

***Additional Materials** (also see Basic Protocol)*

30:70 and 70:30 (v/v) acetone/water
Acetone, reagent grade, room temperature and ice cold
Anhydrous acetone (dried over 4 Å molecular sieves)
Anhydrous acetonitrile, room temperature and 4°C (see recipe)
p-Nitrophenyl chloroformate, 800 mg in 12 ml anhydrous acetonitrile
Dimethylaminopyridine
5% acetic acid in dioxane, ice cold
Methanol, ice cold
Anhydrous isopropanol, ice cold
0.5 and 0.1 M potassium phosphate, pH 7.5
0.1 M ethanolamine, pH 7.5

Prepare the agarose gel

1. Wash the agarose gel (Sepharose CL-4b, 10 g wet weight) on a sintered glass funnel successively with 100 ml of each of the following ice-cold solutions:

   30:70 (v/v) acetone/water
   70:30 (v/v) acetone/water
   100% reagent-grade acetone
   anhydrous acetone
   anhydrous acetonitrile.

2. Suspend the agarose gel in 12 ml of 4°C anhydrous acetonitrile containing 800 mg *p*-nitrophenyl chloroformate. Slowly add 3 equivalents of dimethylaminopyridine in anhydrous acetonitrile and stir the mixture for 1 hr at 0° to 4°C.

BOURNS / CENTRAL UNIVERSITY LIBRARY

3. Wash the agarose gel beads successively with 100 ml of each of the following ice-cold solutions:

   reagent-grade acetone
   5% acetic acid in dioxane
   methanol
   anhydrous isopropanol.

4. Store the agarose gel beads at 0° to 4°C in anhydrous isopropanol until used.

   If kept dry, the agarose gel beads may be stored in anhydrous isopropanol for 6 to 12 months.

Perform the coupling reaction

5. On a suction funnel, wash the stored agarose gel (10 g) with ice-cold distilled water to remove all isopropanol.

6. Transfer the agarose gel to 10 ml of 0.1 M potassium phosphate buffer, pH 7.5, containing the ligand at 1 to 10 mg/ml protein, 0.1 to 10 mg/ml nucleic acid, or 10 to 50 mg/ml low-molecular-weight nucleophilic ligand.

7. Place the agarose gel in a bottle, cap the bottle, and tumble it end over end at 4°C for 24 to 48 hr.

   With stable ligands, 25°C for 16 hr will probably be adequate.

8. Wash the agarose gel by suction filtration with 100 ml of 0.1 M phosphate buffer, pH 7.5.

9. Transfer the agarose gel to 100 ml of 0.1 M ethanolamine, pH 7.5.

   For stable low-molecular-weight ligands, solvents with higher pH values, e.g., pure ethanolamine, may be used.

10. Tumble overnight as in step 7.

11. Wash the agarose gel with 0.1 M potassium phosphate, pH 7.5.

12. Add a small sample of the agarose gel to 0.1 M NaOH. If an intense bright yellow color develops, repeat steps 9 to 11.

13. Assay the immobilized ligand as appropriate for its activity.

ALTERNATE PROTOCOL 2

ACTIVATION WITH TRESYL CHLORIDE

This alternate protocol describes the use of tresyl chloride to activate and couple proteins and other nucleophilic ligands to beaded agarose gel. This method is often employed to secure the ligand to the matrix by an exceptionally stable bond. It also produces an activated intermediate that can be stored for at least 6 months in 1 mM HCl at 0°C.

***Additional Materials** (also see Basic Protocol)*

Pyridine (stored over NaOH pellets; see recipe)
Tresyl chloride
5 mM and 1 mM HCl
Protein ligand sample: typically 1 to 10 mg/ml of protein or 10 to 50 mg/ml low-molecular-weight nucleophilic ligand
0.2 M potassium phosphate, pH 8.0
1 M glycine, pH 8.0

RCU IASE CENTRAL UNIVERSITY LIBRARY

1. Wash 10 g (wet weight) agarose gel successively with 100 ml of each of the following ice-cold solutions:

   30:70 (v/v) acetone/water
   70:30 (v/v) acetone/water
   100% reagent-grade acetone
   anhydrous acetone
   anhydrous acetonitrile.

   Although totally anhydrous conditions are not essential, the use of anhydrous solvents is necessary for maximum activation.

2. Add the agarose gel to a bottle containing 5 ml anhydrous acetone and 0.2 ml pyridine (stored over NaOH pellets) and cool the mixture to 0°C in an ice bath.

3. Add 0.25 ml tresyl chloride to the mixture slowly with stirring.

4. After 10 min, wash the agarose gel with 100 ml of each of the following ice-cold solutions given in step 1, but adding 5 mM HCl to the aqueous component of the acetone/water mixtures:

   anhydrous acetonitrile
   anhydrous acetone
   100% reagent-grade acetone
   70:30 (v/v) acetone/water
   30:70 (v/v) acetone water.

5. Wash the agarose gel with 100 ml ice-cold 1 mM HCl and store the agarose gel beads at 4°C in the same dilute HCl solution.

6. Dissolve the ligand to be bound in 10 ml of 0.2 M potassium phosphate buffer, pH 8.0.

   Usually from 1 to 10 mg/ml protein or 10 to 50 mg/ml low-molecular-weight nucleophilic ligand is employed.

7. Rapidly rinse the activated agarose gel with 100 ml ice-cold 0.2 M phosphate, pH 8.0.

8. Mix the washed agarose gel beads with the ligand solution.

   If a protein or temperature-sensitive ligand is employed, rotate the mixture at 4°C overnight. For more robust ligands and/or for higher yields, higher temperatures (25°C) can be employed.

9. Wash the coupled agarose gel beads with 0.2 M potassium phosphate buffer, pH 8.0, at the coupling temperature, and deactivate any residual tresyl groups by incubating the agarose gel overnight with 1 M glycine, pH 8.0.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

***Cyanogen bromide** (Kohn and Wilchek, 1983b)*

CNBr is commercially available as a 5.0 M (~530 mg/ml) solution in acetonitrile (Aldrich). Because CNBr is volatile and very hazardous, *the premade solution is preferred.* The Basic Protocol can be adjusted by using 3.8 ml of the 5 M solution in place of each milliliter of 2 g/ml CNBr needed. If, however, solid CNBr is purchased, it is most convenient and usually safest to make an appropriate (2 g/ml) solution in anhydrous acetonitrile.

BOSTON / CENTRAL UNIVERSITY LIBRARY

For example, a 25-g bottle of *fresh* CNBr may be cooled in a refrigerator overnight (stored upside down, since CNBr lyophilizes and crystallizes on the inside of the lid if stored refrigerated right side up), and then transferred to a hood where it is carefully opened and 50 ml of anhydrous acetonitrile at 0° to 4°C are added. The mixture is stirred with a magnetic stir bar until all of the CNBr is dissolved. The solution should be used within 2 to 4 weeks of preparation and kept at 0° to 4°C until used. As hydrogen cyanide can develop from the reaction of CNBr with moisture, it should *never* be stored in a cold room.

NOTE: *Because CNBr is very hazardous, all precautions noted in the Material Safety Data Sheet (MSDS) should be followed precisely and disposal should be done in accordance with the recommendations! The MSDS should be carefully read before handling CNBr. Old bottles should not be used, nor should CNBr be stored for a prolonged time, as it is reported that age will cause brown discoloration and the formation of explosive degradation products (see Kohn and Wilchek, 1983b).*

Anhydrous solvents

Anhydrous solvents can be prepared by a variety of methods, the most thorough of which are described by Vogel (1978) and Fieser and Fieser (1967). For our purposes, however, the following procedures are usually adequate.

Acetonitrile. Using the commercial anhydrous solvent, to which 4 Å molecular sieves are added for storage, is probably the best procedure. A new bottle of anhydrous acetonitrile is opened and enough 4 Å molecular sieves are added to cover the bottom of the bottle to a depth of ¼ to ½ in.

Pyridine. The same procedure as for acetonitrile is applied, using a new bottle of anhydrous-grade pyridine and adding NaOH pellets instead of molecular sieves. If reagent-grade pyridine is used, NaOH pellets are added and the bottle is allowed to stand at 25°C for 2 to 3 days with occasional shaking (once or twice a day) before using.

Acetone. Acetone is the most difficult solvent to dry and, no matter how dried, cannot be expected to be totally anhydrous. One procedure is to add ½ to 1 in. of calcium sulfate (*not* calcium chloride) to the bottom of 500 ml of acetone in a reagent bottle. The acetone is mixed occasionally by shaking and kept for 4 to 8 hr. It is then filtered and stored in a reagent bottle with ½ to 1 in. of 4 Å molecular sieves. This is not totally anhydrous, but works for these procedures. Consult Vogel (1978) if more stringent conditions are desired.

COMMENTARY

Background Information

Affinity chromatography has benefited both basic research and biotechnology. Without this tool, purification of restriction enzymes, antibodies, and polymerases, for example, would have been much more difficult. Affinity chromatography is a very diverse method of protein purification, encompassing many combinations of matrices, ligands, methods of activation, and coupling (Turkova, 1993).

The basic considerations in designing an affinity chromatography system include the final application of the product, various cost and safety considerations, and potential scale-up concerns. These must all be evaluated when affinity systems are initially planned. The application of the product dictates the amount of nonspecific binding that can be tolerated. Cost and safety considerations determine whether the matrix can have "acceptable" leakage levels and, therefore, whether inexpensive and less durable or expensive and therapeutically safe materials should be used. Scale-up considerations determine the porosity and mechanical stability required of the matrix.

Matrix considerations

The ideal matrix has sufficient porosity to maintain flow, mechanical and chemical stability, high capacity, and very low nonspecific absorption. Such an ideal matrix does not yet exist. The most commonly used matrices are

RCU IASI - CENTRAL UNIVERSITY LIBRARY

naturally occurring hydroxylic polymers, such as agarose, cellulose, and cross-linked dextrans. Agarose gel, the most widely used matrix, is well suited to laboratory benchtop experiments in which small columns are employed, and in which many matrices containing different activation levels, ligands, and functions are often used. For scale-up, however, synthetic organic polymers may be preferred. A new material on the market, Emphaze (3M Company; Coleman et al., 1990), is a preactivated polymer of a vinyl azolactone. Its preactivation makes it very convenient to use and it exhibits relatively low nonspecific binding and high mechanical stability. Its usable flow rate, however, may be less than that of two-component systems, such as HyperD (BioSepra), Poros (PerSeptive Biosystems; Ugelstad et al., 1983; Afeyen et al., 1990, 1991; Regnier, 1991), and Mono-Q/Mono-S (Pharmacia Biotech; Ugelstad et al., 1983). These matrices have relatively fast throughput rates due to the fact that they are multicomponent materials with large pores but reasonably high capacity. With the "gel-in-a-shell" HyperD system, shown in Figure 9.3.2, the synthetic base provides the necessary mechanical stability and the coating of dextran provides an open hydroxylic framework, which minimizes nonspecific binding and maximizes capacity.

Inorganic materials such as silica have often been successfully used in affinity systems when HPLC affinity chromatography is employed. Unfortunately, for large-scale purifications of proteins with a high degree of purity, the nonspecific binding exhibited by virgin silica may be a problem.

Choice of ligand

Biological ligands used in affinity chromatography can be macromolecular, e.g., proteins and nucleic acids, or low-molecular-weight biomolecular, e.g., substrates, inhibitors, cofactors, antigenic peptides, "phage display" peptides, and biomimetic dyes. Each of these has a biologically relevant interaction with the molecules being purified. Purification based on such immobilized ligands is termed "bioselective adsorption," whereas purification based on resins that bind to a desired molecule via chemical rather than biological interaction is termed "chemiselective adsorption" (Scouten, 1981). Examples of the latter include ion exchange, hydrophobic, boronate, and active thiol ("covalent chromatography") functions bound to a solid matrix. The choice of ligand depends upon which interaction is most nearly unique to the molecule to be purified relative to the other biomolecules in the sample. For example, if it is one of the few glycoproteins in a mixture, a boronate column—which binds selectively to vicinol diols, e.g., sugar groups of glycoproteins—can be used to effect significant purification by a chemiselective process.

Boronates bind glycoproteins via weak covalent bonds (Bergold and Scouten, 1983) such that an equilibrium constant has little meaning. In contrast, biological ligands go from weak to strong noncovalent bonds; they may interact so weakly that a column of immobilized ligands retards the biomolecule being purified only slightly, or, conversely, it may bind almost covalently, as is the case with the biotin-avidin pair. Ligands at either end of the spectrum are unlikely to be useful for normal purification procedures. To be useful, the ligand should bind reasonably selectively, with equilibrium constants K_a from 10^4 to 10^8 M^{-1} (Turkova, 1993).

Although affinity chromatography is considered to be specific for a particular ligand-protein pair, and thus produces remarkable purification in a single step (and sometimes it does!), many nonspecific factors decrease its effectiveness. First, most immobilized ligands have biologically relevant interactions with several proteins—e.g., glucose binds several lectins, many enzymes, and several receptors. Because a given cell-free extract may contain several proteins that bind a single ligand, affinity systems are unlikely to produce a single protein product. In addition, other proteins in the mixture may have an affinity for the immobilized ligand due to nonspecific attraction to the matrix, to the spacer arm, or to charged or hydrophobic components of the ligand. Such nonspecific interactions need to be carefully considered, and minimized, in the design of the affinity media, either by trial and error or by using a matrix known for having little nonspecific binding. Finally, the ligands must be immobilized such that the protein-ligand interaction can still occur after immobilization, e.g., by immobilizing the ligand by means of a nucleophilic residue distant from the point of ligand-protein interaction. Often this means designing special ligands with a nucleophilic attachment site at an appropriate location on the ligand.

Spacers

In many cases it is essential to have a "spacer" between the matrix and the ligand. The spacer is added to eliminate steric hindrance by the matrix, which prevents the ligand from binding the enzyme (see Fig. 9.3.3). To determine if a spacer is needed, immobilize the ligand without it. If the resulting matrix will not capture the desired protein, new matrices with spacer arms must be created. If a spacer is needed, a 2- to 6-carbon diamine is usually coupled either to the ligand or the matrix. The use of bisepoxides creates a built-in spacer and obviates the need for the added step of preparing a spacer. More extensive discussion of spacers is provided by Hermanson et al. (1992).

Ligand classes

There are two distinct classes of ligands (Turkova, 1993): specific ligands that have a reasonably unique interaction (remembering the caveat cited above) for one or a few proteins, and general ligands that, as a result of biological functions, bind to a large class of protein. The former group includes antibodies, most receptors, and many enzymes; the latter group includes lectins, lectin-sugar interactions, and similar broad group–binding proteins. Often a sequence of two affinity steps—a broad group–based one, e.g., the purification of essentially all dehydrogenases on Cibacron Blue (*UNIT 9.2*; Clovis et al., 1987), followed by chromatography on a specific immobilized inhibitor—forms the core of a very simple and efficient purification procedure.

Activation and coupling methods

Hydroxylic matrices—the most commonly used matrices—are polysaccharides such as beaded agarose gel (Axen et al., 1967) and cellulose (Peška et al., 1976). These are generally chemically stable and exhibit minimal non-

BCU IASLIC CENTRAL UNIVERSITY LIBRARY

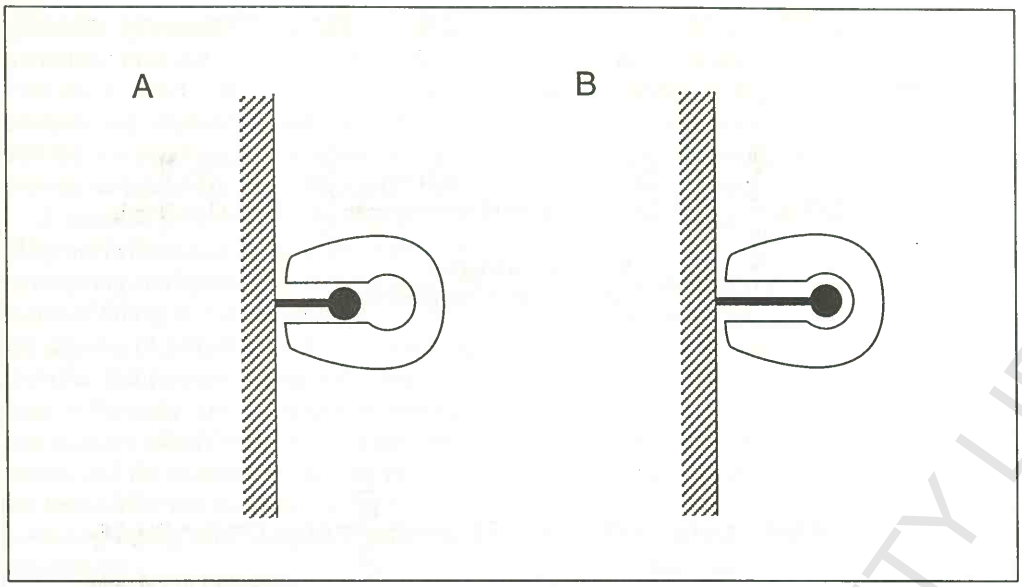

Figure 9.3.3 Effect of spacer arms on enzyme binding to immobilized ligands. (**A**) Direct attachment—the enzyme active site is prevented from reaching the substrate. (**B**) Attachment through a spacer arm—the enzyme active site can freely interact with the substrate. Reproduced from Scouten (1983).

specific adsorption. Most importantly, however, a wide variety of ligands, usually nucleophiles, can be readily coupled to them.

Attaching ligands to hydroxylic matrices, e.g., agarose gel, occurs in two steps: first, activation of the matrix, and second, the coupling process per se.

CNBr activation (Axen et al., 1967; Cuatrecasas, 1970; Porath et al., 1973; Porath, 1974; March et al., 1974; Kohn and Wilchek, 1982, 1983), as described in the Basic Protocol, is the most widely used method, primarily because it is the most studied system. The ligand is readily coupled by this method, but, unfortunately, it is undesirable from the point of view of the safety hazards involved in the activation procedure and the lack of stability of the resulting bond (Parikh et al., 1974; National Research Council, 1981). Furthermore, the procedure generates a positive isourea in the coupling process, which may impart some ion-exchange properties to the resulting product (Fig. 9.3.4A).

p-Nitrophenyl chloroformate (Wilchek and Miron, 1982; Miron and Wilchek, 1987), as described in Alternate Protocol 1, can be used to activate agarose to produce a stable activated agarose gel that when coupled to protein or nucleophilic ligands produces reasonably strong, nonionic bonds to the ligand.

Tresyl chloride (Nilsson and Mosbach, 1980, 1981, 1987; Scouten et al., 1987), as described in Alternate Protocol 2, can be used to activate agarose, resulting in a reasonably stable, but reactive, ester. This can subsequently be coupled to a ligand by an exceptionally stable bond (Fig. 9.3.4B).

Other coupling procedures for hydroxylic matrices worth noting include carbonyldiimidazole (Hearn, 1987), bisepoxide (Sundberg and Porath, 1974), and imine (Stults et al., 1983) systems.

An additional method of creating an activated matrix with synthetic polymers is to form the polymer by polymerizing preactivated monomers. A recent example of this type of synthetic matrix is the previously discussed vinyl azolactone copolymer marketed as Emphaze (3 M Company and Pierce); other new synthetic matrices include two-component systems such as HyperD (gel-in-a-shell) and the macroporous-microporous material Poros, both of which have excellent mechanical stability and fast flow characteristics (see Matrix Considerations). These, along with Pharmacia Biotech's hardened agarose, Superose and Sepharose Fast Flow, are being used in industrial affinity chromatography systems.

Critical Parameters

As noted in Reagents and Solutions, CNBr is very toxic and hazardous. The Material Safety Data Sheet (MSDS) should be read carefully and all precautions should be carefully followed. Note the following in particular (also see Reagents and Solutions):

BRYANT (CENTRAL) UNIVERSITY LIBRARY

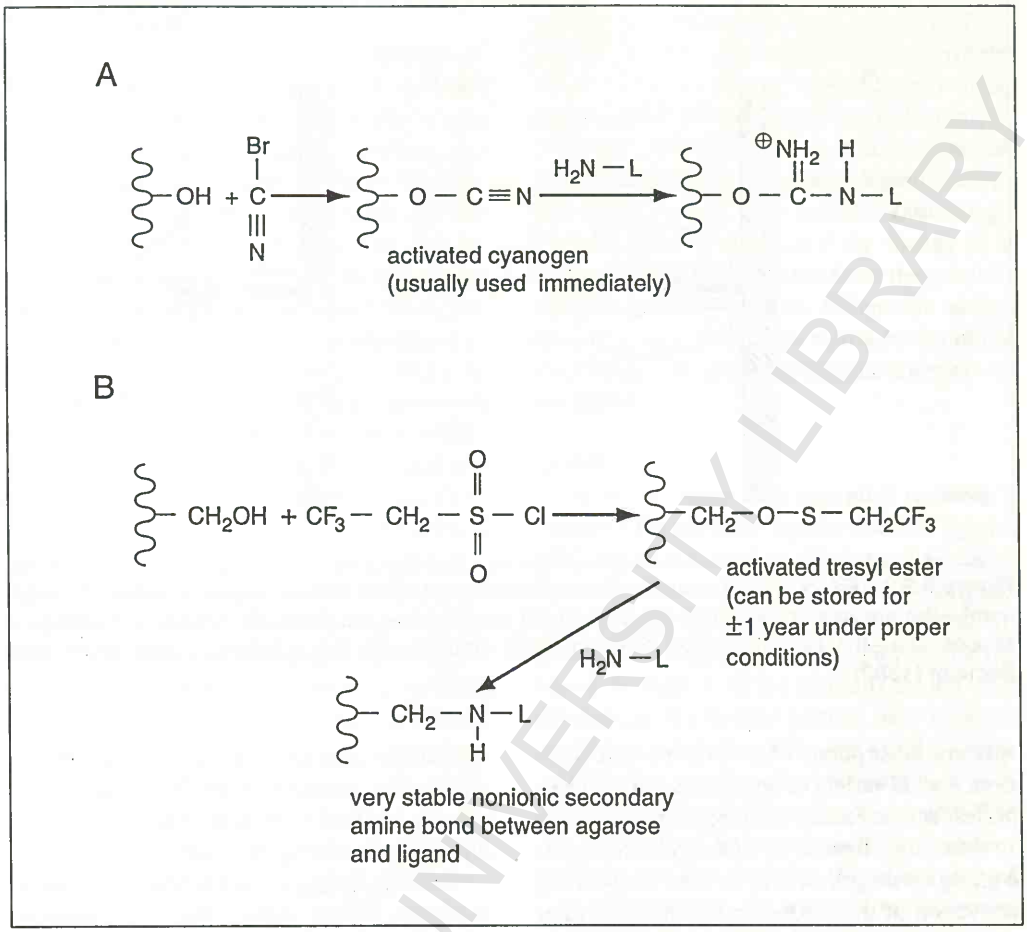

Figure 9.3.4 Activation reactions. (**A**) CNBr activation; (**B**) tresyl chloride coupling.

1. CNBr is very toxic and volatile and releases toxic cyanide fumes.
2. Because CNBr sublimes, bottles should be stored (briefly) in the refrigerator upside down.
3. CNBr should be used only in the hood, with proper equipment, per MSDS instructions, and never in a cold room.
4. Excess CNBr should be destroyed per the MSDS.
5. CNBr should not be stored for prolonged periods.
6. Use of solutions of CNBr in anhydrous acetonitrile is the most convenient method; use of prepared solutions (Aldrich) avoids some of the problems inherent in handling CNBr.

Because of the many variables that influence coupling/activation yields, neither activation nor coupling of ligands to solid matrices is precisely reproducible. For maximum reproducibility, the temperature, rate of addition and mixing, pH (where appropriate), moisture (in anhydrous solvents), and reagent and/or ligand concentration must all be carefully controlled, which is not easy to do. Normally a range of activation and coupling efficiencies is observed, largely because hydrolysis of the activated matrix is a significant process that competes with activation and coupling and that can, sometimes, even be the major reaction. Moreover, in coupling, the reactivity of nucleophilic residues of apparently similar ligands may be quite different, leading to dissimiliar coupling rates and efficiencies. In spite of this, sufficient control of the conditions is possible to achieve reasonably reproducible results *for a given system*, although results and the degree of reproducibility will vary from system to system.

Troubleshooting

It is wise to assay the final degree of activation when using the system described in the Alternate Protocols. This can be done qualitatively for *p*-nitrophenyl chloroformate (Alternate Protocol 1) by adding a small sample of the agarose gel to 0.1 M NaOH. If activation is successful, assuming the washes in step 3 of Alternate Protocol 1 were carried out as described, a bright yellow color will develop. Activation in either Alternate Protocol can be

RCU IASHICE TMAL UNIVERSITY LIBRARY

quantified by elemental analyses for nitrogen (Alternate Protocol 1) or fluoride (Alternate Protocol 2). For CNBr activation, methods of analysis are available (Kohn and Wilchek, 1983b), but usually it is best to base activation success on ligand coupling efficiency.

A common problem in activation and coupling lies in the competition between activation or coupling and hydrolysis. This is usually the result of failing to control temperature, pH, or the dryness of anhydrous solvents, where applicable. Temperature during activation can be kept sufficiently low if mixing is thorough, reactants are added slowly (monitoring temperature), and the reaction vessels are held in an ice bath. CNBr activation mixtures can also be cooled by adding ice whenever the temperature exceeds 5°C.

Anticipated Results

Perhaps the best way to gain an appreciation of the range of potential activation and coupling levels is to check the catalogs of major suppliers (e.g., Pierce, Sigma, and Pharmacia Biotech), where, for example, tresyl chloride is reported in terms of its ability to couple chymotrypsin (4 to 8 mg/ml of 4% cross-linked beaded agarose gel), *p*-nitrophenyl chloroformate is reported in micromoles of activation (10 to 30 μmol/ml of 4% cross-linked beaded agarose gel), and amino acids are immobilized on CNBr-activated 4% beaded agarose gel at from 1 μmol/ml (cysteine) to 20 μmol/ml (histidine). Such broad ranges represent, primarily, the extremes of batch-to-batch and ligand-to-ligand variations. Unfortunately, these values are based sometimes on wet weight and sometimes on dry weight agarose gel; thus, care needs to be taken in interpreting reported activation and/or coupling yields. Moreover, the matrix has a significant effect on yield. For example, Sepharose 4B is a 4% agarose gel with large pore diameters and small surface area, whereas Sepharose 6B is a 6% agarose gel with small pore diameters and large surface area. At a given activation level, Sepharose 6B would couple more of a small ligand, and Sepharose 4B, with its larger pores, might couple more of a very large ligand, e.g., a large protein or nucleic acid. In addition, cross-linked agarose gels (e.g., Sepharose CL-4B; CL = cross-linked) have smaller pores than non-cross-linked agarose gels.

Given the many variables—pore size, surface area, ligand size, ligand reactivity, and lability—it is difficult to predict potential yields for established systems, let alone for systems involving the immobilization of ligands that have never been immobilized. The best suggestion is to peruse catalogs and the literature for *systems* (e.g., agarose gel type and ligand type) that most closely approximate the one to be investigated and to use such a system as the best "predictor" of potential results.

Time Considerations

For the Basic Protocol, activation takes approximately 10 min, washing 10 to 20 min, and coupling is overnight, followed by washing 10 to 15 min. For Alternate Protocol 1, washing the agarose gel takes 20 to 30 min, activation takes 1 hr, and washing requires 30 to 40 min. For coupling, a 5-min wash is followed by a 24- to 48-hr incubation, a 10-min wash, and an overnight deactivation. This is followed by a 10- to 20-min wash and a 5-min test for completeness of deactivation. For Alternate Protocol 2, washing the agarose gel takes 20 to 30 min, and activation requires 10 to 15 min, followed by 30 to 40 min of washing. For coupling, 2 to 3 min is needed for the rapid wash, after which the ligand solution is added to the agarose beads, mixed (2 to 3 min) and the mixture is incubated overnight. This is followed by washing, which takes 20 to 30 min, with a subsequent overnight deactivation step.

Metal-Chelate Affinity Chromatography

Recombinant proteins engineered to have six consecutive histidine residues on either the amino or carboxyl terminus can be purified using a resin containing nickel ions (Ni^{2+}) that have been immobilized by covalently attached nitrilotriacetic acid (NTA). This technique, known as metal-chelate affinity chromatography (MCAC), can readily be performed with either native or denatured protein. The Strategic Planning section discusses techniques for creating a fusion protein consisting of the protein of interest with a histidine tail attached (for purification by MCAC; see *UNIT 6.5* for an example purification of HIV-1 integrase). The Basic Protocol describes expression of histidine-tail fusion proteins and their purification in native form by MCAC. Two alternate protocols describe purification of histidine-tail fusion proteins by MCAC under denaturing conditions and their renaturation by either dialysis or solid-phase renaturation. Support protocols are provided for analysis of the purified product and regeneration of the NTA resin. All of these protocols are easily adaptable to any protein expression system.

Prior to large-scale preparation, the cells should be tested for expression of the protein in soluble form (see *UNITS 6.1 & 6.2*). Even if protein is expressed mostly in insoluble form (i.e., bacterial inclusion bodies; *UNIT 6.3*), there may be a small fraction that remains soluble and can therefore be purified using the Basic Protocol. If little or no soluble protein is observed, one of the denaturing protocols (Alternate Protocols 1 and 2) should be used.

NOTE: All solutions and equipment coming into contact with live cells must be sterile.

STRATEGIC PLANNING

MCAC is designed to purify a specific protein whose complementary DNA (cDNA) sequence is available. A protein-expression system is selected and the cDNA is inserted into the appropriate expression vector (see *UNIT 5.1*). The cDNA sequence must encode a minimum of six histidines at either the amino or carboxyl terminus and must include an initiator methionine at the amino terminus and a termination codon at the carboxyl terminus. This can be accomplished by polymerase chain reaction (PCR) using primers

A 5′-GGGNNNNNNATGCATCATCATCATCATCAT . . . $N_{15\text{-}30}$-3′
RE site – MetHisHisHisHisHisHis . . .

B 5′-GGGNNNNNNTTAATGATGATGATGATGATG . . . $N_{15\text{-}30}$-3′
RE site – ENDHisHisHisHisHisHis . . .

Figure 9.4.1 Sequences of primers required to create histidine tails at protein termini. Functions (e.g., protein sequence) are marked below. Three guanines are included at the 5′ ends of each primer to facilitate restriction enzyme digestion of the PCR product prior to subcloning. NNNNNN represents a unique restriction enzyme site compatible with the selected vector. $N_{15\text{-}30}$ represents 15 to 30 additional nucleotides specific to the cDNA beginning with the second codon. Met represents an initiator methionine and END represents a termination codon. (**A**) Sequence of 5′ primer used to create a histidine tail at the amino terminus. The 3′ primer should include a second unique restriction enzyme site and the final 5 to 10 codons (including a stop codon) of the cDNA sequence. (**B**) Sequence of 3′ (antisense) primer used to create a histidine tail at the carboxyl terminus. The 5′ primer should contain a second unique restriction site and the first 5 to 10 codons of the cDNA sequence.

BOSTON UNIVERSITY LIBRARY

containing unique restriction-site sequences at the 5′ end (Fig. 9.4.1). Properly designed primers will permit insertion and expression of the cDNA in the correct reading frame.

An alternative to PCR is to subclone the cDNA into an existing vector, synthesize complementary oligonucleotides containing the hexahistidine sequence with compatible restriction enzyme site overhangs, and insert them into the subcloned cDNA (Struhl, 1987). It is important to insert the oligonucleotide into the cDNA near one of the termini in the correct reading frame.

Several companies (e.g., Qiagen, Novagen, and Invitrogen; see *SUPPLIERS APPENDIX*) sell expression systems that permit direct subcloning of cDNAs into vectors already containing oligohistidine tail sequences along with adjacent protease cleavage sites to allow removal of the tail after purification. Vectors have been developed for expression of histidine fusion proteins by bacteria, yeast, baculovirus, vaccinia, and various eukaryotic promoters. The protocols that follow are designed for use with a Novagen pET vector (Fig. 9.4.2), but may easily be modified for other vectors.

BASIC PROTOCOL

NATIVE MCAC FOR PURIFICATION OF SOLUBLE HISTIDINE-TAIL FUSION PROTEINS

This protocol describes expression and purification of histidine fusion proteins in *E. coli*. A desired protein is induced in bacteria, which are then harvested and lysed. The lysate is loaded directly onto a column containing Ni^{2+}-NTA resin and the protein is eluted in nearly pure form with MCAC buffer containing imidazole.

Materials

M9ZB medium (see recipe) containing 50 µg/ml ampicillin and 25 µg/ml chloramphenicol
E. coli BL21(DE3)pLysS or other suitable strain (Novagen) containing a pET vector (Fig. 9.4.2) expressing a histidine-tail fusion protein
0.1 M IPTG, filter sterilized
NTA resin slurry: 50% (w/v) suspension in 20% (v/v) ethanol (Qiagen)
100 mM $NiSO_4 \cdot 6H_2O$
MCAC-0, MCAC-20, MCAC-40, MCAC-60, MCAC-80, MCAC-100, MCAC-200, and MCAC-1000 buffers (see recipe)
150× protease inhibitor cocktail (see recipe)
10% (v/v) Triton X-100
1 M $MgCl_2$
MCAC-EDTA buffer (see recipe)
DNase I solution (see recipe)

Centrifuge with Beckman JA-20 rotor or equivalent
1 × 10–cm glass or polypropylene column

Additional reagents and equipment for growth of bacteria in liquid medium (*UNIT 5.3*) and analysis and processing of purified proteins by SDS-PAGE (see Support Protocol 1)

Express the protein

1. Inoculate 10 ml M9ZB/ampicillin/chloramphenicol with *E. coli* BL21(DE3)pLysS containing a pET vector expressing a desired histidine-tail fusion protein. Grow overnight with shaking at 37°C (see *UNIT 5.3*).
2. Inoculate 100 ml M9ZB/ampicillin/chloramphenicol with 1 ml of the overnight culture and grow with shaking at 37°C to OD_{600} = 0.7 to 1.0.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

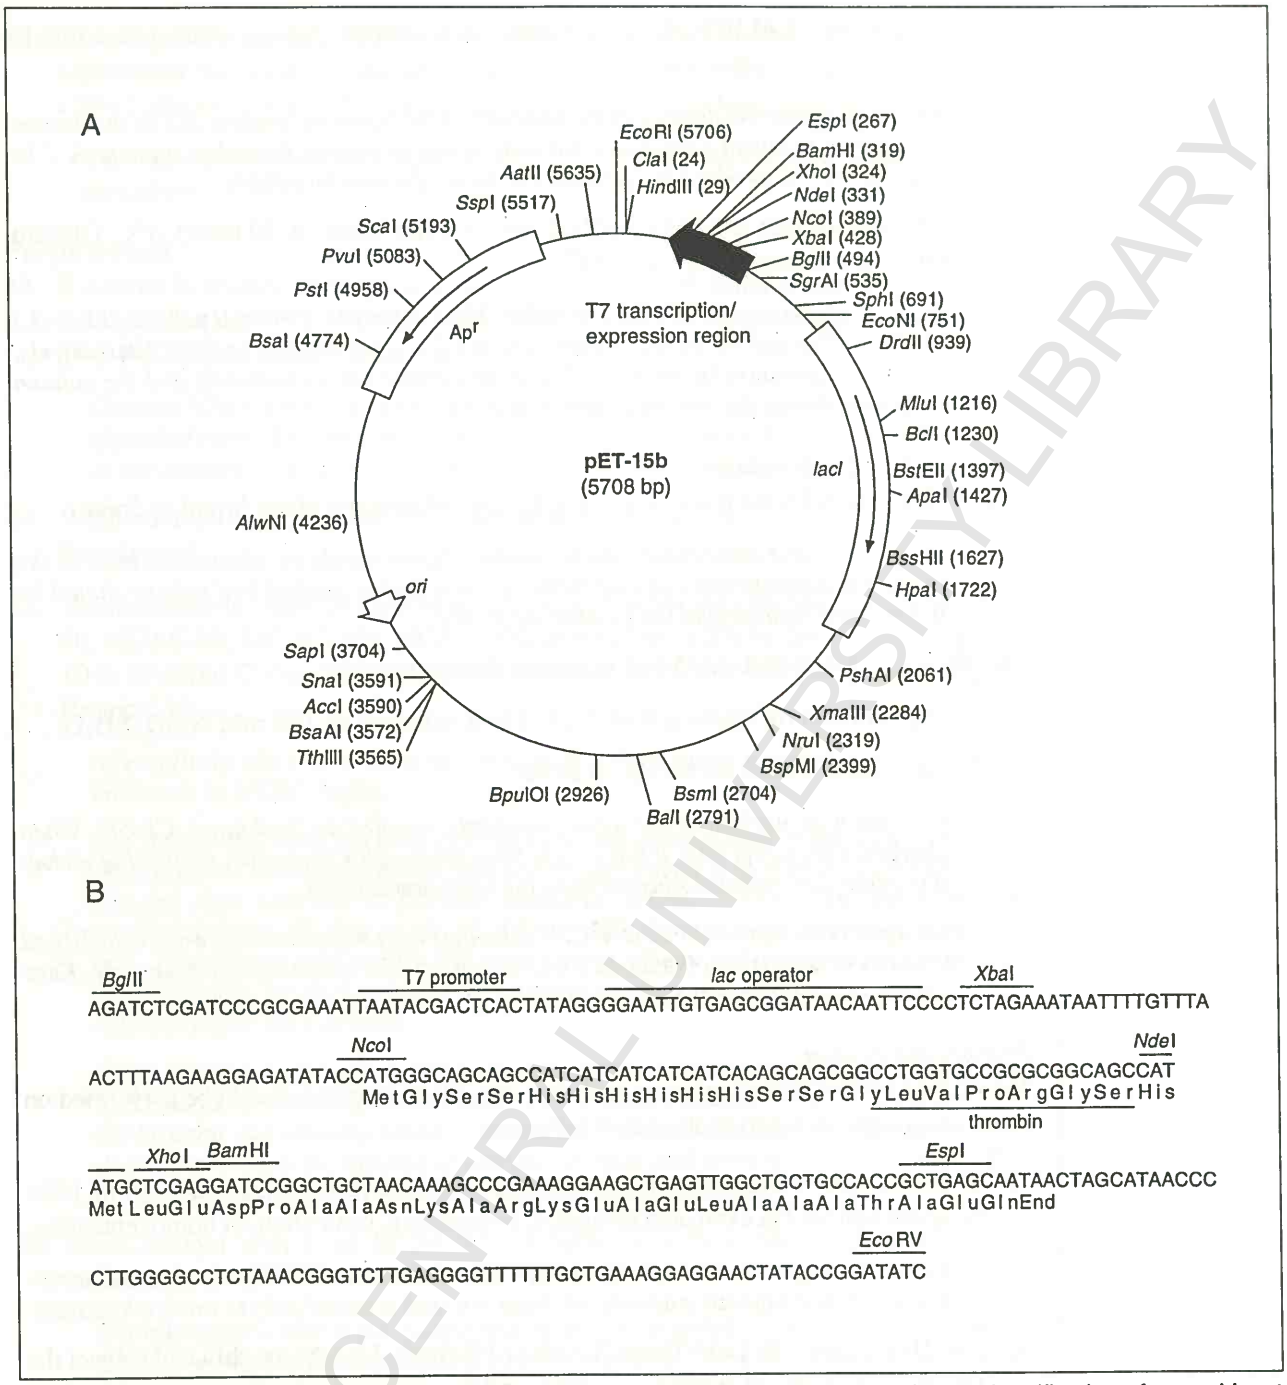

Figure 9.4.2 pET-15b, one of a series of pET vectors designed for cloning, expression, and purification of recombinant proteins. Reprinted with the permission of Novagen. **(A)** pET-15b vector; **(B)** sequence of pET-15b cloning/expression region. The target gene is cloned into the pET plasmid such that its expression is under the control of bacteriophage T7 transcription and translation signals (see *UNIT 5.2*). pET-15b encodes an amino-terminal His·Tag leader that allows purification of the resulting recombinant protein over Ni^{2+}-NTA resin. Following purification, the His·Tag can be removed by thrombin cleavage (see *UNIT 6.5*). The pET series are derivatives of vectors originally described by Studier et al. (1990) and are available from Novagen.

BCU IAS CENTRAL UNIVERSITY LIBRARY

3. Add 1 ml of 0.1 M IPTG (to 1 mM final) and continue shaking incubation 1 to 3 hr at 37°C.

Incubation time will depend on the solubility of the expressed protein. A 3-hr incubation will allow maximal expression but may result in mostly insoluble protein. A 1-hr incubation will produce less protein but more of it may be soluble.

4. Centrifuge 10 min at 4400 × *g* (5000 rpm in a Beckman JA-20 rotor), 4°C. Discard supernatant. Freeze pellet at –70°C.

It is not necessary to wash the cell pellet. The wet weight of the cell pellet will be ~0.5 g. The pellet can be stored indefinitely at –70°C before proceeding. Alternatively, extract preparation (steps 9 to 13) can be carried out immediately and the column prepared during the centrifugation at step 13.

Prepare the affinity column

5. Add 0.2 ml NTA resin slurry to a 1 × 10–cm column and allow liquid to drain.

During this and subsequent column washes, liquid should be allowed to drain to the top of the packed resin bed that forms as resin settles (packed bed volume should be 0.1 ml) and resin should not be allowed to dry.

6. Wash column with 1 ml (5 bed volumes) deionized water.

7. Charge column by washing with 1 ml (5 bed volumes) of 100 mM $NiSO_4 \cdot 6H_2O$.

8. Wash column with 2 ml MCAC-0 buffer.

NTA resin is nitrilotriacetic acid covalently coupled to Sepharose CL-6B. When charged with nickel ions, it has a light blue-green color, and when stripped of nickel, it is white. See supplier's instructions for resin preparation.

Charged resin can be stored at 4°C. If column is to be stored >1 day, wash with 10 bed volumes of 20% ethanol and add 1 bed volume of 20% ethanol prior to storage. Keep column sealed to prevent evaporation.

Prepare the extract

IMPORTANT NOTE: Beginning with this step, all procedures should be performed on ice or in a cold room unless otherwise indicated.

9. Thaw cell pellet (from step 4) on ice. Add 5 ml MCAC-0 buffer and 33 µl of 150× protease inhibitor cocktail and resuspend by pipetting, sonication, or homogenization.

All MCAC buffers contain phenylmethylsulfonyl fluoride (PMSF) as a protease inhibitor; to reduce expense, protease inhibitor cocktail is added only to the crude extract.

10. Add 0.05 ml of 10% (v/v) Triton X-100 (0.1% final). Mix thoroughly and subject the sample to 3 cycles of freezing at –70°C and thawing on ice.

Ionic detergents may interfere with binding of the protein to the resin and should not be used.

Cell lysis is evidenced by a visible increase in viscosity. The pLysS plasmid in these cells encodes an endogenous lysozyme that eliminates the need for exogenous lysozyme treatment to disrupt the bacterial cell wall.

11. Add 0.05 ml of 1 M $MgCl_2$ (final concentration 10 mM) and 0.05 ml of DNase I solution (final concentration 10 µg/ml DNase I). Mix gently and incubate 10 min at room temperature.

The DNase I treatment reduces the viscosity of the lysate.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

12. Centrifuge 15 min at 27,000 × *g* (15,000 rpm in JA-20 rotor), 4°C. Decant the supernatant into a clean container on ice and discard the pellet. Set aside and freeze a 10-µl aliquot at –70°C for later analysis by SDS-PAGE (see Support Protocol 1).

The supernatant can be frozen at –70°C indefinitely before continuing with the procedure.

Purify protein

13. If extract is frozen, thaw on ice. Load onto Ni^{2+}-NTA column and allow to flow through at a rate of 10 to 15 ml/hr. Collect column flowthrough and save for SDS-PAGE (see Support Protocol 1).

Charged NTA resin has a capacity of 5 to 10 mg histidine-tagged protein per milliliter of packed resin. The amount of extract that can be loaded on the column will depend on the amount of soluble histidine-tagged protein in the extract.

14. Wash column with 5 ml MCAC-0 buffer at a flow rate of 20 to 30 ml/hr. Discard flowthrough.

15. Wash column in stepwise fashion with 5 ml each of MCAC-20, MCAC-40, MCAC-60, MCAC-80, MCAC-100, MCAC-200, and MCAC-1000 buffers at a flow rate of 10 to 15 ml/hr. Collect 0.5-ml fractions and save on ice for SDS-PAGE (see Support Protocol 1).

Alternatively, the column can be eluted with a 5-ml linear gradient of 0 to 400 mM imidazole in MCAC buffer.

The second and third fractions of each wash will contain most of the eluted proteins. Most proteins with hexahistidine tails will remain bound in 60 mM imidazole (MCAC-60) and elute with 100 to 200 mM imidazole (MCAC-100 or -200); therefore, the purified protein will elute in MCAC-100 or -200. Proteins with longer histidine tails (e.g., 10 residues) bind to Ni^{2+}-NTA with greater affinity and require higher imidazole concentrations for elution. However, optimum washing and elution conditions must be determined for each protein.

Once optimum washing and elution conditions are established, it is possible to prepare the crude extract in a buffer that contains the highest imidazole concentration in which the histidine tail remains bound to the Ni^{2+}-NTA (e.g., MCAC-40 or -60 buffer). This decreases nonspecific binding of proteins to resin and permits use of a single buffer for extract preparation, column loading, and column washing.

16. Elute column with 1 ml MCAC-EDTA buffer at a flow rate of 10 to 15 ml/hr, collecting 0.5-ml fractions.

The blue-green color of the column will disappear as nickel is removed by EDTA. More tightly bound proteins may be found in these fractions. The resin can now be recharged (repeat steps 6 to 8) and the column reused.

If protein is eluted adequately with imidazole (as determined by overall yield for subsequent preparations), EDTA washing can be omitted. The column can be reequilibrated with MCAC-0 buffer and the purification repeated. The same column can be used three to five times before EDTA stripping and nickel recharging are necessary. Only one protein should be purified on any given column.

17. Analyze fractions for the presence of eluted protein.

An ultraviolet (280-nm) absorbance flow monitor is helpful for following column elution but is not necessary. An alternative is to measure the OD_{280} of individual fractions to identify protein-containing fractions. However, imidazole will also absorb at 280 nm.

A quick and easy method to determine which fractions contain eluted protein is to place 2 µl undiluted Protein Assay Dye Reagent Concentrate (Bio-Rad) on a piece of

BOWLES GREEN UNIVERSITY LIBRARY

Parafilm, add 8 µl from fraction to be tested, and mix by pipetting up and down. Immediate appearance of blue color indicates that the fraction contains protein. This does not work in the presence of Triton X-100 because the detergent itself produces an intense blue color; for this reason, Triton X-100 is excluded from the washing and elution buffers.

18. Combine the fractions containing eluted protein and remove a 10-µl aliquot for SDS-PAGE (see Support Protocol 1). Freeze the remainder in smaller aliquots at –70°C or in liquid nitrogen.

    If a different buffer for the protein is desired (e.g., for proteolytic removal of the histidine tail), the protein should be dialyzed against the buffer of choice to remove the MCAC buffer prior to storage at –70°C or in liquid nitrogen.

19. If time permits, proceed immediately to analysis of fractions by SDS-PAGE and processing of protein (see Support Protocol 1). Otherwise, freeze all samples at –70°C until ready for analysis and processing.

ALTERNATE PROTOCOL 1

DENATURING MCAC FOR PURIFICATION OF INSOLUBLE HISTIDINE-TAIL FUSION PROTEINS

High-level expression of foreign proteins in bacteria and other cells frequently results in poor solubility of the expressed protein (see *UNITS 5.1 & 5.2*). These insoluble proteins form inclusion bodies in bacteria, and strong chaotropic agents such as guanidine, urea, or SDS are usually required to solubilize them. These agents denature the protein and destroy the secondary structure that is essential to other affinity purification methods (e.g., maltose-binding protein or glutathione-*S*-transferase fusion proteins). A significant advantage of metal-chelate affinity chromatography is that the oligohistidine tail will bind to the Ni^{2+}-NTA resin even when the protein is denatured. In denaturing MCAC, the protein extract is solubilized with 6 M guanidine and the entire affinity purification procedure is carried out in guanidine. The purified, denatured protein is renatured during dialysis.

Additional Materials (also see Basic Protocol)

GuMCAC-0, GuMCAC-20, GuMCAC-40, GuMCAC-60, GuMCAC-100, and GuMCAC-500 buffers (see recipe)
GuMCAC-EDTA buffer (see recipe)
Appropriate final buffer for protein (e.g., for proteolytic cleavage or long-term storage)
Guanidine·HCl
Additional reagents and equipment for analysis and processing of purified proteins (see Support Protocol 1) and dialysis (*APPENDIX 3B & UNIT 4.4*)

Express the protein

1. Prepare the pellet of *E. coli* expressing a histidine-tail fusion protein (see Basic Protocol, steps 1 to 4).

   The pellet can be stored indefinitely at –70°C before proceeding. Alternatively, extract preparation (steps 5 and 6) can be carried out immediately and the column prepared during the centrifugation at step 6.

Prepare the affinity column

2. Prepare column (see Basic Protocol, steps 5 to 7).

3. Wash column with 2 ml GuMCAC-0 buffer.

   During this and subsequent column washes, liquid should be allowed to drain to top of packed resin bed and resin should not be allowed to dry.

BCU IASI CENTRAL UNIVERSITY LIBRARY

Prepare cell extract

4. Thaw cell pellet (from step 1) on ice. Resuspend in 5 ml GuMCAC-0 buffer by pipetting, sonication, or homogenization.

5. Freeze 10 min at –70°C and thaw at room temperature.

   Protease inhibitors are omitted because proteases are inactivated by guanidine. Triton X-100 is not needed at this step. Freezing is not necessary but is included because it ensures complete lysis of cells.

   Subsequent steps can be performed at room temperature. However, if solid-phase renaturation is used (see Alternate Protocol 2), it is better to maintain lower temperatures throughout the process.

6. Gently mix samples for 30 min using a rocker, rotating mixer, or magnetic stirrer. Centrifuge 15 min at 27,000 × *g* (15,000 rpm in Beckman JA-20 rotor), 4°C. Decant supernatant into a clean container and discard pellet. Set aside a 10-µl aliquot for analysis by SDS-PAGE (see Support Protocol 1).

   The supernatant can be frozen at –70°C indefinitely before continuing with the procedure.

Purify protein

7. If extract from step 5 is frozen, thaw at room temperature. Load onto Ni^{2+}-NTA column and allow to flow through at a rate of 10 to 15 ml/hr. Collect flowthrough and save a 10-µl aliquot for SDS-PAGE (see Support Protocol 1).

8. Wash column with 5 ml GuMCAC-0 buffer at a rate of 20 to 30 ml/hr. Discard the flowthrough.

9. Wash column in stepwise fashion with 5 ml GuMCAC-20, -40, -60, -100, and -500 buffers at a rate of 10 to 15 ml/hr. Collect 0.5-ml fractions and save for SDS-PAGE (see Support Protocol 1).

   The second and third fractions from each wash will contain most of the unbound protein. The histidine tail binds slightly less avidly under denaturing conditions. Lower imidazole concentrations are therefore required for washing and elution than in the Basic Protocol.

10. Elute with 1 ml GuMCAC-EDTA buffer at a rate of 10 to 15 ml/hr, collecting 0.5-ml fractions.

11. Identify fractions containing the protein, pool together, transfer to dialysis tubing, and seal.

    Alternatively, fractions can be frozen at –70°C indefinitely before continuing with the procedure.

    Guanidine precipitates in the presence of SDS and must be removed by dialysis before SDS-PAGE. An alternative technique employs buffers that switch from 6 M guanidine to 8 M urea during affinity column washing (Stüber et al., 1990). This permits samples to be taken directly from urea fractions without dialysis and analyzed by SDS-PAGE or injected into animals for antibody production.

Renature purified protein by dialysis

12. Prepare appropriate final buffer for protein (e.g., for proteolytic cleavage or long-term storage) and add sufficient guanidine to bring final concentration to 4 M.

13. Dialyze purified protein from step 11 for ≥2 hr at 4°C against 500 ml buffer/4 M guanidine (see *APPENDIX 3B*).

    The MWCO of the dialysis membrane should be chosen to be smaller than the MW of the purified protein. In most cases an MWCO of 12 to 14 kDa is sufficient.

BUDAPEST CENTRAL UNIVERSITY LIBRARY

14. Remove 250 ml buffer/guanidine and add 250 ml buffer without guanidine. Continue dialysis ≥2 hr. Repeat.

    With some proteins, renaturation by dialysis may require longer dialysis periods and more gradual decrements in the guanidine concentration of the buffer. Conditions for each protein must be determined empirically.

15. Remove dialysis bag to a container containing 500 ml of fresh buffer without guanidine at 4°C. Continue dialysis 2 hr to overnight.

16. Remove sample from dialysis bag, divide into aliquots, and freeze at –70°C or in liquid nitrogen.

    If protein precipitates during dialysis, solid-phase renaturation (see Alternate Protocol 2), in which protein bound to the column is renatured before elution, should be employed.

17. Analyze fractions and process protein (see Support Protocol 1).

ALTERNATE PROTOCOL 2

SOLID-PHASE RENATURATION OF MCAC-PURIFIED PROTEINS

In Alternate Protocol 1, removal of denaturants by dialysis will occasionally lead to precipitation of protein, possibly due in part to entanglement or aggregation of separate protein molecules as they refold. To avoid this problem, solid-phase renaturation may be attempted. In this procedure, protein extract is prepared and bound to the column under denaturing conditions. A series of washes removes the denaturing agent before the target protein is eluted and the resulting renatured protein is eluted from the column under native conditions.

***Additional Materials** (also see Basic Protocol)*

1:1 (v/v) MCAC-20/GuMCAC-20 buffer (see recipes)
3:1 (v/v) MCAC-20/GuMCAC-20 buffer (see recipes)
7:1 (v/v) MCAC-20/GuMCAC-20 buffer (see recipes)

1. Prepare protein extract, bind to column, and wash with GuMCAC buffers (see Alternate Protocol 1, steps 1 to 9).

2. Wash column with 5 ml of 1:1 (v/v) MCAC-20/GuMCAC-20 buffer.

   During this and subsequent washes, liquid should be allowed to drain just to top of packed resin bed and resin should not be allowed to dry.

3. Wash column with 5 ml of 3:1 (v/v) MCAC-20/GuMCAC-20 buffer.

4. Wash column with 5 ml of 7:1 (v/v) MCAC-20/GuMCAC-20 buffer.

5. Wash column with MCAC buffers, elute proteins, and analyze (see Basic Protocol, steps 15 to 19).

   Slow elution (between 1 and 2 hr) with a 5-ml linear gradient from 100% GuMCAC-20 buffer to 100% MCAC-20 buffer may also yield efficient renaturation.

BCU IASI CENTRAL UNIVERSITY LIBRARY

ANALYSIS AND PROCESSING OF PURIFIED PROTEINS

The success of the purification scheme (particularly during a small pilot study) should be monitored at each stage by SDS-PAGE. If the fusion protein contains a specific protease cleavage site, the histidine tail can be removed using an appropriate proteolytic procedure, if desired.

Materials

Fractions from MCAC column purification (crude extract, flowthroughs, and purified protein; see Basic Protocol or Alternate Protocols 1 or 2)
2× SDS sample buffer (*UNIT 10.1*)
MCAC-0 buffer (see recipe)

Additional reagents and equipment for one-dimensional SDS-PAGE (*UNIT 10.1*), cleavage of proteins with factor Xa *or* thrombin (*UNIT 6.5*), and dialysis (*UNIT 4.4 & APPENDIX 3B*)

1. Thaw aliquots of fractions to be analyzed on ice. Mix 5 µl from crude extract and crude flowthrough fractions and 10 µl from the second and third fractions from each washing step with an equal volume of 2× SDS sample buffer.

2. Load samples onto a standard SDS-PAGE gel. Run gel and visualize to identify the fractions containing purified protein (*UNIT 10.1*).

   Guanidine must be removed by dialysis prior to addition of SDS sample buffer.

3. Thaw the remaining aliquots of fractions containing purified protein, dialyze against the appropriate proteolysis buffer, and carry out cleavage procedure if desired. If necessary, after cleavage dialyze the protein against an appropriate storage buffer and freeze in aliquots.

   The size of the cleaved histidine tail will generally be <3 kDa, depending on the design of the fusion protein. This fragment will usually be removed by the dialysis. It may also be removed by ultrafiltration (which will also concentrate the protein), size-exclusion chromatography, or a second MCAC (see Basic Protocol, steps 13 to 19). The advantage of a second MCAC is that the histidine tail and any uncleaved protein will bind to the column and only the cleaved protein will be found in the flowthrough from step 12. Aliquots of each fraction should be analyzed by SDS-PAGE to verify recovery of pure protein.

   If an expression vector other than pET has been used, and the fusion protein does not contain an appropriate cleavage site for factor Xa or thrombin, or if the histidine tail will not interfere with subsequent studies, omit the cleavage procedure. Presence of the histidine tail will not generally affect the protein's biologic functions (see Background Information).

BCU IASI / CENTRAL UNIVERSITY LIBRARY

NTA RESIN REGENERATION

NTA resin can be repeatedly charged with Ni^{2+} and stripped. Over time, however, some protein residue will accumulate and decrease the efficiency of the resin, resulting in slow flow rates or lack of blue-green color after charging with Ni^{2+}. Periodic regeneration (e.g., after 5 to 10 cycles of charging and stripping) permits recycling of the resin for long-term use.

Materials

2.5 ml used NTA resin (packed volume)
Stripping solution: 0.2 M acetic acid/6 M guanidine·HCl
2% (w/v) SDS
20%, 25%, 50%, 75%, and 100% (v/v) ethanol
0.1 M EDTA, pH 8.0

1. Wash resin with 5 ml stripping solution.

   In this and all subsequent washes, liquid added to the column should be allowed to drain to top of packed resin bed and resin should not be allowed to dry.

2. Wash with 5 ml water.
3. Wash with 7.5 ml of 2% (w/v) SDS.
4. Wash with 2.5 ml of 25% (v/v) ethanol.
5. Wash with 2.5 ml of 50% (v/v) ethanol.
6. Wash with 2.5 ml of 75% (v/v) ethanol.
7. Wash with 12.5 ml of 100% (v/v) ethanol.
8. Wash with 2.5 ml of 75% (v/v) ethanol.
9. Wash with 2.5 ml of 50% (v/v) ethanol.
10. Wash with 2.5 ml of 25% (v/v) ethanol.
11. Wash with 2.5 ml water.
12. Wash with 12.5 ml of 0.1 M EDTA, pH 8.0.
13. Wash with 7.5 ml water. Proceed either to nickel charging (see Basic Protocol, step 7) or to step 14 below for long-term storage of the resin.
14. Add 2.5 ml of 20% (v/v) ethanol to resin and store at 4°C.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DNase I solution

Dissolve lyophilized DNase I (U.S. Biochemical) at a final concentration of 1 mg/ml in 50% glycerol/1 mM $CaCl_2$. Store ≤1 year at –20°C.

GuMCAC buffers (store ≤6 months at 4°C)

GuMCAC-0 buffer:
20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
6 M guanidine·HCl

GuMCAC-500 buffer:
20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
6 M guanidine·HCl
0.5 M imidazole

GuMCAC-20, GuMCAC-40, GuMCAC-60, and GuMCAC-100 buffers:

These buffers (containing different concentrations of imidazole) are made by mixing GuMCAC-0 buffer and GuMCAC-500 buffer in the appropriate ratios: e.g., for GuMCAC-20 buffer, use 96:4 (v/v) GuMCAC-0/GuMCAC-500.

GuMCAC-EDTA buffer

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
6 M guanidine·HCl
0.1 M EDTA, pH 8.0
Store ≤6 months at 4°C

M9 medium, 10×

30 g Na_2PO_4
15 g KH_2PO_4
5 g NH_4Cl
2.5 g NaCl
15 mg $CaCl_2$ (optional)
H_2O to 1 liter

Heat with stirring until dissolved. Pour aliquots into separate bottles, cap loosely, and autoclave 15 min at 15 lb/in^2. After the bottles cool to <50°C, add nutritional supplements and/or antibiotics as desired. After the bottles cool to <40°C, tighten bottle caps and store indefinitely at room temperature (discard if medium becomes contaminated).

M9ZB medium

Dissolve 10 g N-Z-Amine A (Sigma) and 5 g NaCl in 889 ml water. Autoclave, cool, and add 100 ml of 10× M9 medium (see recipe), 1 ml of 1 M sterile $MgSO_4$, and 10 ml of 40% (w/v) glucose (filter sterilized). Store ≤1 year at room temperature.

BOSTON UNIVERSITY CENTRAL LIBRARY

MCAC buffers (store ≤6 months at 4°C)

MCAC-0 buffer:
20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
1 mM PMSF (phenylmethylsulfonyl fluoride)

MCAC-1000 buffer:
20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
1 M imidazole
1 mM PMSF

Add PMSF immediately before use from a 0.2 M stock in 100% ethanol stored at room temperature. All buffers used with Ni^{2+}-NTA resin contain high salt concentrations to reduce nonspecific electrostatic interactions between proteins and resin. Lower salt concentrations can be used but may lead to nonspecific binding of unwanted proteins to the resin.

MCAC-20, MCAC-40, MCAC-60, MCAC-80, MCAC-100, and MCAC-200 buffers:

These buffers (containing different concentrations of imidazole) are made by mixing MCAC-0 buffer and MCAC-1000 buffer in the appropriate ratios: e.g., for MCAC-60 buffer, 94:6 (v/v) MCAC-0/MCAC-1000.

MCAC-EDTA buffer

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
0.1 M EDTA, pH 8.0
1 mM PMSF
Store ≤6 months at 4°C

Protease inhibitor cocktail, 150×

Stock solutions:
2 mg/ml aprotinin in H_2O
1 mg/ml leupeptin in H_2O
1 mg/ml pepstatin A in methanol

Cocktail: Combine 1.5 vol of each stock solution with 5.5 vol sterile water.

Protease inhibitors can be obtained from Sigma or U.S. Biochemical. The stock solutions and cocktail are stable ≥6 months at –20°C.

COMMENTARY

Background Information

Metal-chelate affinity chromatography (also called immobilized metal affinity chromatography or IMAC) for protein purification was first described in 1975 (Porath et al., 1975). It is based on the ability of certain amino acids acting as electron donors on the surface of proteins (histidine, tryptophan, tyrosine, or phenylalanine) to bind reversibly to transition-metal ions that have been immobilized by a chelating group covalently bound to a solid support. Of these amino acids, histidine is quantitatively the most important in mediating the binding of most proteins to immobilized metal ions. Histidine binds selectively to immobilized metal ions even in the presence of excess free metal ions in solution (Hutchens and Yip, 1990b). Copper and nickel ions have the greatest affinity for histidine (Yip et al., 1989).

Proteins and peptides containing phosphoamino acids (phophoserine, phosphotyrosine,

BCU IAS/CENTRAL UNIVERSITY LIBRARY

or phosphothreonine) have also been purified by MCAC via selective interaction of the terminal phosphate group with Fe^{3+} (Muszynska et al., 1992). Phosphoproteins also bind to less common metals such as lutetium, scandium, and thorium (Andersson and Porath, 1986).

The chelating group that has been used most extensively for MCAC is iminodiacetic acid (IDA). The tridentate IDA group binds to three sites within the coordination sphere of divalent metal ions such as copper, nickel, zinc, and cobalt. When copper ions (coordination number of 4) are bound to IDA, only one site remains available for interaction with proteins (Hochuli et al., 1987). For nickel ions (coordination number of 6) bound to IDA, three sites are available for binding to proteins. Thus Cu^{2+}-IDA complexes are stable on the column but have lower capacity for protein binding. Conversely, Ni^{2+}-IDA complexes bind proteins more avidly, but the Ni^{2+}-protein complexes are more likely to dissociate from the solid support.

A pentadentate chelating group—*N*,*N*,*N*′-tris(carboxymethyl)ethylenediamine (TED)—has also been used for MCAC. This chelator binds five coordination sites of the metal ions, providing highly stable metal ion–TED groups. However, for metal ions with a coordination number of 6, this leaves only one site available for protein interaction.

The development of a new metal-chelating adsorbent, nitrilotriacetic acid (NTA), has provided a convenient and inexpensive tool for purification of proteins containing histidine residues (Hochuli et al., 1987). The quadridentate NTA moiety covalently coupled via a spacer arm to Sepharose CL-6B forms an extremely stable complex with metal ions possessing a coordination number of 6 (e.g., Ni^{2+}). After binding to the NTA, the Ni^{2+} ion has two sites within its octahedral coordination sphere available for binding to electron donor groups (i.e., histidine) on the surface of proteins. Thus the advantage of NTA over IDA is that the Ni^{2+} ion is bound by four rather than three of its coordination sites. This minimizes leaching of the metal from the solid support and allows for more stringent purification conditions. The NTA also binds Cu^{2+} ions with high affinity, but this occupies all of the coordination sites, rendering the resulting complex ineffective for MCAC.

The affinity of histidine residues for immobilized Ni^{2+} ions allows selective purification of proteins containing a high proportion of histidine residues on the surface. Immobilized copper or nickel ions bind native proteins with a K_d of $1–17 \times 10^{-5}$ M (Hutchens and Yip, 1990a). This affinity is enhanced significantly by designing proteins to contain short stretches (6 to 10 residues) of histidines in regions likely to be surface exposed (amino or carboxyl termini) using recombinant DNA technology. Addition of a histidine tail results in a protein that binds to the Ni^{2+}-NTA complex with a K_d of 10^{-13} M at pH 8.0 even in the presence of detergent, ethanol, 2 M KCl (Hoffmann and Roeder, 1991), 6 M guanidine (Hochuli et al., 1988), or 8 M urea (Stüber et al., 1990).

The histidine tail binds to the Ni^{2+}-NTA resin via the imidazole side chains of the histidine residues. At pH ≥7.0, the imidazole side chain is deprotonated, with a net negative charge; at pH 5.97 (the pK of the imidazole side chain of histidine), 50% of the histidines are protonated; and at pH ≤4.5, almost all of the histidines are protonated and do not interact with Ni^{2+}-NTA. Thus, there are two methods of dissociating histidine tails from the Ni^{2+}-NTA resin. The first method, presented in this unit, uses increasing concentrations of imidazole at constant pH to displace the histidine tail from the Ni^{2+}-NTA. This technique provides great versatility because it can be used for both native and denaturing MCAC and buffer preparation is simplified. The second method uses buffers of decreasing pH to elute the histidine tail and is quite efficient for producing pure protein (Hochuli et al., 1988). Disadvantages are that the pH must be maintained accurately at all temperatures and that some proteins may not be able to withstand the extreme pH change.

Creation of a small histidine tail has advantages over other fusion protein systems. Addition of six histidines to the protein adds only 0.84 kDa to the mass of the protein, whereas other fusion protein systems utilize much larger affinity groups that often must be removed to allow normal protein function (e.g., glutathione-*S*-transferase, protein A, maltose-binding protein, and lacZ have masses of 26, 30, 40, and 116 kDa, respectively). The small histidine tail is not immunogenic and therefore need not be removed before the purified protein is injected into animals for antibody production. Histidine tail fusion proteins often retain their normal biologic functions—e.g., dihydrofolate reductase and adenylylcyclase retain their enzymatic activities (Hochuli, 1990; Taussig et al., 1993) and the TATA box binding protein retains its transcriptional regulatory function (Parvin et al., 1992). The aforementioned stud-

BOARD OF TRUSTEES LIBRARY

ies also demonstrate the technique's suitability for purification of membrane, cytoplasmic, and nuclear proteins. However, although it often is not necessary to remove the histidine tail, it is possible to include this step and still generate sufficient quantities of protein pure enough for detailed X-ray crystallographic studies (Nikolov et al., 1992).

The histidine tail can also be used to detect the recombinant protein. Ni^{2+}-NTA covalently coupled to alkaline phosphate (available from Qiagen; see *SUPPLIERS APPENDIX*) can bind directly to histidine tailed proteins, and the bound alkaline phosphatase can be quantitated by standard techniques (*UNIT 10.10*). This allows for direct quantitation of histidine-tailed proteins blotted to membranes without the need for primary and secondary antibodies (Botting and Randall, 1995).

The protocols presented in this unit utilize protein produced in bacteria; an example protocol for the purification of HIV-1 integrase expressed in *E. coli* is presented in *UNIT 6.5*. Histidine-tail fusion proteins have also been expressed and purified from HeLa cells using transient transfection techniques (Janknecht and Nordheim, 1992; Papavassiliou et al., 1992) or a vaccinia expression system (Janknecht et al., 1991) and from baculovirus-infected insect cells (Gearing et al., 1993; Taussig et al., 1993). Therefore, MCAC can be used with any protein expression system currently available.

This technique can also be used to prepare immunoaffinity columns (*UNIT 9.5*). Histidine tails have been covalently linked to oligosaccharide moieties of monoclonal antibodies and then subsequently bound to Ni^{2+}-NTA columns (Loetscher et al., 1992). The advantage of this method over more conventional techniques of antibody immobilization is that the immobilized antibody will retain a much greater ability to bind antigen and is recoverable from the column.

Critical Parameters

NTA can be synthesized according to the protocol provided by Hochuli (1990); more commonly, it is purchased from Qiagen, which provides detailed protocols for its use.

Binding and elution of proteins from the Ni^{2+}-NTA resin depend upon the histidine content of the protein. Each protein will have a slightly different histidine content and optimal elution profile on the Ni^{2+}-NTA resin. Therefore, it is important to establish the buffer imidazole concentrations that will give the best purification of a particular protein. As outlined in the Basic Protocol, gradient or stepwise elution of small-scale preparations should be done before large-scale preparations are attempted. It is also possible to perform batch purification by adding charged resin to a tube containing the extract, mixing for 1 hr, loading into a column, washing, and eluting.

Troubleshooting

The most common problem is low yield of purified protein in the expected fraction. This can be caused by insufficient protein loaded on the column, protein not binding to the column, or protein not eluting from the column.

Insufficient protein

It is important to verify that the desired protein is adequately expressed in the chosen system. Check the crude extract for the presence of the expressed protein by SDS-PAGE or other methods before proceeding to the affinity purification steps.

Protein in the crude lysate may undergo significant proteolytic degradation in some cell types. Always use PMSF, minimize freezing and thawing, maintain low temperatures during purification, and use additional protease inhibitors whenever practical.

Lack of binding

If the protein does not bind to the column, either the protein lacks a histidine tail, the column is inadequately charged with nickel, or the histidine tail is buried in the protein and is inaccessible to the resin. Before expression and purification are attempted, verify that the DNA sequence of the histidine tail and adjacent protein-coding sequence are in frame with each other and that initiation and termination codons are present. If the histidine tail is at the amino terminus, it may be helpful to delete the endogenous codon for initiator methionine; if this is present, translation may initiate downstream of it, producing a full-length protein without a tail. Placing the histidine tail at the carboxyl terminus ensures that only the full-length protein will bind to the Ni^{2+}-NTA resin (if protease activity is controlled). However, a histidine tail at the carboxyl terminus is more likely to be inaccessible to the resin.

Chelating agents (e.g., EDTA and EGTA) must be excluded from all solutions because they will strip the Ni^{2+} ions from the affinity column. Strong reducing agents such as dithiothreitol should also be avoided because they reduce the Ni^{2+} ions to metallic nickel,

BCU IAS / CENTRAL UNIVERSITY LIBRARY

forming a brown precipitate. Some proteins will require the presence of reducing agents to maintain structure. It is possible to use up to 10 mM 2-mercaptoethanol with the Ni^{2+}-NTA resin, although the lowest possible concentration should be used.

The Ni^{2+}-NTA should retain a distinct blue-green color throughout the purification process until EDTA is applied. If the resin is white or if the blue-green color is faint after charging the column with Ni^{2+}, check all buffers and make sure no chelating and reducing agents are present. Recharge the column with Ni^{2+} and if the color is still faint or absent, regenerate the NTA resin (see Support Protocol 2) and repeat Ni^{2+} charging (see Basic Protocol, steps 6 to 8). If the resin is still white, discard it and start over with a new batch.

If the protein has or should have a histidine tail but is not binding to the resin, perform the purification under denaturing conditions (see Alternate Protocol 1 or 2) to unmask the inaccessible histidine tail. Placing the histidine tail at the opposite terminus of the protein may also be helpful.

Failure to elute

If the protein appears to be binding to the column but not eluting, make a final elution with EDTA-containing buffer. Any protein bound to the Ni^{2+}-NTA will be removed with the EDTA. Occasionally the protein bound to the resin will precipitate and not elute; if this problem is suspected, purify the protein under denaturing conditions and analyze all eluted fractions by SDS-PAGE for the presence of the expressed protein.

Anticipated Results

The maximum binding capacity of Ni^{2+}-NTA resin is 5 to 10 mg of protein per milliliter of packed resin. Under ideal conditions, as much as 80% of the bound protein can be recovered. The limiting factor in most instances will probably be the amount of protein loaded on the resin, which depends on the protein expression system.

Time Considerations

Expression of protein and preparation of crude extract require 1 day for the system described here. Column preparation requires 30 to 60 min. Loading, washing, and eluting the column require 4 to 6 hr.

Immunoaffinity Chromatography

This unit describes the isolation of soluble or membrane-bound protein antigens from cells or homogenized tissue by immunoaffinity chromatography. This technique involves the elution of a single protein from an immunoaffinity column after prior elution of nonspecifically adsorbed proteins. Specifically, antibodies are coupled to Sepharose (an insoluble, large-pore-size chromatographic matrix). High-molecular-weight antigens pass freely into and out of the pores and bind to antibodies covalently bound to the matrix. To elute the bound antigen from the immunoaffinity matrix, the antibody-antigen interaction is destabilized by brief exposure to high-pH (Basic Protocol) or low-pH (Alternate Protocol 1) buffer. The use of batch purification of antigens shortens the column loading time (Alternate Protocol 2). The detergent octyl β-D-glucoside can be used instead of Triton X-100 for elution. Because octyl β-D-glucoside has a high critical micelle concentration (CMC) it can be readily removed by dialysis (Alternate Protocol 3). The procedure for covalently linking an antibody to Sepharose using the cyanogen bromide activation method is given in the Support Protocol.

ISOLATION OF SOLUBLE OR MEMBRANE-BOUND ANTIGENS

BASIC PROTOCOL

Two different Sepharose columns in series—a precolumn to remove nonspecifically binding material and a specific column—are used to isolate antigens from a cell or tissue lysate. Column fractions are analyzed by SDS-PAGE and silver staining to detect the antigens.

Materials

Antibody (Ab)-Sepharose (see Support Protocol)
Activated, quenched (control) Sepharose, prepared as for Ab-Sepharose (see Support Protocol) but eliminating Ab or substituting irrelevant Ab during coupling
Cells or homogenized tissue
Tris/saline/azide (TSA) solution (see recipe), ice cold
Lysis buffer (see recipe), ice cold
5% (w/v) sodium deoxycholate (Na-DOC; filter sterilize and store at room temperature)
Wash buffer (see recipe)
Tris/Triton/NaCl buffers, pH 8.0 and 9.0 (see recipe), ice-cold
Triethanolamine solution (see recipe), ice cold
1 M Tris·Cl, pH 6.7 (*APPENDIX 2E*), ice cold
Column storage solution (see recipe), ice cold

Chromatography columns
Ultracentrifuge
Quick-seal centrifuge tubes (Beckman)

Additional reagents and equipment for column chromatography (*UNITS 8.1*), SDS-PAGE (*UNIT 10.1*), and silver staining (*UNIT 10.5*)

NOTE: Carry out all procedures involving antigen in a 4°C cold room or on ice.

Prepare the columns

1. Prepare an Ab-Sepharose immunoaffinity column (5 ml; 5 mg/ml antibody per milliliter packed Sepharose) and an activated, quenched (control) Sepharose precolumn (5 ml packed bed volume) linked in series (Fig. 9.5.1).

Irrelevant antibody can be coupled to the Sepharose in the precolumn.

Column size can vary; adjust amounts of Sepharose and cells proportionally.

BOWLING GREEN STATE UNIVERSITY LIBRARY

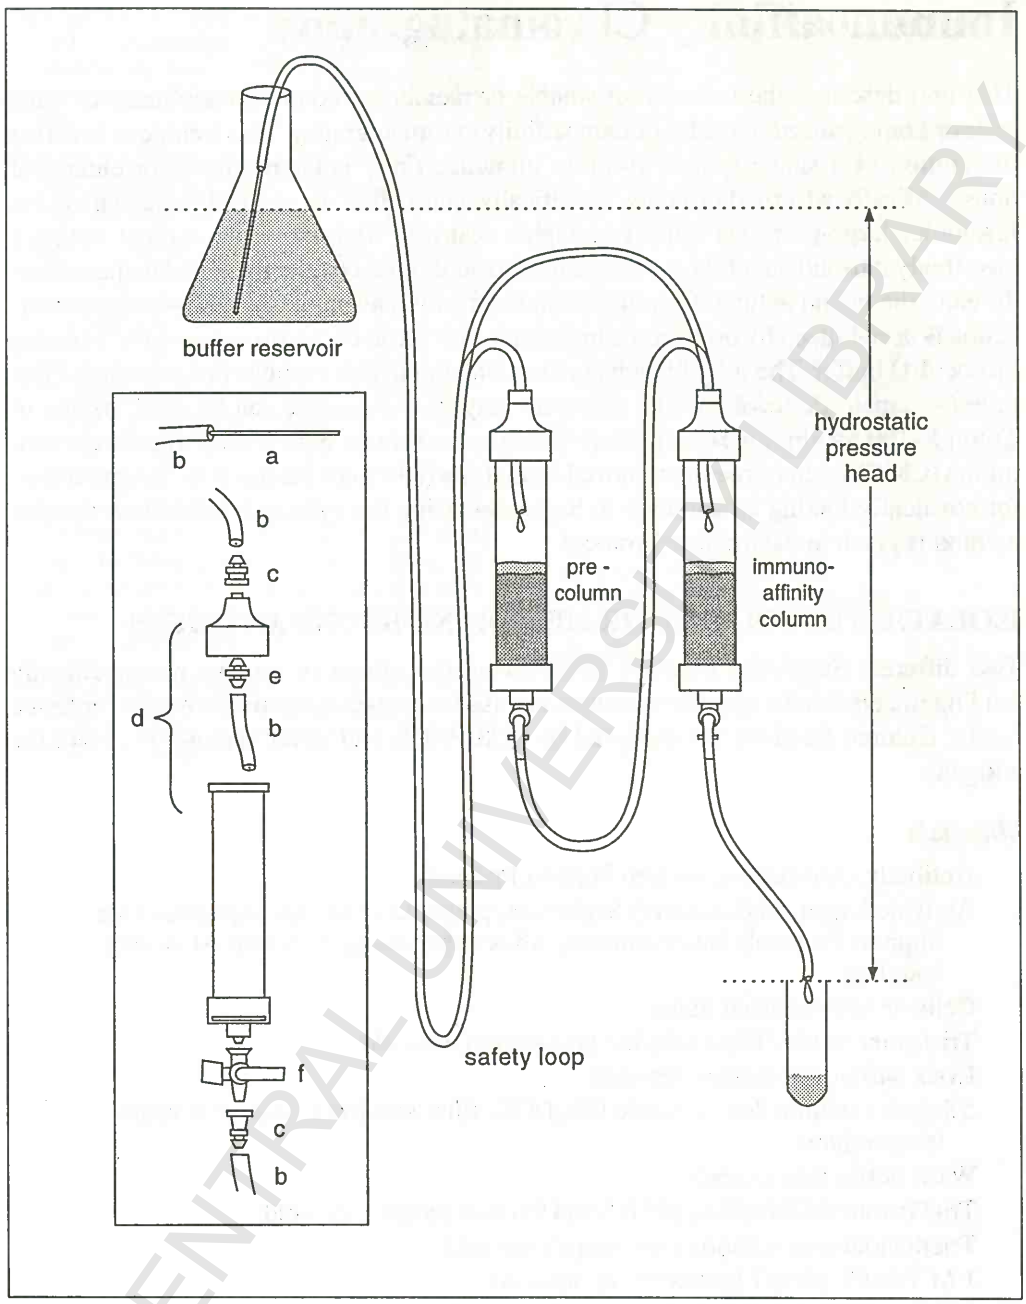

Figure 9.5.1 Immunoaffinity chromatography. During the application of the sample, two Sepharose columns, a Sepharose precolumn (without covalently bound specific antibody or with a covalently bound irrelevant antibody) and an immunoaffinity column (with covalently bound antibody), are attached in series to a buffer reservoir containing the sample. After the sample has been washed through, the precolumn is removed and the tubing of the safety loop is connected to the immunoaffinity column. The hydrostatic pressure head is the distance between the top of the solution in the buffer reservoir and the tip of the tubing at the bottom of the immunoaffinity column. When the elution reservoir is emptied, the hydrostatic head becomes zero when the fluid level reaches the safety loop, preventing columns from running dry. Fluid remaining above the column beds can be removed by raising the safety loop. After rinsing the tubing, the next elution is begun by placing the end of the safety loop in another reservoir containing the next elution buffer.

Inset: Schematic diagram of an immunoaffinity column. (a) 50-µl disposable capillary micropipet. (b) Tubing: Tygon S-54-HL Microbore, 0.05-in. i.d., or Tygon R-3603, 1/16-in. i.d. (softer tubing). BCU IAS CENTRAL UNIVERSITY LIBRARY

Prepare the lysate

2. Suspend 50 g of cells at 1–5 × 10^8 cells/ml in ice-cold TSA solution, or add 1 to 5 vol ice-cold TSA per vol packed cells or homogenized tissue. Add an equal volume of ice-cold lysis buffer and stir 1 hr at 4°C.

   For glycosylphosphatidylinositol (GPI)-anchored proteins (UNIT 12.5), incubate 10 min at 20°C for efficient solubilization.

3. Centrifuge 10 min at 4000 × *g*, 4°C, to remove nuclei. Decant supernatant and save.

   For purification of cytoplasmic (soluble) antigens, it is not necessary to add detergents to the solutions and buffer used in subsequent steps. Detergent is needed only for cell lysis and solubilization of integral membrane proteins.

4. For purification of membrane antigens, add 0.2 vol of 5% Na-DOC to the postnuclear supernatant, and leave 10 min at 4°C or on ice. Transfer to quick-seal centrifuge tubes and centrifuge 1 hr at 100,000 × *g*, 4°C. Carefully remove supernatant and save.

Set up and wash the columns

5. Attach Sepharose precolumn to immunoaffinity column (Fig. 9.5.1).

6. Wash both columns using the following regimen:

   10 column volumes of wash buffer
   5 column volumes of Tris/Triton/NaCl buffer, pH 8.0
   5 column volumes of Tris/Triton/NaCl buffer, pH 9.0
   5 column volumes of triethanolamine solution
   5 column volumes of wash buffer.

Isolate the antigen

7. Apply the supernatant from steps 3 or 4 (reserving some for analysis as described in step 15 below) to the precolumn and allow it to flow through the precolumn and specific column linked in series at a flow rate of 5 column volumes/hr. Collect the flow-through fractions, each 1/10 to 1/100 the volume of the applied supernatant.

   "Fat" chromatography columns, filled with Sepharose to a height of ~2× column diameter, are used to maximize flow rates. A 10- to 20-ml syringe is used for 5 ml of Sepharose. The flow rate is adjusted with a hydrostatic head of up to 250 cm (Fig. 9.5.1). Sample loading can routinely take up to 2 days with no deleterious effect, but longer periods would suggest the column is clogged or the lysate is too viscous. The latter is usually due to the presence of DNA.

8. Wash with 5 column volumes of wash buffer, then close the stopcocks on both columns and disconnect the precolumn from the immunoaffinity column. Open the stopcock of the immunoaffinity column and allow fluid above the top of the column to drain out to bed level.

   The Sepharose has some elasticity and draining can continue until there is no buffer above the Sepharose bed. Draining until cracks appear in the Sepharose should be avoided.

   Fractions of this wash and washes obtained below should be saved.

9. Wash the immunoaffinity column between each change of buffers (steps 10 to 14) as follows. Close the stopcock and remove the end cap of the column. With a syringe connected to the outlet of the tubing from the buffer reservoir, aspirate all buffer from the tubing. Place tubing into the next buffer contained in another reservoir. Aspirating with a syringe, fill the tubing from the reservoir and remove the syringe. Crimp the tubing to regulate flow and rinse the inside wall of the column with the buffer. Open

BOSTON UNIVERSITY MEDICAL CENTRAL LIBRARY

the column stopcock and drain the buffer to bed level. Put end cap loosely on the column and allow buffer to drain into the column to a level several centimeters above the bed. Secure end cap and commence washes or elution.

10. Wash with 5 column volumes of wash buffer.
11. Wash with 5 column volumes of Tris/Triton/NaCl buffer, pH 8.0.
12. Wash with 5 column volumes of Tris/Triton/NaCl buffer, pH 9.0.

    Some nonspecifically bound proteins may be eluted at this step. In addition, some monoclonal antibodies may release some ligand at this pH. This should be checked.

13. Elute the antigen with 5 column volumes of triethanolamine solution. Collect fractions of 1 column volume into tubes containing 0.2 vol of 1 M Tris·Cl, pH 6.7, to neutralize the fractions collected.

    In some cases it may be desirable to lower the pH of the triethanolamine solution to preserve the functional activity of the ligand. The ideal pH gives complete release of the ligand, as verified by SDS-PAGE evaluation of a sample (~20 µl) of the eluted column bed (Ab-Sepharose) and eluate (50 µl).

14. Wash the column with 5 column volumes of TSA solution.

    A column may be reused many times and remain active for several years after storage at 4°C in TSA solution. It is important to prevent drying out of a column during storage. The use of column storage solutions inhibits the growth of microorganisms.

15. Analyze fractions for the presence of antigen—50-µl aliquots of each eluate fraction should be analyzed by SDS-PAGE and silver staining. Analyze 0.5- to 1-ml aliquots of the sample applied to the column and representative flowthrough and wash fractions by immunoprecipitation with Ab-Sepharose, and detect by silver staining to determine whether the column was saturated.

    If antibody leaches off the column during elution, it may be removed from the eluate by passage through protein A–Sepharose (Ey et al., 1978). Even the weakly binding mouse IgG1 subclass can be quantitatively removed at pH 8 (M. Dustin, pers. comm.).

    Preliminary analysis of fractions can be done using A_{280} readings when octyl β-D-glucoside or sodium deoxycholate are used as detergents.

ALTERNATE PROTOCOL 1

LOW-pH ELUTION OF ANTIGENS

Some protein antigens may be eluted more completely with greater retention of native conformation and with fewer contaminants when low-pH buffers are employed.

Additional Materials *(also see Basic Protocol)*

Sodium phosphate buffer, pH 6.3 (see recipe)
Glycine buffer (see recipe)
1 M Tris·Cl, pH 9.0 (*APPENDIX 2E*)

1. Prepare the columns and lysate, wash the columns, and isolate the antigen (see Basic Protocol, steps 1 to 11).

   It is essential to remove sodium deoxycholate from the column before acid elution, because it precipitates or forms a gel at acid to neutral pH.

   TSA and triethanolamine solutions used here may also be modified by substituting 1% octyl β-D-glucoside for 0.1% Triton X-100 (see Alternate Protocol 3).

2. Wash with 5 column volumes of sodium phosphate buffer, pH 6.3.

BCU IASI CENTRAL UNIVERSITY LIBRARY

3. Elute with 5 column volumes of glycine buffer. Collect fractions into tubes containing 0.2 vol of 1 M Tris·Cl, pH 9.0.

   Mix each fraction immediately after collection.

4. Analyze fractions for antigen (see Basic Protocol, step 15).

BATCH PURIFICATION OF ANTIGENS

ALTERNATE PROTOCOL 2

Batch purification of antigens shortens the column loading time. This technique is valuable for viscous lysates that take too long to load on a column and for antigens especially susceptible to proteolysis, because less time is required to complete the steps. A precolumn is not utilized because the supernatant is mixed with Ab-Sepharose and poured into a column. The antigen is then eluted (see Basic Protocol). The drawbacks of this protocol are that more "hands-on" time is required by the investigator and that nonspecifically binding material is not removed by a precolumn.

1. Suspend and centrifuge the cells and purify the membrane antigens (see Basic Protocol, steps 2 to 4) to obtain the postnuclear supernatant.
2. Suspend Ab-Sepharose in the supernatant in a flask. Shake gently on a rotary shaker for 3 hr. Stop shaking and allow the Sepharose to settle.
3. Decant most of the supernatant. Pour the Ab-Sepharose and the remainder of the supernatant into a column and open the stopcock. Continue draining the column until all the Sepharose has been added. Allow the fluid to drain to bed level and close the stopcock.
4. Wash the immunoaffinity column, elute the antigen, and analyze the fractions (see Basic Protocol, steps 9 to 15).

ELUTION IN OCTYL β-D-GLUCOSIDE

ALTERNATE PROTOCOL 3

The detergent octyl β-D-glucoside has a high critical micelle concentration (CMC) of 0.73% and can therefore be readily removed by dialysis. Also, adsorption of membrane proteins to surfaces for ELISA or adhesion assays is much more efficient when solutions containing membrane proteins are diluted so that the concentration of octyl β-D-glucoside is below the CMC. Because octyl β-D-glucoside is expensive, initial steps requiring large volumes may be done as described in the Basic Protocol; the initial detergent is then replaced by octyl β-D-glucoside in the wash step prior to elution.

Additional Materials (also see Basic Protocol)

TSA solution (see recipe) containing 1% octyl β-D-glucoside

1. Prepare the columns and lysate, wash the columns, and isolate the antigen (see Basic Protocol, steps 1 to 11).
2. Wash with 5 column volumes of TSA solution containing 1% octyl β-D-glucoside.
3. Elute with 5 column volumes of triethanolamine solution with 1% octyl β-D-glucoside substituted for 0.1% Triton X-100.
4. Collect fractions of 1 column volume into tubes containing 0.2 vol of 1 M Tris·Cl, pH 6.7, to neutralize the fractions collected.
5. Wash the column and analyze the fractions (see Basic Protocol, steps 14 and 15).

BCU IFSI CENTRAL UNIVERSITY LIBRARY

PREPARATION OF ANTIBODY-SEPHAROSE

This protocol details the procedure for covalently linking an antibody to Sepharose (an insoluble, large-pore-size chromatographic matrix) using the cyanogen bromide activation method (also see *UNIT 9.3*). First, the antibody and Sepharose are prepared separately. The Sepharose is then activated with cyanogen bromide (alternatively, CNBr-activated Sepharose can be purchased from Pharmacia Biotech and used according to the manufacturer's instructions). Finally, the CNBr-activated Sepharose is coupled to the antibody.

CAUTION: CNBr is very toxic, releases toxic vapor, and is reported to create explosive side products upon storage; therefore, it should always be used in a hood and handled with appropriate CNBr- and solvent-resistant gloves. Only a fresh bottle of CNBr should be employed and it should be opened in the hood. Because of the problems involved in handling CNBr, it is best to dissolve a complete bottle in a defined amount of anhydrous acetonitrile. Short-term storage of this solution (several weeks) at 0°C is possible, but prolonged storage is not recommended.

Materials

1 to 30 mg/ml antigen-specific monoclonal or polyclonal antibody
0.1 M $NaHCO_3$/0.5 M NaCl
Sepharose CL-4B (or Sepharose CL-2B for high-molecular-weight antigens; Pharmacia Biotech)
2 M Na_2CO_3
Cyanogen bromide (CNBr)/acetonitrile (see recipe)
1 mM and 0.1 mM HCl, ice-cold
0.05 M glycine (*or* ethanolamine), pH 8.0
Tris/saline/azide (TSA) solution (see recipe)

Dialysis tubing (MWCO >10,000)
Ultracentrifuge
Whatman no. 1 filter paper
Buchner funnel
Erlenmeyer filtration flask
Water aspirator

Prepare the antibody

1. Dialyze 1 to 30 mg/ml antibody against 0.1 M $NaHCO_3$/0.5 M NaCl at 4°C with three buffer changes during 24 hr. Use a volume of dialysis solution that is 500 times the volume of antibody solution.

   Dialysis is performed to remove all small molecules containing free amino or sulfhydryl groups.

2. Centrifuge 1 hr at 100,000 × *g*, 4°C, to remove aggregates. Save the supernatant.

   Removal of aggregates is important. Because only some of the antibody molecules in an aggregate will directly couple to the Sepharose, the noncoupled antibody molecules may leach out during elution.

3. Measure the A_{280} of an aliquot of the solution and determine the concentration of the antibody (mg/ml IgG = A_{280}/1.44). Dilute with 0.1 M $NaHCO_3$/0.5 M NaCl to 5 mg/ml (or to the same concentration as desired for Ab-Sepharose) and keep at 4°C. Measure the A_{280} of this solution for comparison of absorbance in step 10.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Prepare the Sepharose

4. Allow the Sepharose slurry to settle in a beaker or the container in which it is sold; decant and discard the supernatant. Weigh out the desired quantity of Sepharose (assume density = 1.0).

5. Set up a filter apparatus using Whatman no. 1 filter paper in a Buchner funnel and an Erlenmeyer filtration flask attached to a water aspirator. Wash the Sepharose on the filter apparatus with 10 vol water.

   Sintered-glass funnels are traditionally recommended but rapidly become clogged unless coarse-porosity funnels are used.

Activate Sepharose with CNBr

6. Transfer Sepharose to 50-ml beaker and add an equal volume of ice-cold 2 M Na_2CO_3.

7. Activate Sepharose in an ice bath using 3.2 ml CNBr/acetonitrile per 100 ml Sepharose. Add CNBr/acetonitrile dropwise with a Pasteur pipet over 1 min, while slowly stirring the slurry with a magnetic stir bar. Continue stirring slowly for 5 min.

   Excessive and vigorous stirring may fracture the Sepharose beads; this may cause flow problems during column chromatography. The protocol uses 2 g CNBr/100 ml Sepharose. Two to four grams of CNBr/100 ml Sepharose can be used to couple 1 to 20 mg of antibody/ml Sepharose.

   CAUTION: *Activation should be carried out in a fume hood.*

8. Rapidly filter the CNBr-activated Sepharose as in step 5. Aspirate to semidryness (i.e., until the Sepharose cake cracks and loses its sheen). Wash with 10 vol ice-cold 1 mM HCl, then with 2 vol ice-cold 0.1 mM HCl. Hydrate with enough ice-cold 0.1 mM HCl so that the cake regains its sheen, but there is no excess liquid above the cake.

   Washing is most efficient if the wash solution is added evenly over the surface of the cake at about the same rate as the solution is removed by filtration. CNBr-activated Sepharose is very unstable at the alkaline pH necessary for activation; it is much more stable in dilute HCl. CNBr-activated Sepharose can be purchased from Pharmacia Biotech, but the coupling capacity will be lower.

   Destroy the contents of the filter flask, which contains excess CNBr, by slowly adding a 5-fold molar excess (relative to the total initial amount of CNBr used) of 1 M NaOH. Keep the reaction mixture cold by adding pieces of ice. Perform this decomposition in the hood, and keep the mixture there until all CNBr is destroyed.

Couple antibody to CNBr-activated Sepharose

9. Immediately transfer a weighed amount of Sepharose (assume density = 1.0) to a beaker. Add an equal volume of a solution of antibody dissolved in 0.1 M $NaHCO_3$/0.5 M NaCl (from step 3). Stir gently with a magnetic stir bar or rotate end-over-end 2 hr at room temperature or overnight at 4°C.

10. Add 0.05 M glycine (or ethanolamine), pH 8.0, to saturate the remaining reactive groups on the Sepharose and allow the slurry to settle. Remove an aliquot of the supernatant and centrifuge to remove any residual Sepharose. Measure the A_{280} and compare to the A_{280} of the antibody solution from step 3 to determine the percentage coupling.

11. Store the Ab-Sepharose in TSA solution.

BCU IRSIC GEN RAL UNIVERSITY LIBRARY

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

CNBr/acetonitrile

To 25 g of cyanogen bromide in the original bottle *(CNBr should be white, not yellow, crystals)* add 50 ml acetonitrile to make a 62.5% (w/v) solution. Store indefinitely at –20°C in a desiccator over silica. Allow to warm before opening.

CAUTION: *CNBr is a highly toxic lachrymator; handle in a fume hood.*

Column storage solution

Prepare in TSA solution (see recipe) either 1 mM EDTA/20 µg/ml gentamicin *or* 0.01% thimerosal (Aldrich).

Detergent stock solutions

Prepare 10% Triton X-100 *or* 5% sodium deoxycholate in water. Sterilize either solution by Millipore filtration. Both solutions remain stable for 5 years at room temperature; Triton X-100 solution should be stored in the dark to prevent photo-oxidation.

NP-40 can be used in place of Triton X-100.

Glycine buffer

50 mM glycine·HCl, pH 2.5
0.1% Triton X-100 (see recipe for detergent stock solutions)
0.15 M NaCl

Lysis buffer

TSA solution (see recipe) containing:
2% Triton X-100 (see recipe for detergent stock solutions)
5 mM iodoacetamide
Aprotinin (0.2 trypsin inhibitor U/ml)
1 mM phenylmethylsulfonyl fluoride (add fresh from 100 mM stock solution prepared in absolute ethanol)

IMPORTANT NOTE: *Iodoacetamide is a protease inhibitor and prevents oxidation of free cysteines to disulfide-bonded cysteines. It should be omitted for enzymes that require cysteines for activity.*

NP-40 can be used in place of Triton X-100.

Sodium phosphate buffer, pH 6.3

50 mM sodium phosphate, pH 6.3
0.1% Triton X-100 (see recipe for detergent stock solutions)
0.5 M NaCl

Triethanolamine solution

50 mM triethanolamine, pH ~11.5
0.1% Triton X-100 (see recipe for detergent stock solutions)
0.15 M NaCl

Other organic solutions, such as diethylamine, may be used in place of triethanolamine. The pH of this solution should be determined for each antibody as elution conditions may vary (see Critical Parameters).

BCU IASI CENTRAL UNIVERSITY LIBRARY

Tris/saline/azide (TSA) solution

0.01 M Tris·Cl, pH 8.0 (at 4°C)
0.14 M NaCl
0.025% NaN_3

CAUTION: *Sodium azide (NaN_3) is poisonous; wear gloves and handle cautiously.*

Tris/Triton/NaCl buffer, pH 8.0 and 9.0

50 mM Tris·Cl, pH 8.0 or pH 9.0
0.1% Triton X-100 (see recipe for detergent stock solutions)
0.5 M NaCl

Wash buffer

0.01 M Tris·Cl, pH 8.0 (at 4°C)
0.14 M NaCl
0.025% NaN_3
0.5% Triton X-100 (see recipe for detergent stock solutions)
0.5% sodium deoxycholate (see recipe for detergent stock solutions)

CAUTION: *Sodium azide (NaN_3) is poisonous; wear gloves and handle cautiously.*

COMMENTARY

Background Information

The review of affinity chromatography by Wilchek et al. (1984) discusses available methods for activation of solid supports, coupling of ligands, adsorption of proteins, and elution of protein from affinity columns. Table III of that review lists numerous examples of proteins that have been purified by immunoaffinity chromatography and the elution conditions for each purification.

Traditionally, purification of membrane proteins started with a membrane purification step, and in some cases this is still desirable. However, it is difficult to achieve more than a 5-fold purification of plasma membranes and yields are usually only 10% to 40%. Omission of membrane purification in this protocol (Williams and Barclay, 1986; Johnson et al., 1985) results in increased yield and decreased experiment time.

Purification to homogeneity or near-homogeneity can usually be achieved for protein antigens present in ≥10,000 molecules per eukaryotic cell. This protocol can be used for both membrane and intracellular antigens. However, for soluble antigens, immunoaffinity chromatography is completed without detergent.

Critical Parameters

Binding capacities of Ab-Sepharose columns (coupled at 5 mg monoclonal antibody/ml Sepharose) have been found to be 2% to 20% of the theoretical binding capacity. The lowest and highest binding capacity values were found for antigens of 150,000 and 18,000 M_r, respectively, suggesting that increased antigen size may constrain access to antibody in the pores of the affinity matrix. Because of its larger pore size, Sepharose CL-4B (a 4% cross-linked agarose) is far preferable to Sepharose 6B (a 6% agarose), which is the usual commercially available preactivated agarose. The cross-links in the CL series yield mechanically more robust beads and do not appreciably decrease activation with cyanogen bromide (CNBr).

The Support Protocol for coupling protein antigens to CNBr-activated Sepharose is a modification of the methods of Cuatrecasas (1970) and March et al. (1974). As originally described, the washing was done at alkaline pH. Because activated Sepharose is very unstable at this pH, it was originally recommended that washing, adding the protein ligand, and mixing be done in <90 sec (Cuatrecasas, 1970). However, with the use of an acid wash buffer (Gelb, 1973) as described in the Support Protocol, activated groups remain stable for ≥30 min. Wilchek et al. (1984) described an alternative activation procedure with CNBr triethanolamine in acetone/water that is highly efficient and minimizes side-reaction derivatization of the Sepharose. The 0.1 M $NaHCO_3$ buffer in which antibody is dissolved provides an optimal pH of ~8.4 after mixing with activated Sepharose. The small amount of CNBr recommended is sufficient to obtain a coupling yield of 80% to 95%. Higher amounts of CNBr may result in multipoint attachment of IgG molecules to the matrix, thereby inactivating

B.C.U. „M. Eminescu" IAŞI
CHIMIE

BIBLIOTECA CENTRALĂ UNIVERSITY LIBRARY

antigen binding sites and reducing accessibility to antigen. Coupling efficiencies on the order of 99% are usually associated with lower antigen binding capacity and are to be avoided; coupling efficiencies of 80% to 90% are ideal. Smaller amounts of CNBr per milliliter of Sepharose also result in lower derivatization of the Sepharose with charged groups. These charged groups can cause nonspecific binding.

The amount of CNBr used in commercially available activated Sepharose is not specified, but is probably high. Many investigators purchase CNBr-activated Sepharose; others activate their own. Commercially activated Sepharose is stabilized by drying. Not all Sepharose can withstand drying; e.g., Sepharose 2B (2% agarose beads) is less robust than Sepharose 4B (4% agarose) and is not available in a preactivated form. Activating your own Sepharose allows more control over coupling efficiency; enables use of CL (cross-linked) Sepharose, which is more robust and has faster flow rates; enables use of Sepharose CL-2B; and is more cost effective.

A binding capacity of 40% was reported for coupling at 2 to 3 mg antibody/ml Sepharose. Successful purification has been achieved using monoclonal antibodies with affinity constants ranging from 2×10^7 to 4×10^8 M^{-1}. The column should be saturated with antigen by allowing some of the antigen to flow through the column during loading. This will result in the highest antigen purity and a mass yield, and will diminish the relative level of antibody eluted along with the antigen when antibody is leaching off the column.

Sodium deoxycholate is used in the solubilization protocol (Johnson et al., 1985) because it dissociates proteins from the membrane more effectively than Triton X-100. However, because sodium deoxycholate releases DNA from nuclei, it must be added to the lysate after the nuclei are removed. Sodium deoxycholate forms a mixed micelle with Triton X-100. Although sodium deoxycholate can be substituted for Triton X-100 during high-pH elution, it gels at low pH and in high salt. Both sodium deoxycholate and nonionic detergents may dissociate subunits of protein complexes, which interact within the membrane. Addition of phospholipid, low concentrations of Triton X-100, and mild detergents (e.g., digitonin, octylglucoside, and CHAPS) preserves membrane protein complexes (Helenius et al., 1979; Rivnay et al., 1982; Tsuchiya and Saito, 1984).

Glycosylphosphatidylinositol (GPI)-anchored proteins (*UNIT 12.5*) are resistant to detergent solubilization at 4°C (Schroeder et al., 1994). Preparation of the lysate (Basic Protocol, step 2) should be conducted for 10 min at 20°C for these antigens.

Octyl β-D-glucoside is an expensive detergent that is readily removable by dialysis. Furthermore, adsorption of proteins to substrates is enhanced by dilution below a CMC of 0.73%. In Alternate Protocol 3, the initial detergent is replaced with octyl β-D-glucoside prior to elution of antigen from the affinity column.

Protein antigens eluted by acid or base can frequently be renatured by neutralization. However, some protein antigens are irreversibly denatured. The structure of certain antigens is preserved after acid, but not base, elution (Plunkett and Springer, 1986), whereas the structure of other antigens is preserved after base, but not acid, elution (Johnson et al., 1985). Some antigens are eluted at low pH, but not at high pH; for others the reverse is true. For each antibody-antigen combination, the optimal pH for elution of specific antigens as well as contaminants must be empirically defined. Antibody binding capacity is usually retained after repeated exposure to low and high pH elution buffers (see Alternate Protocol 1 and see Basic Protocol, respectively). The use of chaotropic agents (e.g., potassium thiocyanate and urea) for elution is a seldom-employed alternative (Johnson et al., 1985).

Troubleshooting

Immunoaffinity chromatography relies on the elution of a single protein from an immunoaffinity column after prior elution of all other nonspecifically adsorbed proteins. Thus, depending on the elution conditions used, the desired protein antigen may be contaminated with other proteins. It is very important to determine whether a contaminant is present if the protein is to be analyzed for amino acid composition or protein sequence. One-dimensional gel electrophoresis (*UNIT 10.1*) should be used to verify elution of contaminating proteins during washing of the immunoaffinity column, as well as the purity of the protein in the final eluate. If the protein is not pure, the wash steps must be optimized to ensure that other contaminating proteins are removed.

Anticipated Results

Antigen yield is typically 40% to 70% of starting material (Kürzinger and Springer, 1982; Johnson et al., 1985) and purification factors of 1,000- to 10,000-fold may be achieved (Kürzinger and Springer, 1982; Williams and Bar-

BCU IAS CENTRAL LIBRARY

clay, 1986; Plunkett and Springer, 1986). Further purification can usually be achieved by a second cycle of immunoaffinity chromatography. Monoclonal antibodies are most convenient, but affinity-purified polyclonal IgG can also be used.

Time Considerations

Pouring the column takes a few minutes and lysate preparation requires ~6 hr. Purification proceeds over 1 to 2 days depending on the flow rate of the immunoaffinity column. The majority of this time involves loading the sample on the column, which may be done from a reservoir and requires little hands-on time. The use of batch purification (Alternate Protocol 2) reduces the sample application time to 3 hr. Elution of an immunoaffinity column requires 5 to 6 hr.

Purification of Sequence-Specific DNA-Binding Proteins by Affinity Chromatography

Many biological processes, such as recombination, replication, and transcription, involve the action of sequence-specific DNA-binding proteins. Analysis and purification of these proteins by conventional chromatographic methods is often difficult because DNA-binding proteins typically make up <0.01% of the total cellular protein. Various methods have been developed for purifying such proteins. Affinity chromatography is a very effective means of purifying a protein based on its sequence-specific DNA-binding properties and is relatively straightforward if proper care is taken. The affinity chromatography procedure described in this unit uses DNA containing specific recognition sites for the desired protein that has been covalently linked to a solid support. Researchers in the past have purified proteins based on the proteins' ability to bind DNA, only to be disappointed to find that the DNA-binding activity of their highly purified products was not sequence-specific. This situation can be avoided by carefully performing all of the preliminary steps and experimental controls.

Basic Protocol 1 describes preparation of a DNA affinity resin, including cyanogen bromide (CNBr) activation of the agarose support. The Alternate Protocol provides a method to couple DNA to commercially available CNBr-activated Sepharose. Support Protocol 1 describes how to purify crude synthetic oligonucleotides by gel electrophoresis prior to preparation of the affinity resin. Basic Protocol 2 outlines the affinity chromatography procedure. Support Protocol 2 describes determination of the appropriate type and quantity of nonspecific competitor DNA that should be used in the procedure and its preparation. Parameters essential to the success of an affinity chromatography experiment are discussed in detail in the Commentary. Figure 9.6.1 provides a summary diagram of the entire chromatography procedure.

PREPARATION OF DNA AFFINITY RESIN

BASIC PROTOCOL 1

Correct choice of oligonucleotide sequence (discussed in detail in the Commentary) and preparation of the affinity resin are probably the most important parts of the affinity chromatography procedure. Preparation of affinity resin can be broken down into four steps: (1) preparing oligonucleotides; (2) activating Sepharose; (3) coupling DNA to resin; and (4) blocking unreacted CNBr. The first step requires highly purified oligonucleotides that contain the recognition sequence for the desired protein. Once purified, the complementary oligonucleotides are annealed, phosphorylated with T4 polynucleotide kinase, and ligated into long, multimeric chains (averaging ≥10-mers) with T4 DNA ligase. Sepharose CL-2B is activated with CNBr, the ligated DNA added, and the coupling reaction carried out overnight. Because CNBr is very toxic, researchers may prefer to employ the Alternate Protocol, which uses commercially available CNBr-activated Sepharose and therefore avoids direct handling of CNBr. After the coupling reaction, the remaining reactive groups are blocked with ethanolamine. This protocol is designed to prepare 10 ml of affinity resin.

NOTE: Glass-distilled or other high-quality water should be used throughout these procedures.

UCU IASI / CENTRAL UNIVERSITY LIBRARY

Materials

440 µg each of two synthetic oligonucleotides with desired binding site (see Support Protocol 1; or commercial HPLC-purified)
TE buffer, pH 7.8 (*APPENDIX 2E*)
10× T4 polynucleotide kinase buffer (see recipe)
20 mM ATP (Na^+ salt), pH 7.0
150 mCi/ml [γ-^{32}P]ATP (6000 Ci/mmol)
10 U/µl T4 polynucleotide kinase (New England Biolabs)
10 M ammonium acetate (*APPENDIX 2E*)
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol
24:1 (v/v) chloroform/isoamyl alcohol
3 M sodium acetate (*APPENDIX 2E*)
100% and 75% ethanol
10× linker/kinase buffer (see recipe)
6000 U/ml T4 DNA ligase (measured in Weiss units; New England Biolabs)
Buffered phenol
Isopropanol (2-propanol)
Sepharose CL-2B (Pharmacia Biotech)
Cyanogen bromide (CNBr; Aldrich)
N,*N*-dimethylformamide
5 N NaOH (*APPENDIX 2E*)
10 mM and 1 M potassium phosphate buffer, pH 8.0 (*APPENDIX 2E*)
1 M ethanolamine hydrochloride, pH 8.0 (see recipe)
NaOH, solid
Glycine
1 M KCl (*APPENDIX 2E*)
Column storage buffer (see recipe)

15-ml screw-cap polypropylene tubes
Heating blocks or water baths, 15°C, 37°C, 65°C, and 88°C
60-ml coarse-sintered glass funnel
Rotating wheel

5′-phosphorylate the oligonucleotides

1. In a 1.5-ml microcentrifuge tube, prepare a mixture containing 440 µg of each oligonucleotide in TE buffer in a total volume of 130 µl. Add 20 µl of 10× T4 polynucleotide kinase buffer. Incubate 2 min at 88°C, 10 min at 65°C, 10 min at 37°C, and 5 min at room temperature.

   A 1-µmol synthesis of oligonucleotide should yield enough purified DNA for ~20 ml of affinity resin.

2. Divide mixture in half in separate microcentrifuge tubes. To each 75-µl aliquot, add 15 µl of 20 mM ATP (pH 7.0), ~5 µCi [γ-^{32}P]ATP, and 10 µl of 10 U/µl T4 polynucleotide kinase (100 U total). Incubate 2 hr at 37°C.

   Dividing the reaction in half at this point facilitates the steps that follow. To add the labeled ATP, do not thaw, but simply touch (do not jab) the top of the frozen [γ-^{32}P]ATP with a yellow pipet tip and transfer the resulting tiny amount to the reaction tube.

3. Inactivate the kinase by adding 50 µl of 10 M ammonium acetate and 100 µl water to each tube and heating 15 min at 65°C. Allow to cool to room temperature.

BOSTON UNIVERSITY / CENTRAL LIBRARY

Purify phosphorylated oligonucleotides

4. Add 750 µl of 100% ethanol and mix by inversion. Microcentrifuge at high speed 15 min at room temperature to pellet DNA. Discard supernatant.
5. Resuspend each pellet in 225 µl TE buffer.
6. Add 250 µl of 25:24:1 phenol/chloroform/isoamyl alcohol to each tube. Vortex 1 min. Microcentrifuge 5 min at high speed to separate phases. Transfer the aqueous phase (upper layer) to a new tube.
7. Add 250 µl of 24:1 chloroform/isoamyl alcohol to aqueous phase. Vortex 1 min. Microcentrifuge 5 min at high speed to separate phases. Transfer the aqueous phase (upper layer) to a new tube.
8. Add 25 µl of 3 M sodium acetate to aqueous phase and mix by vortexing. Then add 750 µl of 100% ethanol and mix by inversion. Microcentrifuge 15 min at high speed to pellet DNA. Discard supernatant.
9. Wash pellet with 800 µl of 75% ethanol. Mix by vortexing. Microcentrifuge 5 min at high speed. Discard supernatant.
10. Dry pellet in vacuum evaporator (e.g., Speedvac).

Ligate oligonucleotides

11. Add 65 µl water and 10 µl of 10× linker/kinase buffer to each pellet. Dissolve DNA by vortexing. Add 20 µl of 20 mM ATP (pH 7.0) and 5 µl of 6000 U/ml T4 DNA ligase (30 Weiss units). Incubate ≥2 hr at room temperature or overnight at 15°C.

    Depending upon the oligonucleotides used, the optimal temperature for ligation will vary from 4° to 30°C. Short oligonucleotides (≤15-mers) tend to ligate better at lower temperatures (4° to 15°C), whereas oligonucleotides that have a moderate degree of palindromic symmetry tend to self-anneal and therefore ligate better at higher temperatures (15° to 30°C).

12. Monitor the ligation reaction by agarose gel electrophoresis, using 0.5 µl of ligation reaction per gel lane and including lanes containing size markers. Visualize DNA by ethidium bromide staining and UV photography.

    5′-phosphorylated oligonucleotides often do not ligate on the first attempt. If ligation has not occurred, extract the DNA once with 25:24:1 phenol/chloroform/isoamyl alcohol and once with 24:1 chloroform/isoamyl alcohol, then ethanol precipitate using sodium acetate as the precipitating salt. Dissolve the DNA in 225 µl TE, add 25 µl of 3 M sodium acetate, and reprecipitate with 750 µl of 100% ethanol. Wash with 75% ethanol, dry in Speedvac, and repeat ligation.

    The average length of the ligated oligonucleotides should be ≥10-mers. Ligating the oligonucleotides increases the binding capacity of the affinity resin and helps avoid potential problems due to steric hindrance between the factor and the Sepharose support. However, oligonucleotide multimers <10-mers will probably also work.

Purify oligonucleotide multimers

13. Add 100 µl buffered phenol to the 100-µl ligation reactions. Vortex 1 min. Microcentrifuge 5 min at high speed. Transfer aqueous phase (upper layer) to a new tube.
14. Add 100 µl of 24:1 chloroform/isoamyl alcohol to aqueous phase. Vortex 1 min. Microcentrifuge 5 min at high speed. Transfer aqueous phase (upper layer) to a new tube.
15. Add 33 µl of 10 M ammonium acetate to the aqueous phase. Mix by vortexing.

UCLA CENTRAL UNIVERSITY LIBRARY

16. Add 133 µl isopropanol. Mix by inversion. Incubate 20 min at –20°C. Microcentrifuge 15 min at high speed to pellet DNA. Discard supernatant.

The ammonium acetate/isopropanol precipitation removes residual ATP, which would otherwise interfere with coupling of the ligated DNA to the CNBr-activated Sepharose.

17. Add 225 µl TE buffer. Vortex to dissolve pellet. Add 25 µl of 3 M sodium acetate. Mix by vortexing. Add 750 µl of 100% ethanol. Mix by inversion. Microcentrifuge 15 min at high speed to pellet DNA. Discard supernatant.

18. Wash DNA twice with 75% ethanol. Dry pellet in vacuum evaporator.

19. Dissolve DNA in 50 µl water. Store at –20°C.

Do not dissolve the DNA in TE buffer, as the Tris buffer in TE will interfere with the coupling reaction.

Prepare CNBr-activated Sepharose

It is best to assemble all equipment and reagents required for the activation and coupling reactions *before* proceeding with the following steps.

20. Place 10 to 15 ml (settled bed volume) of Sepharose CL-2B in a 60-ml coarse-sintered glass funnel and wash extensively with 500 ml water.

To wash, add water to resin in funnel, stir gently with a glass rod, and remove water by vacuum suction, making sure to release vacuum before the resin is suctioned into a dry cake. Repeat until all 500 ml water is used.

21. Transfer moist Sepharose resin to a 25-ml graduated cylinder, estimating 10 ml of resin. Add water to 20 ml final volume. Transfer the resulting slurry to a 150-ml glass beaker containing a magnetic stir bar. Place beaker in a water bath equilibrated to 15°C and set up over a magnetic stirrer in a fume hood. Turn on stirrer to slow medium speed.

Keep the water bath at 15°C by periodically adding small chunks of ice as needed. Occasional variation of a degree or two is not critical.

22. In the fume hood, measure 1.1 g CNBr into a 25-ml Erlenmeyer flask, keeping the mouth of the flask covered with Parafilm or a ground glass stopper as much as possible (it is better to have slightly more than 1.1 g than slightly less). Add 2 ml *N,N*-dimethylformamide (the CNBr will dissolve instantly). Over the course of 1 min, add the resulting CNBr solution dropwise to the stirring Sepharose slurry.

CAUTION: *CNBr is highly toxic and volatile. Use only in a fume hood with extreme caution. Observe appropriate decontamination and disposal procedures.*

23. Immediately add 5 N NaOH as follows: add 30 µl to the stirring mixture every 10 sec for 10 min until 1.8 ml NaOH has been added.

It is convenient to measure 1.8 ml NaOH into a small tube before addition to the reaction to avoid having to change pipet tips during the 10-sec additions.

24. Immediately add 100 ml ice-cold water to the beaker and pour the mixture into a 60-ml coarse-sintered glass funnel.

IMPORTANT NOTE: *At this point, it is very important to avoid suction-filtering the resin into a dry cake. If the resin is accidentally dried into a cake, do not use; instead, repeat steps 20 to 24 with fresh resin.*

25. Still working in the fume hood, wash the resin in the funnel with four 100-ml washes of ice-cold (≤4°C) water followed by two 100-ml washes of ice-cold 10 mM potassium phosphate, pH 8.0.

BOSTON UNIVERSITY MEDICAL LIBRARY

26. Immediately transfer the resin to a 15-ml polypropylene screw-cap tube and add ~4 ml of 10 mM potassium phosphate (pH 8.0) until the resin has the consistency of a thick slurry.

Couple oligonucleotide multimers to CNBr-Sepharose

27. Immediately add the two 50-µl aliquots of DNA from step 19. Incubate on a rotating wheel overnight (≥8 hr) at room temperature.

28. In the fume hood, transfer the resin to a 60-ml coarse-sintered glass funnel and wash with two 100-ml washes of water and one 100-ml wash of 1 M ethanolamine hydrochloride, pH 8.0.

Using a Geiger counter, compare the level of radioactivity in the first few milliliters of filtrate with the level of radioactivity in the washed resin to estimate the efficiency of incorporation of DNA to the resin. Usually, all detectable radioactivity is present in the resin.

29. In the fume hood, transfer the resin to a 15-ml polypropylene screw-cap tube and add 1 M ethanolamine hydrochloride (pH 8.0) until the mixture is a smooth slurry. Incubate the tube on a rotating wheel 2 to 4 hr at room temperature.

This step inactivates unreacted CNBr-activated Sepharose.

It is important to clean up all CNBr waste carefully. In the fume hood, add solid NaOH and glycine (~10 to 20 mg/ml) to inactivate the CNBr. Soak contaminated instruments in a similar solution. Let sit overnight in the fume hood, then discard.

30. Wash the resin in a 60-ml coarse-sintered glass funnel with 100 ml of 10 mM potassium phosphate (pH 8.0), 100 ml of 1 M potassium phosphate (pH 8.0), 100 ml of 1 M KCl, 100 ml water, and 100 ml column storage buffer.

31. Store the resin at 4°C (stable at least 1 year; do not freeze).

ALTERNATE PROTOCOL

COUPLING THE DNA TO COMMERCIALLY AVAILABLE CNBr-ACTIVATED SEPHAROSE

The major advantage of this alternate procedure is that it begins with commercially available CNBr-activated chromatography resin, avoiding the need for preparation of CNBr-activated resin (see Basic Protocol 1). However, commercial CNBr-Sepharose is considerably more expensive than the homemade variety; moreover, the resulting column tends to run more slowly than one prepared as described above. Both resins are effective, leaving it up to the researcher's discretion which to use.

Additional Materials (also see Basic Protocol 1)

1 mM HCl (*APPENDIX 2E*), prepared fresh before use
CNBr-activated Sepharose 4B (Pharmacia Biotech)

1. Prepare oligonucleotide multimers by phosphorylation and ligation (see Basic Protocol 1, steps 1 to 19).

2. Weigh out 3 g CNBr-activated Sepharose 4B (1 g freeze-dried resin gives ~3.5 ml final gel volume).

3. Place the dry resin in a 15-ml conical polypropylene tube. Hydrate resin with 10 ml of 1 mM HCl and mix gently by flicking and inverting the tube. After 1 min, transfer slurry to a 60-ml coarse-sintered glass funnel. Wash and swell the beads by gradually pouring 500 ml of 1 mM HCl through the funnel (this will take ~15 min).

JCU IAS/CENTRAL UNIVERSITY LIBRARY

4. Wash the resin with 100 ml water and then with 100 ml of 10 mM potassium phosphate, pH 8.0.
5. Proceed with coupling of oligonucleotide multimers to the resin (see Basic Protocol 1, steps 26 to 31).

PURIFICATION OF OLIGONUCLEOTIDES BY PREPARATIVE GEL ELECTROPHORESIS

SUPPORT PROTOCOL 1

Preparation of affinity resin requires a large amount (1-µmol synthesis) of purified synthetic oligonucleotides. The oligonucleotides used to prepare the affinity resin must be of high purity because contaminating, incompletely synthesized oligonucleotides can interfere with the ligation reaction. HPLC-purified oligonucleotides are of sufficient purity for preparation of DNA affinity resins; however, it is normally expensive to obtain such oligonucleotides. An alternative is to purify crude oligonucleotides by the following method.

Additional Materials (also see Basic Protocol 1)

16% polyacrylamide-urea gel (see recipe)
Oligonucleotides to be purified
Formamide loading buffer (see recipe)
sec-butanol (2-butanol)
Diethyl ether
1 M $MgCl_2$ (*APPENDIX 2E*)

Saran wrap or other UV-transparent plastic wrap
Intensifying screen (e.g., Lightning Plus, NEN Life Sciences)
Hand-held short-wavelength UV light source
Silanized glass wool
Dry ice/ethanol bath (–78°C)

Additional reagents and equipment for denaturing polyacrylamide gel electrophoresis (*UNIT 10.3*)

Purify oligonucleotides by gel electrophoresis

1. Prepare a 20 cm × 40 cm × 1.5 mm denaturing polyacrylamide gel with four wells 3 cm in width, using 16% polyacrylamide/urea for separating oligonucleotides ~10 to ~45 bases long (or 8% or 6% polyacrylamide/urea for longer oligonucleotides). Let gel polymerize for ≥30 min, then prerun at 30 W for ≥1 hr.

2. Dissolve each oligonucleotide in formamide loading buffer to 200 µl final. Heat 15 min at 65°C to remove any secondary structure in the DNA. Load 50 µl of samples into separate wells, and run the gel at 30 W for ~4 hr.

   The amount of oligonucleotide that is prepared in a 1-µmol synthesis (~1 to 2 mg) can be loaded on one gel (0.25 µmol per 3-cm well). This is the maximum amount that can be applied to the gel without overloading it.

   It takes ~4 hr for the bromphenol blue in the loading buffet to migrate three-quarters of the way down the gel, which is far enough to purify oligonucleotides of 15 to 30 bases. In a 16% gel, bromphenol blue comigrates with ~10-base oligonucleotides and xylene cyanol comigrates with ~30-base oligonucleotides. If the oligonucleotide is 25 to 35 bases long, it is recommended that the formamide loading buffer be made without xylene cyanol.

Visualize gel by UV shadowing

3. Remove one of the glass gel plates and cover the gel with Saran wrap. Flip gel over and remove the other plate so that the gel is lying on the Saran wrap. Cover the other side of the gel with Saran wrap.

BOSTON COLLEGE CENTRAL UNIVERSITY LIBRARY

4. In a darkroom, lay the gel on an intensifying screen and hold a hand-held short-wavelength UV light source directly over it to visualize the DNA. Identify the major oligonucleotide band and mark its position directly on the Saran wrap using a marker, making sure that the light is directly over the band.

   The major band (usually the largest oligonucleotide but sometimes the next-to-largest) should be visible as a thick, dark band in the gel.

Purify oligonucleotides from gel

5. Carefully cut out the band with a razor blade, trying to avoid shredding the gel material or pulverizing the gel slice into small pieces.
6. Soak the gel piece in 5 ml TE buffer in a 15-ml polypropylene tube overnight at 37°C with shaking.
7. Place a silanized glass wool plug in a Pasteur pipet and prerinse with ~5 ml water. Filter the supernatant containing the DNA through the glass wool.
8. Concentrate the DNA to ≤180 µl by repeated extractions with *sec*-butanol.
9. Extract the DNA once with diethyl ether and place in a vacuum evaporator (e.g., Speedvac) until all traces of ether are removed.
10. Adjust the volume of the liquid to 180 µl with TE buffer. Add 20 µl of 3 M sodium acetate and 2 µl of 1 M $MgCl_2$. Mix by vortexing.
11. Add 600 µl of 100% ethanol. Mix by inversion. Chill 10 min in dry ice/ethanol. Let stand 5 min at room temperature. Microcentrifuge 15 min at high speed, room temperature, to pellet DNA. Discard supernatant.
12. Add 180 µl TE buffer. Dissolve pellet by vortexing. Add 20 µl of 3 M sodium acetate and 2 µl of 1 M $MgCl_2$. Mix by vortexing.
13. Add 600 µl of 100% ethanol. Mix by inversion. Chill 10 min in dry ice/ethanol. Let stand 5 min at room temperature. Microcentrifuge 15 min at high speed, room temperature. Discard supernatant.
14. Add 800 µl of 75% ethanol. Mix by vortexing. Microcentrifuge 5 min at high speed, room temperature. Discard supernatant.
15. Carefully dry pellet in vacuum evaporator (sometimes static electricity will cause the pellet to jump out of the tube).
16. Dissolve DNA in 200 µl TE buffer and measure A_{260} and A_{280}. Store at –20°C indefinitely.

    For sequence-specific DNA affinity resins, assume that 1 A_{260} unit = 40 µg/ml DNA.

BASIC PROTOCOL 2

DNA AFFINITY CHROMATOGRAPHY

Affinity chromatography is performed by combining a partially purified protein sample with appropriate competitor DNA, pelleting the insoluble protein-DNA complexes by centrifugation, and loading the resulting soluble material by gravity flow onto the affinity resin. Nonspecific DNA-binding proteins flow through the column while the specific protein is retained by the column. The protein is then eluted by gradually increasing the salt concentration of the buffer and individual fractions are tested for DNA-binding activity and purity. Fractions containing appropriate DNA-binding activity can be reapplied to the affinity resin if further purification is desired. By using two sequential affinity chromatography steps, a typical protein can be purified 500- to 1000-fold with ~30% yield. The method described below is performed with buffer Z, but many other buffers will work as well. Buffer choice is addressed in the Commentary.

IGU IAS/CENTRAL UNIVERSITY LIBRARY

Materials

Prepared DNA affinity resin (see Basic Protocol 1 or Alternate Protocol)
Buffer Z or other column buffer (e.g., buffers Z^e or TM; see recipes) made with varying KCl concentrations (buffers Z/0.1 M KCl through Z/1 M KCl)
Partially purified protein fraction dialyzed against buffer Z/0.1 M KCl
Nonspecific competitor DNA (see Support Protocol 2)
Column regeneration buffer (see recipe)
Column storage buffer (see recipe)

Disposable chromatography column (Poly-Prep, Bio-Rad)
Sorvall SS-34 rotor or equivalent
Liquid nitrogen
Narrow glass rod, silanized

Additional reagents and equipment for DNA-binding assays (Brenowitz, et al., 1989; Buratowski and Chodosh, 1996; Baldwin et al., 1996), SDS-PAGE (*UNIT 10.1*), and silver staining (*UNIT 10.5*)

1. Equilibrate 1 ml settled bed volume of the DNA affinity resin in a disposable chromatography column with two 10-ml washes of buffer Z/0.1 M KCl.
2. Combine the partially purified protein fraction in buffer Z/0.1 M KCl with nonspecific competitor DNA as determined by DNA-binding studies (see Commentary and Support Protocol 2).
3. Incubate mixture 10 min on ice.
4. Centrifuge mixture 10 min at 12,000 × *g* (10,000 rpm in Sorvall SS-34 rotor), 4°C, to pellet insoluble protein-DNA complexes.
5. Load the supernatant onto the column at gravity flow (e.g., 15 ml/hr per column for Sepharose CL-2B).

   A single 1-ml column is sufficient for a standard nuclear extract (e.g., 12 liters of HeLa cells or 150 g of Drosophila embryos). When purifying a larger quantity of material, it is preferable to use multiple 1-ml columns. It is common practice to apply as much as 50 ml of protein sample onto a single 1-ml column.

   Typically, 1 ml of affinity resin contains ~80 to 90 µg DNA, which corresponds to a protein-binding capacity of 7 nmol/ml of resin, assuming one recognition site per 20 bp.

6. After loading the starting material, wash the column four times with 2-ml aliquots of buffer Z/0.1 M KCl, rinsing the sides of the column each time.

   It is very important to wash the affinity column thoroughly at this step by rinsing down the sides of the column with the 2-ml wash buffer aliquots; a single 8-ml wash is not effective.

   DNA affinity columns will often yield >100-fold purification of the desired factor. When a protein is purified 100-fold, however, a 1% contamination of the starting material due to inefficient washing of the column will lead to major contamination of the affinity-purified factor.

7. Elute the protein from the column by successive addition of 1-ml portions of buffer Z/0.2 M KCl, buffer Z/0.3 M KCl, buffer Z/0.4 M KCl, buffer Z/0.5 M KCl, buffer Z/0.6 M KCl, buffer Z/0.7 M KCl, buffer Z/0.8 M KCl, and buffer Z/0.9 M KCl, followed by three 1-ml aliquots of buffer Z/1 M KCl. Collect 1-ml fractions that correspond to the addition of the 1-ml portions of buffer. Quick-freeze the protein samples in liquid nitrogen and store at –80°C. Samples can generally be stored for at least 2 years.

B.C.U. „M. Eminescu" IAŞI
CHIMIE

BOSTON UNIVERSITY LIBRARY

It is convenient to save separate aliquots of each fraction for DNA-binding assays (20 µl each) and SDS-PAGE analysis (50 µl each).

8. Assay the protein fractions for the sequence-specific DNA-binding activity using a DNA-binding assay (Brenowitz, et al., 1989; Buratowski and Chodosh, 1996; Baldwin et al., 1996). Estimate the purity of the protein fractions by SDS-PAGE (*UNIT 10.1*) followed by silver staining to visualize the protein.

   If further purification is desired, combine the fractions that contain the activity and, depending on the KCl concentration, either dilute (using buffer Z without KCl) or dialyze (against buffer Z/0.1 M KCl) to 0.1 M KCl. Then combine the protein fraction with nonspecific competitor DNA (the amount and type of which must be determined experimentally as described in Support Protocol 2) and reapply to either fresh or regenerated DNA affinity resin.

   In some instances, proteins might still be bound to the affinity resin after the 1 M salt elution step (step 7). Thus, if the desired protein is not detected in either the column fractions or flowthrough, it is possible that the protein is still on the column, and a wash at a higher salt concentration (e.g., 2 M KCl) may be needed to elute the protein from the resin.

9. Regenerate the affinity resin as follows: At room temperature, stop the column flow and add 5 ml column regeneration buffer to the column. Stir the resin with a silanized narrow glass rod to mix the resin with the regeneration buffer. Let the buffer flow out of the column. Repeat step.

10. To store column, add 10 ml column storage buffer and allow to flow through. Repeat this wash, then close the bottom of the column and add another 5 ml buffer. Cover top of column and store at 4°C.

    The column may be stored for ≤1 year. Alternatively, the affinity resin may be removed from the column after the two washes and stored in a clean polypropylene tube with the 5 ml buffer.

SUPPORT PROTOCOL 2

SELECTION AND PREPARATION OF NONSPECIFIC COMPETITOR DNA

Proper use of competitor DNA is essential for successful purification of DNA-binding proteins by affinity chromatography. Common competitor DNAs include poly(dI-dC), poly(dA-dT), poly(dG-dC), and calf thymus DNA. The amount and type of competitor to use in a given experiment must be determined experimentally. A typical method is to mix a protein sample (the exact fraction that will be applied to the affinity resin) with varying amounts of different competitor DNAs and evaluate DNA binding using assays such as DNase I footprinting (Brenowitz et al., 1989) or gel mobility shifts (Buratowski and Chodosh, 1996). The competitor DNA that inhibits DNA binding the least should be used for DNA affinity chromatography. It is perhaps easiest to think of these binding experiments as scaled-down affinity columns. First, determine the highest amount of competitor DNA that can be added to a DNA-binding reaction that does not interfere with the binding of the sequence-specific factor. To move up to a full-scale experiment, use one-fifth of the amount that would be required if the binding reaction were directly scaled up.

The following example with a hypothetical factor M illustrates how to determine the amount of competitor to use in an affinity chromatography experiment. Using DNase I footprinting, a strong footprint was observed with 5 µl of a 0.4 M heparin fraction. Testing various competitors reveals that calf thymus DNA, poly(dI-dC), and poly(dG-dC) all strongly inhibit binding of factor M. However, no detectable inhibition of factor M binding is observed with 2 µg poly(dA-dT), weak but detectable inhibition is observed with 3 µg poly(dA-dT), and strong inhibition is observed with 4 µg poly(dA-dT). In this example,

UCLA CENTRAL UNIVERSITY LIBRARY

with 5 µl of the 0.4 M heparin fraction, the highest amount of poly(dA-dT) that does not inhibit factor M binding is 2 µg. If 5 ml of the 0.4 M heparin fraction is available, the direct scale-up would be 1000-fold, so 1000 × 2 µg = 2000 µg poly(dA-dT) would be needed. Because in an affinity chromatography experiment one-fifth of the direct scale-up amount is used, the appropriate amount of poly(dA-dT) to add to 5 ml of the 0.4 M heparin fraction is 2000 µg × 1/5 = 400 µg.

The optimal amount of competitor DNA will vary with the purity of the partially purified protein sample. Fractions that contain more nonspecific DNA-binding proteins will normally require more competitor DNA and thus it is necessary to determine experimentally the optimal amount of DNA to use with each protein fraction. In addition, the amount of competitor DNA is estimated as the mass of DNA (in micrograms) to add per volume (in milliliters) of protein fraction; this is because it is likely that competitor DNA acts by forming a complex with high-affinity, nonspecific DNA-binding proteins in the crude extract. Different competitor DNAs can be used in a single experiment.

To prepare poly(dI-dC), poly(dG-dC), and poly(dA-dT), dissolve the desired amount of competitor DNA to a final concentration of 10 A_{260} units in TE buffer per 100 mM NaCl. Heat the sample to 90°C and slowly cool to room temperature over 30 to 60 min. If the average length of the DNA is >1 kb, degrade it by sonication. Estimate the length of the DNA by agarose gel electrophoresis.

REAGENTS AND SOLUTIONS

Buffer TM

50 mM Tris·Cl, pH 7.9 (*APPENDIX 2E*)
0 M *or* 1 M KCl
12.5 mM $MgCl_2$
1 mM dithiothreitol (DTT; add fresh just before use)
20% (v/v) glycerol
0.1% (v/v) Nonidet P-40 (NP-40)

Do not make a 10× buffer. To generate aliquots of buffer with the range of KCl concentrations described in the protocol, make two 500-ml batches of 1× buffer containing no KCl and 1 M KCl respectively, and mix together appropriate quantities. Store at 4°C. Just prior to use, place 1.5-ml aliquots of each concentration in separate 1.5-ml microcentrifuge tubes, and add DTT.

Buffer Z

25 mM HEPES (K^+ salt), pH 7.6
0 M *or* 1 M KCl
12.5 mM $MgCl_2$
1 mM DTT (add fresh just before use)
20% (v/v) glycerol
0.1% (v/v) NP-40
Adjust pH to 7.6 with KOH

Do not make a 10× buffer. To generate aliquots of buffer with the range of KCl concentrations described in the protocol, make two 500-ml batches of 1× buffer containing no KCl and 1 M KCl respectively, and mix together appropriate quantities. Store at 4°C. Just prior to use, place 1.5-ml aliquots of each concentration in separate 1.5-ml microcentrifuge tubes, and add DTT.

BCU RAY CENTRAL UNIVERSITY LIBRARY

Buffer Z[e]

25 mM HEPES (K^+ salt), pH 7.6
0 M *or* 1 M KCl
1 mM DTT (add fresh just before use)
20% (v/v) glycerol
0.1% (v/v) NP-40
Adjust the pH to 7.6 with KOH

Do not make a 10× buffer. To generate aliquots of buffer with the range of KCl concentrations described in the protocol, make two 500-ml batches of 1× buffer containing no KCl and 1 M KCl respectively, and mix together appropriate quantities. Store at 4°C. Just prior to use, place 1.5-ml aliquots of each concentration in separate 1.5-ml microcentrifuge tubes, and add DTT.

Column regeneration buffer

10 mM Tris·Cl, pH 7.8 (*APPENDIX 2E*)
1 mM EDTA, pH 8.0
2.5 M NaCl
1% (v/v) NP-40
Store at room temperature

The solution will be cloudy and separate into two phases (NP-40 and aqueous) upon storage. Mix by swirling and shaking just before use.

Column storage buffer

10 mM Tris·Cl, pH 7.8 (*APPENDIX 2E*)
1 mM EDTA, pH 8.0
0.3 M NaCl
0.04% (w/v) sodium azide

Store at room temperature without sodium azide. Make a 4% (w/v) sodium azide stock solution and add just before use.

Ethanolamine hydrochloride, pH 8.0, 1 M

1 M ethanolamine
Adjust pH to 8.0 with HCl
Filter sterilize
Store at room temperature

Formamide loading buffer

90 ml deionized formamide
10 ml 10× TBE (see recipe below)
40 mg xylene cyanol
40 mg bromphenol blue
Store at –20°C

Linker-kinase buffer, 10×

660 mM Tris·Cl, pH 7.6 (*APPENDIX 2E*)
100 mM $MgCl_2$
100 mM DTT
10 mM spermidine
Store at –20°C
Add an extra 10 mM DTT just before use

DCU IAST / CENTRAL UNIVERSITY LIBRARY

16% polyacrylamide-urea gel

50 ml 40% (w/v) 19:1 acrylamide/bisacrylamide
12.5 ml 10× TBE (see recipe below)
62.5 g urea
17 ml H_2O
Mix, filter, briefly degas, and then add:
750 µl 10% (w/v) ammonium persulfate
20 µl TEMED

Pour immediately into prepared gel plates.

T4 polynucleotide kinase buffer, 10×

500 mM Tris·Cl, pH 7.6 (*APPENDIX 2E*)
100 mM $MgCl_2$
50 mM DTT
1 mM spermidine
1 mM EDTA, pH 8.0
Store at –20°C
Add an extra 50 mM DTT just before use

TBE (Tris/borate/EDTA) electrophoresis buffer, 10×

108 g Tris base (890 mM)
55 g boric acid (890 mM)
900 ml H_2O
40 ml 0.5 M EDTA, pH 8.0 (20 mM)
H_20 to 1 liter

COMMENTARY

Background Information

Purification of sequence-specific DNA-binding proteins has historically been a difficult task, mainly because such proteins are a small fraction of the total cellular protein. However, it is now possible to purify these factors quickly, simply, and effectively by using multimerized synthetic oligonucleotides that contain the recognition sequence for a particular DNA-binding protein. Early efforts with DNA-affinity chromatography involved adsorption or coupling of nonspecific DNA (such as calf thymus DNA) to either cellulose (Alberts and Herrick, 1971) or agarose (Arndt-Jovin et al., 1975) supports. These methods paved the way for the development of a variety of sequence-specific DNA affinity chromatography techniques, including the procedures described in this unit.

Other methods have been described to purify sequence-specific DNA-binding proteins, including chromatography using biotinylated DNA fragments attached to various supports by biotin-avidin or biotin-streptavidin coupling (*UNIT 10.6*; Chodosh et al., 1986; Kasher et al., 1986; Leblond-Francillard et al., 1987), oligonucleotides synthesized onto Teflon-based beads (Duncan and Cavalier, 1988), or synthetic oligonucleotide monomers attached to agarose supports (Wu et al., 1987; Blanks and McLaughlin, 1988; Hoey et al., 1993); and preparative gel mobility shifts (Gander et al., 1988). Although more than 50 sequence-specific DNA-binding proteins have been purified by the method described in this unit (Kadonaga, 1991, and references therein), it is likely that many of the techniques listed above are also effective for purifying sequence-specific DNA-binding proteins.

There are a variety of reasons that CNBr activation is commonly used in the preparation of affinity resins: it is simple, works well with agarose matrices, and is mild enough to bind ligands such as DNA. Briefly, the chemistry of the CNBr activation reaction is as follows. At high pH, the hydroxyl groups on the agarose resin react with CNBr. The majority of the CNBr added to the reaction reacts with water to yield inert cyanate ions, which is part of the reason such a large amount of CNBr is required. Additionally, the majority of the cyanate esters that are formed on the agarose either are hydrolyzed to form inert carbamate or react with the matrix hydroxyls to form imidocarbonates. The imidocarbonates that form can act effectively

BOSTON UNIVERSITY LIBRARY

as chemical cross-links, thus stabilizing the matrix (which is in most cases beneficial, particularly if the agarose resin chosen is not covalently cross-linked). The remaining active cyanate esters are coupled to the amino-containing ligands (in this case, oligonucleotides) at physiological pH. Finally, the unreacted cyanate esters are blocked with an excess of a suitable reagent, such as ethanolamine, to prevent coupling of the protein sample to the matrix (Janson and Rydén, 1989).

Critical Parameters and Troubleshooting

Basic strategy

The general approach to affinity purification of DNA-binding proteins is as follows. First, estimate the binding site of the desired protein by a technique such as DNase I footprinting (Brenowitz et al., 1989). If possible, it is best to survey a variety of promoters and enhancers. Next, determine the optimal conditions for protein binding to the DNA, considering factors such as temperature, ionic strength, pH, and Mg^{2+} concentration. Using conventional chromatography, partially purify the protein to remove contaminants such as nucleases that may degrade the affinity resin. Test a variety of nonspecific competitor DNAs, including poly(dI-dC), poly(dG-dC), poly(dA-dT), and calf thymus DNA to determine their effect on protein-DNA interactions. For best results, prepare two or more different DNA affinity resins with naturally occurring, high-affinity binding sites, preferably containing different flanking DNA sequences. The desired protein should bind with high affinity to both resins; if it does not, then it is likely that the protein that has been purified is not specific to the desired binding site. Finally, it is important to prepare a control resin that does not contain the recognition sequence for the desired protein. A control resin will make it possible to identify proteins that bind nonspecifically to DNA-Sepharose. Using this approach, it is possible to obtain a preparation containing a highly purified, sequence-specific DNA-binding protein.

Starting material and conventional chromatography

Extensive purification of the DNA-binding protein is not required for effective affinity chromatography. However, partial purification of the protein by conventional chromatography is recommended prior to affinity chromatography to remove proteases and nucleases that might degrade either the protein or the affinity resin. Keep in mind that sequence-specific and nonspecific DNA-binding proteins will often copurify in conventional chromatography, possibly because they may both interact with negatively charged polymers that resemble DNA. It is important to note that the most persistent contaminants in sequence-specific DNA-binding protein preparations are nonspecific, high-affinity DNA-binding proteins. Various conventional chromatographic methods may be employed prior to affinity purification of a DNA-binding protein; methods that have been used successfully in the past are discussed below.

Ion-exchange chromatography. One obvious first step might be cation-exchange chromatography with resins such as S-Sepharose Fast Flow/Mono S (Pharmacia Biotech), CM-52 (Whatman), CM Sepharose Fast Flow (Pharmacia Biotech), P11 phosphocellulose (Whatman), or Bio-Rex 70 (Bio-Rad). DNA-binding proteins (both specific and nonspecific) will normally bind to cation-exchange resins in buffers containing from 50 mM to 100 mM NaCl, and can be eluted with higher salt concentrations.

Affinity chromatography. Nonspecific DNA-cellulose (Alberts and Herrick, 1971) or DNA-agarose (Arndt-Jovin et al., 1975) resins can be used for a preliminary purification step. These resins are typically prepared with salmon sperm or calf thymus DNA. Also, sequence-specific DNA affinity resins can be prepared with oligonucleotides that do not contain binding sites for the desired factor. A strategy for chromatography with either nonspecific DNA affinity resin (e.g., see Rosenfeld and Kelly, 1986) or sequence-specific DNA affinity resins that lack the binding site for the desired factor (e.g., see Kaufman et al., 1989) is as follows. Once the protein sample is applied to a nonspecific DNA affinity resin, the desired factor will either (1) flow through the resin or (2) elute from the resin at a low salt concentration. High-affinity, nonspecific DNA-binding proteins should remain bound to the resin and will thus be separated from the desired protein. If this strategy is successful, it will not be necessary to add the competitor DNA prior to the subsequent sequence-specific affinity chromatography step because the high-affinity nonspecific DNA-binding proteins will already have been separated from the sample.

A resin that works well if the desired protein contains O-linked *N*-acetylglucosamine monosaccharide residues is wheat germ agglutinin-agarose. This method has been used successfully in the past with transcription factors such as Sp1 (Jackson and Tjian, 1989) and HNF1 (Lichtsteiner and Schibler, 1989).

Heparin-agarose chromatography. Heparin-agarose resins are also excellent for the purification of DNA-binding proteins because they possess properties similar to those of both ion-exchange and affinity resins. It is important to be aware that variability exists between different heparin-agarose preparations. This variability may be due to differences in the methods of coupling heparin to agarose, because alternate methods for coupling and blocking the agarose may produce different functional groups on the resin. If a particular batch of heparin-agarose is used successfully, it is wise to continue to use that batch to ensure reproducibility.

Gel-filtration chromatography. Finally, gel-filtration chromatography may be used effectively for partial purification of a DNA-binding protein because separation is based on size and shape, not DNA-binding properties. For example, gel filtration may be useful for separating a desired protein from contaminating nucleases and other nonspecific DNA-binding proteins, in contrast to chromatography using ion-exchange, heparin-agarose, and nonspecific DNA affinity resins that may actually enrich for DNA-binding proteins. In some cases gel filtration may be undesirable because significant sample dilution occurs; however, further concentration can be obtained by subsequent affinity chromatography.

DNA binding studies

Binding conditions. In order to use affinity chromatography to purify a DNA-binding protein, it is necessary to optimize binding conditions. It is important to determine these conditions experimentally, as ionic strength, temperature, pH, and presence or absence of Mg^{2+} can affect protein-DNA interactions. In addition, although HEPES and PIPES are often considered to be superior to Tris buffers, some commercially available preparations of HEPES and PIPES buffers contain contaminants that inhibit binding of proteins to DNA. Therefore, in some respects, it may be safer to use Tris buffer. It is also important to note that some factors, such as Sp1, bind with higher affinity to DNA in the absence of Mg^{2+} than in its presence. Thus, in some cases it may be useful to omit Mg^{2+} from the chromatography buffer. In addition, although the procedures in this unit use buffers containing KCl, NaCl could probably be substituted. Although it is usually preferable to handle proteins at 4°C, proteins have been described that will not bind DNA at 4°C, yet bind perfectly well at room temperature; in such cases the temperature at which the affinity chromatography is performed should be adjusted accordingly. Finally, to minimize nonspecific adsorption of affinity-purified proteins to plastic and glass, chromatography and storage buffers should contain a nonionic detergent such as NP-40 at a concentration of ~0.01% to 0.1% (v/v).

Binding assays. There are many methods for identifying proteins that are bound to DNA, including DNAse I footprinting (Galas and Schmitz, 1978; Brenowitz et al., 1989), Fe-EDTA footprinting (Tullius et al., 1987), methidiumpropyl-EDTA·Fe^{2+} (MPE; Hertzberg and Dervan, 1982), methylation interference (Baldwin et al., 1996), and gel mobility shift assays (Buratowski and Chodosh, 1996). Although binding information may be obtained from all these techniques, it is most straightforward to use DNase I footprinting to identify a protein binding site. Additionally, DNase I is active over a broad range of buffer conditions, which allows for considerable variation in binding conditions. Visualization of the protected region by footprinting makes designing oligonucleotides for affinity chromatography relatively simple (as discussed later in this section). Both DNase I footprinting and gel mobility shift assays are useful for assaying affinity-column fractions.

Design of oligonucleotides

Many different parameters are important in designing oligonucleotides for an affinity resin. The first step, as described above, is to determine the protein-binding site on the DNA. The DNA affinity resin should be prepared from naturally occurring, high-affinity binding sites. Using a consensus sequence may work in some instances, but in most situations a "real" binding site is best. Given that the length of the oligonucleotides can be reasonably flexible (14-mers to 61-mers have been used successfully), use of oligonucleotides that include the DNase I footprint as well as some flanking DNA (at least a few bases beyond the borders of the footprint) is recommended. In the early stages, it is better to copurify factors that bind

BOSTON CENTRAL UNIVERSITY LIBRARY

to the flanking region than to fail to purify the desired factor because the binding site is too short. It may be wise to avoid using oligonucleotides that are 21 or 42 bases in length because the DNA, if bent, might have a greater tendency to circularize during the ligation step. The oligonucleotides should also be designed with a single-stranded overhang, for two reasons: first, the ligation reaction will be more efficient (as compared to a blunt-end ligation), and second, it is likely that the DNA couples to the resin via the primary amine groups of the single-stranded overhang of the ligated multimers. The sequence GATC-XXX-BINDING SITE-XXX (where XXX represents the DNA flanking the binding site) works well, though it may also be convenient to use the sequences flanking the binding site as the overhang.

Inadvertent purification of nonspecific DNA-binding proteins

Throughout this unit, an attempt has been made to emphasize how to avoid inadvertent purification of nonspecific DNA-binding proteins. Unfortunately, this problem is quite common, particularly when the gel mobility shift assay is used to monitor DNA binding. Proper use of the control resin (to identify proteins that bind nonspecifically to DNA-Sepharose), two different affinity resins (to identify proteins that might be interacting with the linker DNA), and competitor DNA (to deplete nonspecific DNA-binding proteins from the extract) should virtually eliminate purification of nonspecific DNA-binding proteins. In addition, DNase I footprinting is recommended for assaying DNA binding because it allows visualization of the actual protein binding site and to confirm sequence specificity. To correlate DNA binding with a particular polypeptide, it would be informative to purify the polypeptide from a polyacrylamide gel by using the denaturation/renaturation procedure described by Hager and Burgess (1980). Two common nonspecific DNA-binding proteins that have been purified from HeLa cells by affinity chromatography are poly(ADP-ribose) polymerase, which has an M_r of 116,100 (Ueda and Hayaishi, 1985; Slattery et al., 1983), and the Ku antigen, which consists of two polypeptides of M_r 70,000 and 80,000 (Mimori et al., 1986).

Anticipated Results

After two rounds of affinity chromatography, it is possible to achieve a 500- to 1000-fold purification with a 30% overall yield. The concentration of affinity-purified proteins is typically 5 to 50 µg/ml. About 0.2 to 1 µl of protein (2 to 10 ng) can be expected to be sufficient for a "blanked-out" footprint (with ~10 fmol of DNA probe). Affinity resin is stable for >1 year if stored at 4°C. Affinity-purified proteins are typically stable for >2 years if stored at –80°C in an appropriate buffer and handled properly. Proteins should always be quick-frozen in liquid nitrogen and quick-thawed in either cold or room-temperature water (although if room-temperature water is used to accelerate thawing, the sample must not be allowed to warm up above 4°C). Although many DNA-binding proteins remain active after several freeze-thaw cycles, it is preferable to divide protein preparations into small aliquots rather than to freeze and thaw the entire sample many times.

Time Considerations

The time required to optimize DNA-binding conditions of a particular protein is variable and depends on assay type, probe preparation time, and competitor choices. The time to prepare extracts and to perform conventional chromatography is also variable depending on factors such as starting material and type of chromatography. Beginning with purified oligonucleotides, preparation of the DNA affinity resin takes 2 days (with either commercially available or homemade CNBr-activated resin). If the oligonucleotides are to be gel-purified, an additional day and a half should be added. Affinity chromatography takes ~4 to 8 hr, dependent mainly on the flow rate of the resin: Sepharose CL-2B runs at ~15 ml/hr, while Sepharose-4B runs somewhat slower. Therefore, it is possible to estimate chromatography time by calculating the volume of sample that is to be applied to the column plus 8 ml for the wash steps and 11 ml for the elution steps. If the volume of starting material is not too large, it is possible to assay the affinity column on the day it is run (either by DNA-binding assays, SDS-PAGE, or both). It is important to freeze the affinity fractions in liquid nitrogen and store at –80°C as soon as the column is complete.

Purification of DNA-Binding Proteins Using Biotin/Streptavidin Affinity Systems

Short fragments of DNA—either natural or formed from oligonucleotides—containing a high-affinity site for a DNA-binding protein provide a powerful tool for purification. The biotin/streptavidin purification system is based on the tight and essentially irreversible complex that biotin forms with streptavidin. The experimental design of this system is illustrated in Figure 9.7.1. First, a DNA fragment is prepared that contains a high-affinity binding site for the protein of interest. A molecule of biotinylated nucleotide is incorporated into one of the ends of the DNA fragment. The protein of interest is allowed to bind to the high-affinity recognition site present in the biotinylated fragment. The tetrameric protein streptavidin is then bound to the biotinylated end of the DNA fragment. Next, the protein/biotinylated fragment/streptavidin ternary complex is efficiently removed by adsorption onto a biotin-containing resin. Since streptavidin is multivalent, it is able to serve as a bridge between the biotinylated DNA fragment and the biotin-containing resin. Proteins remaining in the supernatant are washed away under conditions that maximize the stability of the DNA-protein complex. Finally, the protein of interest is eluted from the resin with a high-salt buffer.

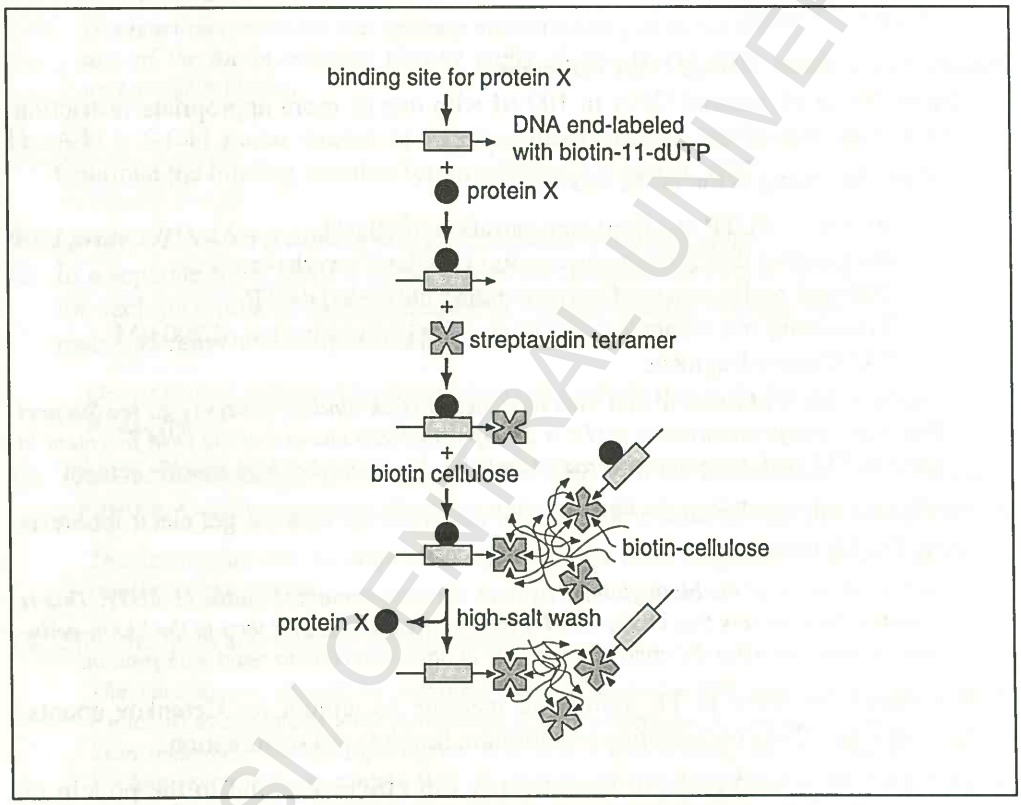

Figure 9.7.1 Purification of DNA-binding proteins using the biotin/streptavidin affinity technique. The protocol involves the following steps: (1) a biotinylated, labeled DNA fragment is prepared containing a binding site for the protein to be purified; (2) the biotin-cellulose resin is prepared; (3) a binding reaction containing a crude protein fraction and the biotinylated probe is set up; (4) free streptavidin is added to the binding reaction; (5) the protein/biotinylated DNA fragment/streptavidin complex is bound to the biotin-cellulose resin; (6) unbound protein is removed by extensive resin washing; and (7) the protein is eluted from the resin with high-ionic-strength buffer. Each of these steps can be monitored and optimized in solution, using a mobility shift DNA-binding assay (see Support Protocol and Buratowski and Chodosh, 1996).

PURIFICATION USING BATCH METHOD

Materials

Plasmid DNA with binding site for the protein of interest
Appropriate restriction endonucleases
Biotin-11-dUTP (Life Technologies)
Labeled and unlabeled dNTPs
Klenow fragment of *E. coli* DNA polymerase I
TE buffer (*APPENDIX 2E*)
Biotin-cellulose (Pierce)
Biotin-cellulose binding buffer (see recipe)
BSA
Bulk carrier DNA [e.g., poly(dI-dC)·poly(dI-dC), salmon sperm DNA, or *E. coli* DNA]
Biotin-cellulose elution buffer (see recipe)
Protein solution
Streptavidin (Celltech; may be stored as 5 mg/ml stock for at least 2 months)

DEAE membrane (Schleicher & Schuell NA45)
0.025-μm filter discs (Millipore VS)

Additional reagents and equipment for mobility-shift DNA binding assay (see Support Protocol)

Prepare biotinylated, labeled DNA fragment

1. Digest 50 μg of plasmid DNA in 100 μl with one or more appropriate restriction endonucleases to obtain DNA probe.
2. Add the following to the probe mixture:

   Biotin-11-dUTP to a final concentration of 20 μM
   Radioactive dNTP for incorporation into the 5′ overhang
   100-fold molar excess of corresponding unlabeled dNTP
   Remaining two unlabeled dNTPs to a final concentration of 200 μM
   5 U Klenow fragment.

   This reaction is identical to that used in standard DNA-binding assays (e.g., see Support Protocol), except biotinylated dUTP is incorporated into one end of the DNA fragment in place of TTP and the fragment is radiolabeled to low instead of high specific activity.

3. Precipitate the biotinylated probe. Isolate the probe by agarose gel electrophoresis using DEAE membrane.

   Gel purification of the biotinylated fragment removes unreacted biotin-11-dUTP. This is essential because any free biotin-dUTP binds to streptavidin and then to the biotin-cellulose column, reducing the apparent capacity of both materials to react with protein.

4. Resuspend the probe in TE buffer and measure an aliquot for Cerenkov counts. Estimate the DNA concentration by ethidium bromide dot quantitation.
5. Test the biotinylated probe to be certain it will efficiently bind to the protein of interest. Use a standard binding assay (e.g., see Support Protocol) with the biotinylated fragment as probe.

Prepare biotin-cellulose resin

6. Place 200 μl biotin-cellulose in a 1.5-ml microcentrifuge tube. Spin the resin for 30 sec in a microcentrifuge and remove the supernatant. Add to the pellet:

   1.0 ml biotin-cellulose binding buffer
   500 μg/ml BSA
   200 μg carrier DNA

CU IASI CENTRAL UNIVERSITY LIBRARY

Gently mix the tube 5 min on a rotating wheel.

This step blocks nonspecific protein and nucleic acid binding sites present on the biotin-cellulose resin.

7. Spin the resin, remove the supernatant, and resuspend pellet in 1.0 ml of biotin-cellulose elution buffer. Gently mix 5 min on a rotating wheel. Repeat this wash.

   Washing removes molecules on the biotin-cellulose resin that might later be eluted from the resin by the biotin-cellulose elution buffer.

8. Spin the resin, remove the supernatant, and resuspend pellet in 1.0 ml of biotin-cellulose binding buffer. Repeat this wash.

   This 1:6 dilution of pretreated biotin-cellulose is ready for use and can be stored for several months.

Set up binding reaction

9. Determine the molar concentration of the protein to be purified via a mobility-shift assay (e.g., see Support Protocol).

10. Set up a standard binding reaction containing the protein to be purified, carrier DNA, and a 10-fold molar excess of biotinylated fragment relative to the protein to be purified. Allow the reaction to go to completion for ~15 min.

    Use reaction conditions that optimize protein binding to its recognition site. The composition of the biotin-cellulose binding buffer should be the same as that optimized for protein-DNA binding.

11. Add a 5-fold molar excess of streptavidin relative to the biotinylated fragment. Continue the binding reaction for an additional 5 min at 30°C.

Bind protein/DNA/streptavidin complex to biotin-cellulose resin

12. In a separate tube, place 2 µl pretreated biotin-cellulose (12 µl of the 1:6 dilution) for each picomole of biotinylated DNA fragment in the binding reaction. Spin the resin and remove the supernatant.

    One or two microliters of biotin-cellulose can easily be seen at the bottom of the microcentrifuge tube.

13. Transfer the binding reaction mix into the tube with the biotin-cellulose resin using a pipettor. Gently resuspend the resin and incubate on a rotating wheel for 30 min.

    This incubation can be done either at 4°C or at room temperature, depending on the stability of the protein.

14. Spin the resin and remove the supernatant.

    The supernatant should be measured using a mobility shift assay (e.g., see Support Protocol) to determine what percentage of the biotinylated fragment and the protein has been removed from the supernatant. It is also useful to assay the supernatant from the binding reaction for a control DNA-binding protein to determine whether the protein of interest has been specifically depleted or whether multiple DNA-binding proteins have been depleted nonspecifically. The latter observation would suggest that the matrix is acting as a nonspecific DNA-affinity column. For some applications, a protein fraction specifically depleted for a particular DNA-binding protein is a valuable reagent.

Wash the resin

15. Resuspend the biotin-cellulose pellet in 500 µl biotin-cellulose binding buffer. Mix by gently inverting the tube 1 to 2 min. Spin the resin and remove the supernatant.

BU AMI CENTRAL UNIVERSITY LIBRARY

Repeat this procedure twice. The second time, transfer to a clean microcentrifuge tube.

Transferring the reaction avoids elution of proteins that were bound nonspecifically to the walls of the tube in the first binding incubation.

Elute the protein

16. Resuspend the biotin-cellulose pellet in at least an equal volume of biotin-cellulose elution buffer. Mix gently on a rotating wheel for 20 min.

    The salt concentration in the biotin-cellulose elution buffer must be determined empirically. Successively higher salt concentrations may be tested until the concentration of eluted protein is maximal.

17. Spin the resin. Save the supernatant and assay for binding activity.

    Small volumes of protein solutions can be dialyzed effectively on 0.025-μm filter discs.

ALTERNATE PROTOCOL 1

PURIFICATION USING A MICROCOLUMN

Although the batch method in the basic protocol is rapid and well-suited for analytical-scale purification, larger volumes of biotin-cellulose resin can be better handled in a microcolumn. This method is also used to elute the protein in as small a volume (i.e., as high a concentration) as possible.

***Additional Materials** (also see Basic Protocol)*

Silanized glass wool
1.0-ml pipet tip
Ring stand

1. Prepare the biotinylated DNA fragment and biotin-cellulose resin and set up binding reaction (see Basic Protocol, steps 1 to 11).

2. Place a small plug of silanized glass wool in the bottom of a 1.0-ml pipet tip. Firmly attach the pipet-tip microcolumn to a ring stand.

   Prewet the glass wool in biotin-cellulose binding buffer before insertion into the pipet tip to avoid trapping air bubbles which might denature proteins.

3. Add 500 μl binding buffer to the microcolumn. Maintain a steady flow through the glass wool plug.

   If the column does not flow smoothly, a pipettor can be gently inserted into the top of the microcolumn. Slightly depressing the plunger will start the column or increase the flow.

4. Add at least 40 μl of 1:1 biotin-cellulose slurry to the microcolumn. Allow the buffer to run down to the surface of the resin.

5. Equilibrate the resin with 3 column volumes of biotin-cellulose binding buffer if the resin has already been pretreated (Basic Protocol, steps 6 to 8). If the resin has not been pretreated, wash sequentially with 3 column volumes each of biotin-cellulose binding buffer, biotin-cellulose binding buffer with 500 μg/ml BSA and 200 μg/ml poly(dI-dC)·poly(dI-dC), and biotin-cellulose elution buffer. Finally, equilibrate with biotin-cellulose binding buffer.

   The biotin-cellulose microcolumn can be washed very rapidly. Each wash takes 2 or 3 min. The drop size from the pipet tip is ~25 μl but this will change with alterations in the ionic strength and protein concentration of the eluate.

CU IAS/CENTRAL UNIVERSITY LIBRARY

6. Load the binding reaction mix (Basic Protocol, step 11) onto the microcolumn and collect the flowthrough.

   The column can be run as fast as 6 to 10 column volumes/hr without affecting the amount of biotinylated fragment bound by the resin. If the flow rate is too slow, use a pipettor to apply pressure to the column. If the flow rate is too fast, plug the tip of the microcolumn with Parafilm in between drops.

7. Wash with 4 column volumes of biotin-cellulose binding buffer. Discard the flow-through.

8. Wash with 3 column volumes of biotin-cellulose elution buffer. Collect 2-drop fractions and assay.

   Fractions as small as 5 µl may be rapidly and effectively dialyzed on 0.025-µm filter discs with minimal loss of volume and activity. Float a filter (shiny side up) in a petri dish on top of 20 ml dialysis buffer. Allow the filter 10 min to wet. Place the sample (5 to 100 µl) to be dialyzed onto the surface of the filter. Surface tension will keep the sample confined in a drop unless there is a detergent in the sample. After 1 hr remove the sample. Once the protein has been eluted from the resin, the resin is effectively the same as a sequence-specific DNA-affinity microcolumn.

PURIFICATION USING STREPTAVIDIN-AGAROSE

ALTERNATE PROTOCOL 2

When high-quality free streptavidin is not available or cellulose is an inappropriate resin, a simple variation on the basic protocol may be employed. In this protocol, the same biotinylated DNA fragment is used but is removed from solution directly by streptavidin-agarose (see Fig. 9.7.2).

Additional Materials (also see Basic Protocol)

Streptavidin-agarose

1. Prepare biotinylated DNA fragment and resin, substituting streptavidin-agarose for biotin-cellulose, and set up binding reaction (see Basic Protocol, steps 1 to 11).

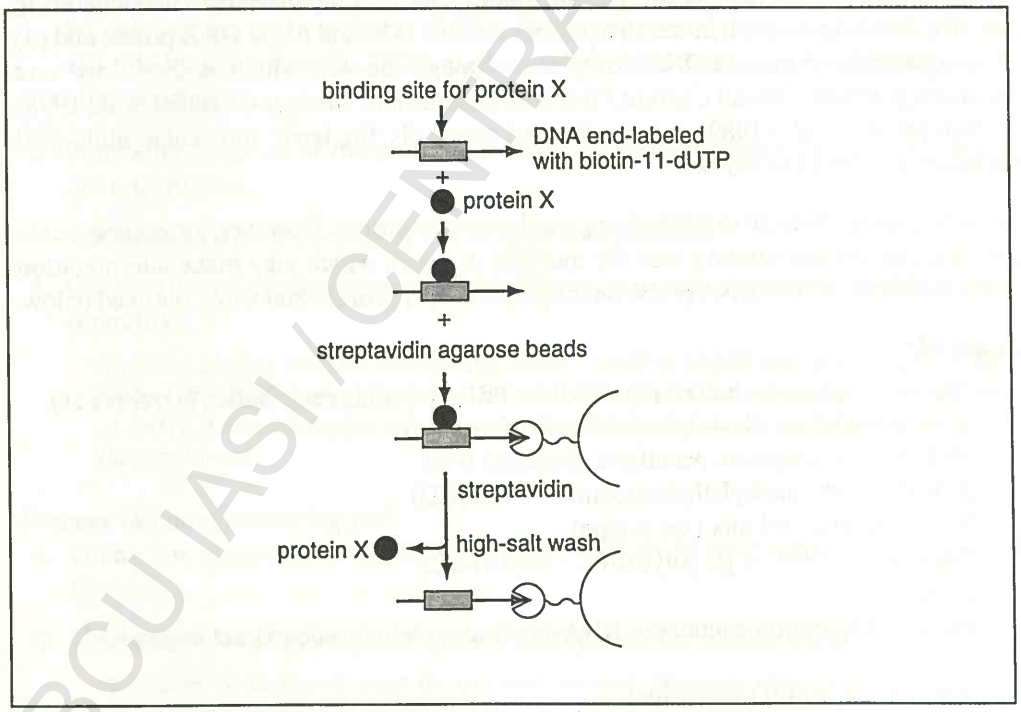

Figure 9.7.2 Purification of DNA-binding proteins using streptavidin-agarose.

RCU IASI / CENTRAL UNIVERSITY LIBRARY

2. In a separate tube, add 50 µl pretreated streptavidin-agarose (300 µl of the 1:6 dilution) for each picomole of biotinylated DNA fragment in the binding reaction. Spin the resin and remove the supernatant.
3. Transfer the binding-reaction mix into the tube with the streptavidin-agarose using a pipettor. Gently resuspend the resin and incubate on a rotating wheel for 30 min to 2 hr.
4. Wash and elute the protein (see Basic Protocol, steps 14 to 17).

Like biotin-cellulose, streptavidin-agarose may also be used in a microcolumn. Follow the microcolumn alternate protocol.

SUPPORT PROTOCOL

MOBILITY-SHIFT ASSAY

The DNA-binding assay using nondenaturing polyacrylamide gel electrophoresis (PAGE) provides a simple, rapid, and extremely sensitive method for detecting sequence-specific DNA-binding proteins. Proteins that bind specifically to an end-labeled DNA fragment retard the mobility of the fragment during electrophoresis, resulting in discrete bands corresponding to the individual protein-DNA complexes. The assay can be used to test binding of purified proteins (see Basic Protocol) or of uncharacterized factors found in crude extracts. This assay also permits quantitative determination of the affinity, abundance, association rate constants, dissociation rate constants, and binding specificity of DNA-binding proteins.

The utility of this technique is underscored by the many proteins that have been characterized using this assay. It has become clear that there is no single protocol that works best for all proteins. Rather, several variables can be changed to optimize binding. There are several options available for the design of the DNA probe, the binding reaction conditions, and the gel running conditions. The reader is referred to Buratowski and Chodosh (1996) for additional details and protocols.

This protocol can be divided into four stages: (1) preparation of a radioactively labeled DNA probe containing a particular protein binding site; (2) preparation of a nondenaturing gel; (3) a binding reaction in which a protein mixture is bound to the DNA probe; and (4) electrophoresis of protein-DNA complexes through the gel, which is then dried and autoradiographed. Consult *Current Protocols in Molecular Biology* (Ausubel et al., 1998) or Sambrook et al. (1989) for details and protocols for basic molecular biological techniques referred to below.

DNA fragments from 20 to 300 bp long may be used as probes. However, longer fragments are likely to contain binding sites for multiple proteins, which may make interpretation of the gel difficult. The DNA probe can be prepared in one of several ways, outlined below.

Materials

10× electrophoresis buffer: e.g., TAE or TBE electrophoresis buffer (*APPENDIX 2E*) or Tris-glycine electrophoresis buffer (*UNIT 10.3*)
30% (w/v) ammonium persulfate, prepared fresh
N,N,N′,N′-tetramethylethylenediamine (TEMED)
Nondenaturing gel mix (see recipe)
Bulk carrier DNA, e.g., poly(dI-dC)·poly(dI-dC)
BSA
Protein preparation containing DNA-binding protein (crude extract or purified fraction)
10× loading buffer (see recipe)

PSU IAST / PENNSTATE UNIVERSITY LIBRARY

Constant-temperature water bath
Two-head peristaltic pump
10-µl glass capillary pipet (optional)
Clay-Adams screw-top loader (optional)
Whatman 3MM filter paper (or equivalent)

Additional reagents and equipment for digesting DNA with restriction endonucleases, DNA labeling, agarose and nondenaturing polyacrylamide gel electrophoresis, recovery of DNA from gels, oligonucleotide synthesis, PCR, ethanol precipitation, ethidium bromide dot quantitation, and autoradiography (see Ausubel et al., 1998, or Sambrook et al., 1989)

Prepare the DNA probe

1a. *For restriction endonuclease fragments:* Isolate a small DNA fragment containing the binding site of interest from a plasmid using a standard restriction endonuclease digestion. Label the fragment by filling in a 5′ overhang with the Klenow fragment of *Escherichia coli* DNA polymerase and ^{32}P-labeled nucleotide or by end labeling using polynucleotide kinase. Separate the fragment from the plasmid by gel electrophoresis.

Kinased probes should be avoided in experiments using crude protein preparations that might contain phosphatase activity.

Agarose gels are useful for resolving fragments as small as 50 bp. Fragments can be recovered using low-melting-temperature agarose or DEAE paper. For smaller DNA fragments, nondenaturing polyacrylamide gels can be used.

1b. *For synthetic oligonucleotides:* Synthesize and anneal complementary oligonucleotides to generate a double-stranded DNA fragment containing the binding site of interest. Label the probe using polynucleotide kinase.

The kinase reaction can be performed before annealing to label only one strand, or after annealing to label both strands. Alternatively, the oligonucleotides can be designed to leave an overhang that can be filled in with labeled nucleotide and Klenow fragment.

1c. *For PCR fragments:* Generate a DNA fragment containing the binding site of interest by polymerase chain reaction (PCR). End-label one of the primers with polynucleotide kinase before the PCR reaction, or label the double-stranded PCR product after purification.

2. Following isolation of the probe, determine its concentration by ethidium bromide dot quantitation.

Concentrations in the range of 2 to 50 ng/µl are convenient.

3. Count 1 µl for Cerenkov counts in a scintillation counter to determine specific activity (cpm/µl).

A typical binding reaction will contain about ~5,000 to 20,000 cpm and ~10 to 100 fmol probe (10 fmol DNA in a final reaction volume of 10 µl gives a total DNA concentration of 1 nM). If desired, probes can be stored up to 4 to 6 weeks at 4°C before proceeding with the experiment.

Prepare the nondenaturing gel

4. Dilute 10× electrophoresis buffer to prepare enough 1× electrophoresis buffer to fill the tank.

5. Assemble washed glass plates and 1.5-mm spacers for casting the gel.

All traces of detergent must be removed because detergent will disrupt protein-DNA interactions.

BOSTON UNIVERSITY MEDICAL CENTER LIBRARY

6. Add 150 µl of 30% ammonium persulfate and 70 µl TEMED to 60 ml nondenaturing gel mix prepared using the same buffer as that used for electrophoresis. Swirl gently to mix.

   The amounts of ammonium persulfate, TEMED, and nondenaturing gel mix can be scaled up or down as necessary depending on the size and number of gels.

7. Pour the gel mix between the plates and insert a comb. Allow the gel to completely polymerize for 20 min.

   For optimal results, use a comb with teeth that are ≥7 mm wide.

8. Remove the comb and bottom spacer and attach the plates to the electrophoresis tank after filling the lower reservoir with 1× electrophoresis buffer. Fill the upper reservoir of the tank with 1× electrophoresis buffer. With a bent-needle syringe, remove any air bubbles trapped beneath the gel and flush out the wells. Prerun the gel 30 to 60 min at 100 V.

   For low-ionic-strength buffers (≤0.5×), use a pump with two heads and a flow rate of 5 to 30 ml per min to exchange buffer between the upper and lower reservoirs. Recirculation of the buffer is essential to prevent polarization due to the low buffering capacity of the buffer.

Prepare the binding reactions

9. While the gel is prerunning, assemble the binding reaction by combining the following in a 0.5-ml or 1.5-ml microcentrifuge tube:

   5,000 to 20,000 cpm radiolabeled probe DNA (0.1 to 0.5 ng, ≥10 fmol)
   0.1 to 2 µg nonspecific carrier DNA
   300 µg/ml BSA
   ≥10% (v/v) glycerol
   Appropriate buffer and salt
   Water or buffer to obtain a final reaction volume of 10 to 15 µl
   DNA-binding protein (~15 µg crude extract or ~5 to 25 ng purified protein).

   The protein should be added last.

10. Mix gently by tapping the bottom of the tube with a finger.

    Avoid introducing bubbles in the mix.

11. Incubate the binding reaction mix 15 to 30 minutes in a constant-temperature water bath.

    Optimal incubation temperatures for different proteins can vary from room temperature to 37°C.

Run the gel

12. Load each binding reaction into the appropriate well of the prerun gel using either a 10-µl glass capillary pipet and Clay-Adams screw-top loader, or a pipettor. Load a small volume of 10× loading buffer with dyes into a separate well.

    The dyes are used to monitor the progress of electrophoresis.

    There is no stacking gel in this system, so precise loading with little mixing with the gel buffer is necessary to obtain sharp bands on the gel. Allow the sample to fall along one side of the well to prevent dilution and avoid bubbles in the well.

13. Electrophorese at ~30 to 35 mA for the minimum time required to give good separation of free probe and the protein-DNA complexes. Stop the gel before the bromphenol blue approaches the bottom of the gel (~1.5 to 2 hr for a 15- to 20-cm gel).

    Longer run times may cause a weaker signal due to partial dissociation of complexes during electrophoresis.

CSU IASL CENTRAL UNIVERSITY LIBRARY

Bromphenol blue migrates at approximately the same position as a 70-bp DNA probe. For probes <70 bp, do not run the bromphenol blue to the bottom of the gel.

If electrophoresis is performed at room temperature, the glass plates should be allowed to become only slightly warm. Decrease the voltage if the plates become any hotter. To run the gel faster, put the apparatus in a cold room, so that higher voltages may be used without heating the glass plates.

Analyze the gel

14. Remove the glass plates from the gel box and carefully remove the side spacers.
15. Using a spatula, slowly pry the glass plates apart, allowing air to enter between the gel and the glass plate.

    The gel should remain attached to only one of the plates. Prying the plates apart too quickly may tear the gel or cause it to stick to both plates. If this occurs or if the gel has become distorted, squirt a stream of water underneath it. This will reduce the stickiness of the gel. Be careful not to let the gel slide off the plate.

16. Lay the glass plate with the gel attached on the bench with the gel facing up. Place three sheets of Whatman 3MM filter paper cut to size on top of the gel.
17. Support both sides of the gel sandwich and carefully flip it over so that the filter paper is on the bottom and the glass plate is on the top.
18. Carefully lift up one end of the glass plate. Peel the filter paper with the gel attached to it from the plate.
19. Cover the gel with plastic wrap and dry under vacuum with heat.
20. Autoradiograph the dried filter overnight without an intensifying screen or 2 to 3 hr with an intensifying screen (*UNIT 10.11*).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Biotin-cellulose binding buffer

12% glycerol
12 mM HEPES-NaOH, pH 7.9
4 mM Tris·Cl, pH 7.9 (*APPENDIX 2E*)
60 mM KCl
1 mM EDTA
1 mM DTT
Store at –20°C upon addition of DTT

This is a typical binding buffer. The composition of binding buffer—especially with respect to pH, ionic strength, and the presence or absence of $MgCl_2$—should be determined by those conditions which optimize the binding of the protein of interest to its recognition site.

Biotin-cellulose elution buffer

12% glycerol
20 mM Tris·Cl, pH 6.8 (*APPENDIX 2E*)
1 M KCl
5 mM $MgCl_2$
1 mM EDTA
1 mM DTT
200 µg/ml BSA
Store at –20°C upon addition of DTT

continued

B.C.U. „M. Eminescu" IAŞI
CHIMIE

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

This is a typical elution buffer. The composition of elution buffer—especially with respect to pH, ionic strength, and the presence or absence of $MgCl_2$—should be determined by those conditions that maximize the dissociation rate of the protein from its recognition site. Another carrier protein, such as insulin or hemoglobin, may be substituted for BSA. The small size of insulin can be useful if protein gels will be run to determine the size of the regulatory factor.

Loading buffer, 10×

20% Ficoll 400
0.1 M Na_2EDTA, pH 8 (*APPENDIX 2E*)
1.0% sodium dodecyl sulfate (SDS; *APPENDIX 2E*)
0.25% bromphenol blue
0.25% xylene cyanol (optional)

Xylene cyanol runs ~50% as fast as bromphenol blue and can interfere with visualization of bands of moderate molecular weight, but can be helpful for monitoring very long runs)

Nondenaturing gel mix

For 60 ml:
6.0 ml 10× TAE or TBE elecrophoresis buffer (*APPENDIX 2E*) or Tris-glycine electrophoresis buffer (*UNIT 10.3*)
8.1 ml 30% (w/v) acrylamide
3.0 ml 2% (w/v) bisacrylamide
42.9 ml H_2O
Prepare fresh for each use

CAUTION: *Acrylamide monomer is neurotoxic. Gloves should be worn when handling the solution, and the solution should not be pipetted by mouth.*

COMMENTARY

Background Information

The biotin/streptavidin purification method works well because the interaction between biotin and avidin (or avidin-like proteins) is one of the strongest known noncovalent interactions. The dissociation constant for the streptavidin-biotin complex is ~10^{-15} M. Avidin, from egg white, and streptavidin, from *Streptomyces avidinii*, are tetrameric proteins containing four high-affinity binding sites for the vitamin biotin. Since streptavidin is multivalent, it is able to serve as a bridge between the biotinylated DNA fragment and the biotin-containing resin. The strong interaction is extremely useful for purification of DNA-binding proteins, because DNA-affinity columns with streptavidin/biotin bridges can be washed under a wide variety of conditions (i.e., 2 M KCl and 1% SDS) without removing either the streptavidin or the biotinylated DNA fragment from the matrix.

Two properties of streptavidin make it more suitable than avidin for use in DNA-affinity purification. The first is that streptavidin, unlike avidin, is not a glycoprotein, and the second is that streptavidin is slightly acidic whereas avidin is basic. Therefore, streptavidin is less likely to bind nonspecifically to cellular glycoproteins and to acidically charged cell components such as nucleic acids.

Several factors make this method simple, rapid, and effective. The same binding conditions and DNA fragment used in the mobility-shift DNA-binding assay to identify a protein (see Support Protocol; Buratowski and Chodosh, 1996) can be used to effect its purification. In addition, the binding of the protein to its DNA recognition site in solution is more efficient than protein-DNA interactions that take place on a column matrix (discussed below). Most importantly, binding in solution allows each reaction parameter to be optimized on an analytical scale by using the gel binding assay.

As an analytical technique, biotin/streptavidin DNA-affinity purification permits the direct identification of a wide variety of sequence-specific DNA-binding proteins. It has already been successfully used to identify hormone receptors, components in mRNA splicing complexes, and RNA polymerase II and III transcription factors (Haeuptle et al., 1983; Chodosh et al., 1986; Grabowski and Sharp, 1986; Kasher et al., 1986).

CSU IAS CENTRAL UNIVERSITY LIBRARY

Another method is commonly used for purifying DNA-binding proteins, whereby DNA-protein binding interactions occur on a column matrix. In this technique, catenated DNA-binding sites are covalently coupled with cyanogen bromide to Sepharose CL-2B (Kadonaga and Tjian, 1986; Rosenfeld and Kelly, 1986). A partially purified protein fraction is combined with competitor DNA and passed through a DNA-Sepharose resin, binding the protein to the surface of the matrix. Generally, multiple passes through the column are used to effect purification, with 25- to 50-fold purification achieved with each column passage. The biotin/streptavidin technique, on the other hand, typically yields 50- to 250-fold purification.

Critical Parameters

Only one end of the DNA fragment should be labeled with biotin. If both ends are labeled, the biotinylated fragment may bind to the resin in such a fashion as to sterically displace the protein bound to the DNA fragment. Thus, one of the restriction enzymes used must be chosen to permit the incorporation of biotin-11-dUTP in place of TTP. Furthermore, since only one end of the fragment is biotin-labeled, the restriction enzyme generating the nonbiotinylated end should leave no overhang, a 3′ overhang, or a 5′ overhang that will not incorporate biotin-dUTP. For binding sites cloned into the pUC polylinker, an *Eco*RI and *Hinc*II fragment fulfills these requirements. Biotin-11-dUTP may be incorporated into the *Eco*RI overhang along with a low-specific-activity dATP radioactive label. The blunt *Hinc*II end of the fragment remains unlabeled.

Alternately, if both ends have 5′ overhangs which permit incorporation of biotin-dUTP, the plasmid may first be digested with one of the enzymes and end-labeled with biotin-dUTP and a radioactive dNTP using the Klenow fragment. After heat-inactivating the Klenow fragment, the plasmid may then be digested with the second restriction endonuclease. Use of annealed complimentary oligonucleotides with the desired ends obviates the need to find appropriate restriction sites.

The low-specific-activity label incorporated into the biotinylated DNA fragment is used to help monitor both the binding of the protein to the biotinylated fragment and the binding of the biotinylated fragment to the biotin-cellulose resin via a streptavidin bridge. The amounts of the radioactive dNTP and the nonradioactive dNTP added to the Klenow reaction should be in a ratio such that 1% to 2% of the biotinylated fragments are labeled. For example, 100 μCi of 6000 Ci/mmol dATP (0.2 μM) may be added to a reaction containing 20 μM unlabeled dATP.

If the radioactive dNTP and the biotin-dUTP residue are incorporated on the same end of the DNA fragment, as in an *Eco*RI site, decay of the radioactive nuclide will result in formation of an unlabeled, nonbiotinylated probe that binds to the protein but is incapable of binding to streptavidin. This molecule is a competitive inhibitor during protein purification and can be kept to a minimum by labeling to a lower specific activity.

Over time, streptavidin tetramers dissociate into monomers. The integrity of the tetramer may be monitored by performing native (nondenaturing) gel electrophoresis. Since streptavidin monomers will bind to the biotinylated DNA fragment, but will be unable to bind to the biotin-cellulose resin, the monomeric form of streptavidin will inhibit purification.

Most proteins can be eluted from their binding site with 1 M KCl. Since the added elution buffer is diluted by the binding buffer in the biotin-cellulose pellet, the actual salt concentration in the resuspended pellet will be lower than that of the elution buffer. As a result, it is useful to remove a small aliquot, dilute it, and measure the actual salt concentration with a conductivity meter. Otherwise, the time, temperature, and composition of the buffer used in the elution step should be chosen to maximize the protein's dissociation rate from its binding site. Thus, if a protein's dissociation rate is 15 sec in 1 M KCl at room temperature, and 3 hr in 1 M KCl at 4°C, a 5-min incubation in 1 M KCl at room temperature should be sufficient to elute the protein. Dissociation rates can easily be measured using a mobility shift DNA-binding assay described in this chapter (Support Protocol; Buratowski and Chodosh, 1996).

Troubleshooting

A major advantage of the biotin/streptavidin method is the ability to monitor the purification on an analytical scale using a mobility-shift assay. Because different parameters can be independently examined, it is possible to pinpoint the particular step that is not working. Several parameters can be examined routinely. Using the biotinylated radiolabeled fragment, the specific binding of the DNA fragment to its protein can be directly determined. In addition, the binding conditions can be optimized in a binding reaction containing the DNA probe and protein. The probe can be a biotinylated or a

BOSTON BIOMEDICAL RESEARCH INSTITUTE LIBRARY

nonbiotinylated radiolabeled DNA fragment. The complex is then resolved by native (nondenaturing) gel electrophoresis.

Streptavidin binding to the probe can be monitored and titrated by varying the amount of streptavidin in a binding reaction. The resulting streptavidin-DNA complex is resolved from free DNA by native gel electrophoresis.

Binding of this complex to the biotin-cellulose matrix can be directly monitored. First, biotin-cellulose is incubated with the complex. Next the resin is spun and aliquots of the supernatant are assayed for the presence of the radiolabeled fragment on a polyacrylamide gel. This basic procedure allows several relevant parameters to be examined, including the amount of streptavidin required for complete binding of the fragment to the resin, the amount of biotin-cellulose required to bind a given amount of fragment, the binding time, and the optimal binding conditions. These three final steps can also be monitored for the specific adsorption of the protein to the column. By assaying the amount of binding activity in the supernatant before and after addition of biotin cellulose, the adsorption efficiency can be determined.

Nonspecific resin binding can be examined by assaying the binding activity in a supernatant containing the protein, the DNA carrier poly(dI-dC)·poly(dI-dC), streptavidin, and biotin-cellulose, but lacking the biotinylated DNA fragment with the protein's binding site. Alternatively, a nonspecific biotinylated DNA fragment can be added. Interestingly, nonspecific protein binding to the resin is minimized with a lower poly(dI-dC)·poly(dI-dC) concentration than is required to generate a discrete band in the mobility shift assay.

The conditions for protein elution from the column can also be directly examined and optimized. After protein adsorption onto the matrix, elution parameters such as time, temperature, pH, carrier protein, and ionic strength can be varied. The amount of protein released into the supernatant is then assayed by the mobility shift assay. In optimizing this step, it is very helpful to know as much as possible about the variables affecting the dissociation rate of the protein from its DNA binding site. These can be studied quickly and rigorously with the mobility shift assay. Troubleshooting guidelines for this assay are presented in Buratowski and Chodosh (1996).

Anticipated Results

The strong interaction between biotin and avidin can result in 25 nmol of biotinylated DNA fragment binding to 1 ml of biotin-cellulose resin. This corresponds to 1.5 mg of a 60 kDa polypeptide. After parameter optimization, ~50- to 250-fold purification of the DNA-protein complex can be obtained. Once the protein has been adsorbed to the column >99% of the remaining protein can be removed with repeated column washing using the binding buffer. Moreover, ~30% to 80% of the binding activity can be recovered from the column. The recovery efficiency depends on how effectively nonspecific binding sites have been blocked. This purification scheme may be used either with crude extracts or with partially purified protein fractions.

Time Considerations

Starting with a biotinylated DNA fragment, the batch protocol (Basic Protocol) can be performed in ~1.5 hr, the microcolumn (Alternate Protocol 1) in ~2.5 hr, and the streptavidin-agarose (Alternate Protocol 2) protocol in ~1.5 hr. The DNA-binding assay (Support Protocol) may take 4 to 5 hr to complete from the time the gel is poured to the time it is dried onto filter paper. Only a small fraction of this time is labor intensive. Thus, several DNA-binding gels can be run simultaneously while other experiments are being performed. Furthermore, the results are often available within 2 to 3 hr after completion of the experiment.

CHAPTER 10
Electrophoresis

INTRODUCTION

Electrophoresis of protein samples in polyacrylamide gels is an indispensable analytical and, in some cases, preparative tool for the protein scientist. Electrophoresis can be used to separate and compare complex protein mixtures, evaluate purity of a protein during the course of its isolation, and provide estimates of physical characteristics such as subunit composition, isoelectric point, size, and charge.

Each type of electrophoretic separation can be conducted in a variety of gel sizes ranging from microgels (e.g., Phast gels from Hoefer Pharmacia) only slightly larger than a postage stamp to giant gels much larger than this page (Garrels, 1979; Young et al., 1983). In general, the time required to electrophorese, stain, and destain small gels is very short, and a minimal amount of sample is consumed. In contrast, larger gels consume more reagents, sample, and time, but provide increased resolution. Small gels are therefore recommended for rapid screening, and larger gels are indicated when maximum resolution is required, as in analysis of complex mixtures or samples containing very similar components.

The most common one-dimensional gel methods utilize the detergent sodium dodecyl sulfate (SDS) to solubilize, denature, and impart a strong negative charge to proteins (*UNIT 10.1*). Although many one-dimensional SDS gel methods have been published over the past 30 years, the single most widely used method is that initially described by Laemmli (1970). SDS-based gel separations are very robust as most, but not all, proteins are readily solubilized in SDS solutions. Most proteins bind a uniform amount of SDS per microgram of protein, which imparts a uniform charge density per unit mass to provide a separation based on the mass of the polypeptide chain.

An alternative one-dimensional separation methodology is based on the protein's isoelectric point and is usually performed in the presence of denaturants such as urea (*UNIT 10.2*). Like one-dimensional SDS gel separations, this denaturing isoelectric focusing method is capable of separating a large number of components in a single dimension. A third one-dimensional method uses native conditions to separate proteins based on intrinsic charge (*UNIT 10.3*). Although this method has less resolving power than the previous two methods, it can be particularly useful for associating a specific electrophoretically separated component with a biological activity, since no denaturants are used.

Two-dimensional electrophoresis (*UNIT 10.4*) involves the orthogonal combination of two different electrophoretic methods. Any two electrophoresis methods can be combined in this manner to produce useful separations. The most common two-dimensional method combines two individually high-resolution methods, consisting of isoelectric focusing (*UNIT 10.2*) followed by SDS gel electrophoresis (*UNIT 10.1*). Each of these separations individually is capable of resolving up to about 100 protein bands; when the two methods are combined, however, more than 1,000 proteins can be separated on a single two-dimensional gel (O'Farrell, 1975; Garrels, 1979). Hence this method can be used to analyze and compare complex protein mixtures, including whole-cell or tissue extracts. Other applications include assessment of the purity and homogeneity of a purified protein,

including recombinant proteins (Chapter 7), and evaluation of some post-translational modifications (Chapters 12 and 13).

After electrophoretic separation, proteins are usually detected using general protein staining methods, such as Coomassie blue staining or the more sensitive silver staining. These staining methods "fix" the proteins in the gel matrix by either chemical cross-linking or denaturation to prevent subsequent diffusion of the protein bands (*UNIT 10.5*). When proteins are to be eluted or extracted from the gels for subsequent analyses, however, fixation-based stains should usually be avoided. In these cases, methods for protein detection without fixation should be used (*UNIT 10.6*) when it is necessary to stain a gel to locate the protein of interest.

An increasingly useful method of isolating proteins from gels for subsequent analysis involves electroblotting onto an inert support, such as polyvinylidene difluoride (PVDF) membranes (*UNIT 10.7*). As a result of the versatility of PVDF membranes, electroblotting has largely replaced electroelution as the method of choice for isolating proteins from most types of polyacrylamide gels (LeGendre and Matsudaira, 1988). PVDF membranes have very high protein binding capacities, good handling characteristics when either dry or wet, and are highly chemically inert. Hence they are compatible with many methods for subsequent analysis, including amino acid analysis, in situ chemical modification, in situ protease digestion, and N-terminal sequence analysis (Chapter 11). A wide range of general protein stains exist that are compatible with most blotting membranes (*UNIT 10.8*). Alternatively, radiolabeled proteins can be detected by autoradiography either in the gel or after transfer to a PVDF membrane (*UNIT 10.11*). The latter is normally preferable; as long as the proteins of interest are electrotransferred in high yield, autoradiography signals of weak β emitters such as ^{14}C or ^{35}S are usually higher on electroblotted membranes than in dried gels (even when fluorophores are impregnated in the gel), because the protein is primarily located on the surface of the membrane that was in contact with the gel during electroblotting. Historically, autoradiography was performed using medical X-ray films. More recently, a relatively wide range of commercially available autoradiography films and exposure methods have been developed that provide superior contrast and higher sensitivity for specific isotopes (*UNIT 10.11*).

The dimensional stability and chemical resistance of PVDF membranes provides an optimal medium for combining multiple detection methods, either sequentially on the same membrane, or on parallel lanes that can be reassembled after different detection methods have been performed. For example, sets of lanes containing replicate samples can be run on a single gel separated by prestained standards, which are used as guides to cut the resulting membrane. Each lane set can be subjected to different detection methods such as protein staining and immunoblotting with different antibodies (*UNIT 10.10*). The analyzed membranes can then be precisely reassembled to determine the relationships between bands detected by different methods. As there is no shrinkage or swelling of the membrane, this approach is particularly valuable for detecting slight differences in migration between components detected by different methods.

Capillary electrophoresis (CE) has recently emerged as a useful analytical method for separating peptides and, to a more limited extent, proteins (*UNIT 10.9*). In addition, CE protocols have been developed for preparative peptide isolation in adequate amounts for subsequent high sensitivity measurements such as micro-sequencing (Chapter 11) and mass spectrometry (Chapter 16). CE employs a fused-silica capillary column that may contain either free solution or a fluid matrix. In contrast to the relatively simple equipment requirements of polyacrylamide-based electrophoretic methods, commercial CE instruments are similar in complexity and expense to high-performance liquid chromatography (HPLC) instruments, due to the necessity for a high-voltage supply, a high-performance

BCU IAS CENTRAL UNIVERSITY LIBRARY

cooling system, and a very sensitive detector. Because CE separates components by charge rather than by hydrophobicity as in reversed-phase HPLC, it is a highly useful orthogonal separation method that is frequently used to complement HPLC peptide separation strategies. Compared with polyacrylamide methods, CE offers much higher resolution, flexibility, sensitivity, and speed for separating peptides (<6 kDa), whereas polyacrylamide methods are more generally applicable for protein separations.

Documentation of gel electrophoresis results for either archival or publication purposes historically used primarily silver halide–based photography. In recent years, the availability of economical hardware and software for capturing, storing, and analyzing digital images has led to the replacement of photography by digital analysis as the preferred documentation method (*UNIT 10.12*). Advantages of digital-based methods include more convenient storage and retrieval, inexpensive and rapid production of backup or additional copies, facile manipulation such as resizing and inserting into reports, and rapid data distribution to colleagues over the Internet. Digital processing of electrophoretic results is particularly essential for comparing large numbers of gels, developing databases of gel patterns and related information, and performing quantitative comparisons such as proteome studies utilizing two-dimensional gels.

One-Dimensional SDS Gel Electrophoresis of Proteins

Electrophoresis is used to separate complex mixtures of proteins, to investigate subunit compositions, and to verify homogeneity of protein samples. It can also serve to purify proteins for use in further applications. In polyacrylamide gel electrophoresis, proteins migrate in response to an electrical field through pores in the gel matrix; pore size decreases with higher acrylamide concentrations. The combination of gel pore size and protein charge, size, and shape determines the migration rate of the protein.

Basic Protocol 1 gives the standard Laemmli method used for discontinuous gel electrophoresis under denaturing conditions, that is, in the presence of sodium dodecyl sulfate (SDS). In Basic Protocol 2, the standard method for full-size gels (e.g., 14 × 14 cm) is adapted for the minigel format (e.g., 7.3 × 8.3 cm). Minigels provide rapid separation but give lower resolution.

Several alternate protocols are provided for specific applications. The first and second alternate protocols cover electrophoresis of peptides and small proteins, separations that require modification of standard buffers; Alternate Protocol 1 uses a Tris-tricine buffer system, and Alternate Protocol 2 employs modified Tris buffers in the absence of urea. Alternate Protocol 3 describes continuous SDS-PAGE, a simplified method in which the same buffer is used for both gel and electrode solutions and the stacking gel is omitted. Other protocols cover the preparation and electrophoresis of various types of gels: ultrathin gels (Alternate Protocol 4), multiple single-concentration gels (Support Protocol 1), gradient gels (Alternate Protocol 5), multiple gradient gels (Support Protocol 2), and multiple gradient minigels (Support Protocol 3). Two-dimensional electrophoresis is discussed in *UNIT 10.4*.

CAUTION: Before any protocols are used, it is extremely important to read the following section about electricity and electrophoresis.

ELECTRICITY AND ELECTROPHORESIS

Many researchers are poorly informed concerning the electrical parameters of running a gel. It is important to note that the voltages and currents used during electrophoresis are dangerous and potentially lethal. Thus, safety should be an overriding concern. A working knowledge of electricity is an asset in determining what conditions to use and in troubleshooting the electrophoretic separation, if necessary. For example, an unusually high or low voltage for a given current (milliampere) might indicate an improperly made buffer or an electrical leak in the chamber.

Safety Considerations

1. Never remove or insert high-voltage leads unless the power supply voltage is turned down to zero and the power supply is turned off. Always grasp high-voltage leads one at a time with one hand only. Never insert or remove high-voltage leads with both hands. This can shunt potentially lethal electricity through the chest and heart should electrical contact be made between a hand and a bare wire. On older or homemade instruments, the banana plugs may not be shielded and can still be connected to the power supply at the same time they make contact with a hand. Carefully inspect all cables and connections and replace frayed or exposed wires immediately.

2. Always start with the power supply turned off. Have the power supply controls turned all the way down to zero. Then hook up the gel apparatus: generally, connect the red

BCM&S CENTRAL UNIVERSITY LIBRARY

Copyright © 1995 by John Wiley & Sons, Inc.

high-voltage lead to the red outlet and the black high-voltage lead to the black outlet. Turn the power supply on with the controls set at zero and the high-voltage leads connected. Then, turn up the voltage, current, or power to the desired level. Reverse the process when the power supply is turned off: i.e., to disconnect the gel, turn the power supply down to zero, wait for the meters to read zero, turn off the power supply, and then disconnect the gel apparatus one lead at a time.

CAUTION: *If the gel is first disconnected and then the power supply turned off, a considerable amount of electrical charge is stored internally. The charge will stay in the power supply over a long time. This will discharge through the outlets even though the power supply is turned off and can deliver an electrical shock.*

Ohm's Law and Electrophoresis

Understanding how a gel apparatus is connected to the power supply requires a basic understanding of Ohm's law: voltage = current × resistance, or $V = IR$. A gel can be viewed as a resistor and the power supply as the voltage and current source. Most power supplies deliver constant current or constant voltage. Some will also deliver constant power: power = voltage × current, or $VI = I^2R$. The discussion below focuses on constant current because this is the most common mode in vertical SDS-PAGE.

Most modern commercial equipment is color-coded so that the red or positive terminal of the power supply can simply be connected to the red lead of the gel apparatus, which goes to the lower buffer chamber. The black lead is connected to the black or negative terminal and goes to the upper buffer chamber. This configuration is designed to work with vertical slab gel electrophoreses in which negatively charged proteins or nucleic acids move to the positive electrode in the lower buffer chamber (an anionic system).

When a single gel is attached to a power supply, the negative charges flow from the negative cathode (black) terminal into the upper buffer chamber, through the gel, and into the lower buffer chamber. The lower buffer chamber is connected to the positive anode (red) terminal to complete the circuit. Thus, negatively charged molecules, such as SDS-coated proteins and nucleic acids, move from the negative cathode attached to the upper buffer chamber toward the positive anode attached to the lower chamber. SDS-PAGE is an anionic system because of the negatively charged SDS.

Occasionally, proteins are separated in cationic systems. In these gels, the proteins are positively charged because of the very low pH of the gel buffers (e.g., acetic acid/urea gels for histone separations) or the presence of a cationic detergent (e.g., cetyltrimethylammonium bromide, CTAB). Proteins move toward the negative electrode (cathode) in cationic gel systems, and the polarity is reversed compared to SDS-PAGE: the red lead from the lower buffer chamber is attached to the black outlet of the power supply, and the black lead from the upper buffer chamber is attached to the red outlet of the power supply.

Most SDS-PAGE separations are performed under constant current (consult manufacturer's instructions to set the power supply for constant current operation). The resistance of the gel will increase during SDS-PAGE in the standard Laemmli system. If the current is constant, then the voltage will increase during the run as the resistance goes up.

Power supplies usually have more than one pair of outlets. The pairs are connected in parallel with one another internally. If more than one gel is connected directly to the outlets of a power supply, then these gels are connected in parallel. In a parallel circuit, the voltage is the same across each gel. In other words, if the power supply reads 100 V, then each gel has 100 V across its electrodes. The total current, however, is the sum of the individual currents going through each gel. Therefore, under constant current it is necessary to

Figure 10.1.1 Series and parallel connections of gel tanks to power supply.

increase the current for each additional gel that is connected to the power supply. Two identical gels require double the current to achieve the same starting voltages and electrophoresis separation times.

Multiple gel apparatuses can also be connected to one pair of outlets on a power supply. This is useful with older power supplies that have a limited number of outlets. When connecting several gel units to one outlet, make certain the connections between the units are shielded and protected from moisture. The gels can be connected in parallel or in series (Fig. 10.1.1). In the case of two or more gels running off the same outlet in series, the current is the same for every gel. If 10 mA is displayed by the power supply meter, for example, each gel in series will experience 10 mA. The voltage, however, is additive for each gel. If one gel at a constant 10 mA produces 100 V, then two identical gels in series will produce 200 V (100 V each) and so on. Thus, the voltage can limit the number of units connected in series on low-voltage power supplies.

Gel thickness affects the above relationships. A 1.5-mm gel can be thought of as consisting of two 0.75-mm-thick gels run in parallel. Because currents are additive in parallel circuits, a 0.75-mm gel will require half the current of the 1.5-mm gel to achieve the same starting voltage and separation time. If a gel thickness is doubled, then the current must also be doubled. There are limits to the amount of current that can be applied. Thicker gels require more current, generating more heat that must be dissipated. Unless temperature control is available in the gel unit, a thick gel should be run more slowly than a thin gel.

NOTE: Milli-Q-purified water or equivalent should be used throughout the protocols.

DENATURING (SDS) DISCONTINUOUS GEL ELECTROPHORESIS: LAEMMLI GEL METHOD

BASIC PROTOCOL 1

One-dimensional gel electrophoresis under denaturing conditions (i.e., in the presence of 0.1% SDS) separates proteins based on molecular size as they move through a polyacrylamide gel matrix toward the anode. The polyacrylamide gel is cast as a separating gel (sometimes called resolving or running gel) topped by a stacking gel and secured in an electrophoresis apparatus. After sample proteins are solubilized by boiling in the presence of SDS, an aliquot of the protein solution is applied to a gel lane, and the individual proteins are separated electrophoretically. 2-Mercaptoethanol (2-ME) or dithiothreitol (DTT) is added during solubilization to reduce disulfide bonds.

This protocol is designed for a vertical slab gel with a maximum size of 0.75 mm × 14 cm × 14 cm. For thicker gels, or minigels (see Basic Protocol 2 and Support Protocol 5),

BOSTON COLLEGE UNIVERSITY LIBRARY

the volumes of stacking and separating gels and the operating current must be adjusted. Support protocols describe the preparation of ultrathin gels (see Support Protocol 1) and gradient gels (see Support Protocol 3), as well as the use of gel casters to make multiple gels, both single-concentration gels (see Support Protocol 2) and gradient gels (see Support Protocol 4).

Materials

Separating and stacking gel solutions (Table 10.1.1)
H_2O-saturated isobutyl alcohol
1× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table 10.1.1)
Protein sample to be analyzed
2× and 1× SDS sample buffer (see recipe)
Protein molecular-weight-standards mixture (Table 10.1.2)
6× SDS sample buffer (see recipe; optional)
1× SDS electrophoresis buffer (see recipe)

Electrophoresis apparatus: Protean II 16-cm cell (Bio-Rad) or SE 600/400 16-cm unit (Hoefer Pharmacia) with clamps, glass plates, casting stand, and buffer chambers
0.75-mm spacers
0.45-µm filters (used in stock solution preparation)
25-ml Erlenmeyer side-arm flask
Vacuum pump with cold trap
0.75-mm Teflon comb with 1, 3, 5, 10, 15, or 20 teeth
25- or 100-µl syringe with flat-tipped needle
Constant-current power supply (see introduction)

Pour the separating gel

1. Assemble the glass-plate sandwich of the electrophoresis apparatus according to manufacturer's instructions using two clean glass plates and two 0.75-mm spacers.

   If needed, clean the glass plates in liquid Alconox or RBS-35 (Pierce). These aqueous-based solutions are compatible with silver and Coomassie blue staining procedures.

2. Lock the sandwich to the casting stand.

3. Prepare the separating gel solution as directed in Table 10.1.1, degassing using a rubber-stoppered 25-ml Erlenmeyer side-arm flask connected with vacuum tubing to a vacuum pump with a cold trap. After adding the specified amount of 10% ammonium persulfate and TEMED to the degassed solution, stir gently to mix.

   Table 10.1.1 was prepared as a convenient summary to aid in the preparation of separating and stacking gels. The stacking gel is the same regardless of the separating gel used.

   The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. Generally, use 5% gels for SDS-denatured proteins of 60 to 200 kDa, 10% gels for SDS-denatured proteins of 16 to 70 kDa, and 15% gels for SDS-denatured proteins of 12 to 45 kDa (Table 10.1.1).

4. Using a Pasteur pipet, apply separating gel solution to the sandwich along an edge of one of the spacers until the height of the solution between the glass plates is ~11 cm.

   Use the solution immediately; otherwise it will polymerize in the flask.

   Sample volumes <10 µl do not require a stacking gel. In this case, cast the resolving gel as you normally would, but extend the resolving gel into the comb to form the well. The proteins are then separated under the same conditions as used when a stacking gel is present. Although this protocol works well with single-concentration gels, a gradient gel is recommended for maximum resolution (see Alternate Protocol 5).

PGU IASLIC-PEYRA UNIVERSITY LIBRARY

Table 10.1.1 Recipes for Polyacrylamide Separating and Stacking Gels[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in separating gel (%)[c]									
	5	6	7	7.5	8	9	10	12	13	15
30% acrylamide/ 0.8% bisacrylamide	2.50	3.00	3.50	3.75	4.00	4.50	5.00	6.00	6.50	7.50
4× Tris·Cl/SDS, pH 8.8	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.50	7.25	6.75	6.25	5.25	4.75	3.75
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution, 4× Tris·Cl/SDS, pH 8.8 (see reagents, below), and H_2O. Degas under vacuum about 5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

STACKING GEL (*3.9% acrylamide*)

In a 25-ml side-arm flask, mix 0.65 ml of 30% acrylamide/0.8% bisacrylamide, 1.25 ml of 4× Tris·Cl/SDS, pH 6.8 (see reagents, below), and 3.05 ml H_2O. Degas under vacuum 10 to 15 min. Add 25 µl of 10% ammonium persulfate and 5 µl TEMED. Swirl gently to mix. Use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

REAGENTS USED IN GELS

30% acrylamide/0.8% bisacrylamide

Mix 30.0 g acrylamide and 0.8 g *N,N'*-methylenebisacrylamide with H_2O in a total volume of 100 ml. Filter the solution through a 0.45-µm filter and store at 4°C in the dark. The 2× crystallized grades of acrylamide and bisacrylamide are recommended. Discard after 30 days, as acrylamide gradually hydrolyzes to acrylic acid and ammonia.

CAUTION: *Acrylamide monomer is neurotoxic. Mask should be worn when weighing acrylamide powder. Gloves should be worn while handling the solution, and the solution should not be pipetted by mouth.*

4× Tris·Cl/SDS, pH 6.8 (0.5 M Tris·Cl containing 0.4% SDS)

Dissolve 6.05 g Tris base in 40 ml H_2O. Adjust to pH 6.8 with 1 N HCl. Add H_2O to 100 ml total volume. Filter the solution through a 0.45-µm filter, add 0.4 g SDS, and store at 4°C up to 1 month.

4× Tris·Cl/SDS, pH 8.8 (1.5 M Tris·Cl containing 0.4% SDS)

Dissolve 91 g Tris base in 300 ml H_2O. Adjust to pH 8.8 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter, add 2 g SDS, and store at 4°C up to 1 month.

[a]The recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for a gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See annotation to step 3, Basic Protocol 1.
[d]Best to prepare fresh.

RESTRICTED - MSU RETTER UNIVERSITY LIBRARY

5. Using another Pasteur pipet, slowly cover the top of the gel with a layer (~1 cm thick) of H_2O-saturated isobutyl alcohol, by gently layering the isobutyl alcohol against the edge of one and then the other of the spacers.

Be careful not to disturb the gel surface. The overlay provides a barrier to oxygen, which inhibits polymerization, and allows a flat interface to form during gel formation.

The H_2O-saturated isobutyl alcohol is prepared by shaking isobutyl alcohol and H_2O in a separatory funnel. The aqueous (lower) phase is removed. This procedure is repeated several times. The final upper phase is H_2O-saturated isobutyl alcohol.

6. Allow the gel to polymerize 30 to 60 min at room temperature.

A sharp optical discontinuity at the overlay/gel interface will be visible on polymerization. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED (N,N,N′,N′-tetramethylethylenediamine), or both. Ammonium persulfate solution should be made fresh before use. Ammonium persulfate should "crackle" when added to the water. If not, fresh ammonium persulfate should be purchased. Purchase TEMED in small bottles so, if necessary, a new previously unopened source can be tried.

Pour the stacking gel

7. Pour off the layer of H_2O-saturated isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8.

Residual isobutyl alcohol can reduce resolution of the protein bands; therefore, it must be completely removed. The isobutyl alcohol overlay should not be left on the gel longer than 2 hr.

8. Prepare the stacking gel solution as directed in Table 10.1.1.

Use the solution immediately to keep it from polymerizing in the flask.

9. Using a Pasteur pipet, slowly allow the stacking gel solution to trickle into the center of the sandwich along an edge of one of the spacers until the height of the solution in the sandwich is ~1 cm from the top of the plates.

Be careful not to introduce air bubbles into the stacking gel.

10. Insert a 0.75-mm Teflon comb into the layer of stacking gel solution. If necessary, add additional stacking gel to fill the spaces in the comb completely.

Again, be careful not to trap air bubbles in the tooth edges of the comb; they will cause small circular depressions in the well after polymerization that will lead to distortion in the protein bands during separation.

11. Allow the stacking gel solution to polymerize 30 to 45 min at room temperature.

A sharp optical discontinuity will be visible around wells on polymerization.

Prepare the sample and load the gel

12. Dilute a portion of the protein sample to be analyzed 1:1 (v/v) with 2× SDS sample buffer and heat 3 to 5 min at 100°C in a sealed screw-cap microcentrifuge tube. If the sample is a precipitated protein pellet, dissolve the protein in 50 to 100 µl of 1× SDS sample buffer and boil 3 to 5 min at 100°C. Dissolve protein-molecular-weight standards mixture in 1× SDS sample buffer according to supplier's instructions as a control (Table 10.1.2).

For dilute protein solutions, consider adding 5:1 protein solution/6× SDS sample buffer to increase the amount of protein loaded. Proteins can also be concentrated by precipitation in acetone, ethanol, or trichloroacetic acid (TCA), but losses will occur.

RNA polymerase, *E. coli*	160,000
Myosin, heavy chain (rabbit muscle)	205,000

[a]Protein standards are commercially available in kits (e.g., Hoefer Pharmacia Biotech, GIBCO/BRL, Bio-Rad, or Sigma).

For a 0.8-cm-wide well, 25 to 50 μg total protein in <20 μl is recommended for a complex mixture when staining with Coomassie blue, and 1 to 10 μg total protein is needed for samples containing one or a few proteins. If silver staining is used, 10- to 100-fold less protein can be applied (0.01 to 5 μg in <20 μl depending on sample complexity).

To achieve the highest resolution possible, the following precautions are recommended. Prior to adding the sample buffer, keep samples at 0°C. Add the SDS sample buffer (room temperature) directly to the 0°C sample (still on ice) in a screw-top microcentrifuge tube. Cap the tube to prevent evaporation, vortex, and transfer directly to a 100°C water bath for 3 to 5 min. Let immunoprecipitates dissolve for 1 hr at 56°C in 1× SDS sample buffer prior to boiling. DO NOT leave the sample in SDS sample buffer at room temperature without first heating to a 100°C to inactivate proteases (see Critical Parameters and Troubleshooting). Endogenous proteases are very active in SDS sample buffer and will cause severe degradation of the sample proteins after even a few minutes at room temperature. To test for possible proteases, mix the sample with SDS sample buffer without heating and leave at room temperature for 1 to 3 hr. A loss of high-molecular-weight bands and a general smearing of the banding pattern indicate a protease problem. Once heated, the samples can sit at room temperature for the time it takes to load samples.

13. Carefully remove the Teflon comb without tearing the edges of the polyacrylamide wells. After the comb is removed, rinse wells with 1× SDS electrophoresis buffer.

    The rinse removes unpolymerized monomer; otherwise, the monomer will continue to polymerize after the comb is removed, creating uneven wells that will interfere with sample loading and subsequent separation.

14. Using a Pasteur pipet, fill the wells with 1× SDS electrophoresis buffer.

BOURSE CENTRAL UNIVERSITY LIBRARY

If well walls are not upright, they can be manipulated with a flat-tipped needle attached to a syringe.

15. Attach gel sandwich to upper buffer chamber using manufacturer's instructions.
16. Fill lower buffer chamber with the recommended amount of 1× SDS electrophoresis buffer.
17. Place sandwich attached to upper buffer chamber into lower buffer chamber.
18. Partially fill the upper buffer chamber with 1× SDS electrophoresis buffer so that the sample wells of the stacking gel are filled with buffer.

    Monitor the upper buffer chamber for leaks and if necessary, reassemble the unit. A slow leak in the upper buffer chamber may cause arcing around the upper electrode and damage the upper buffer chamber.

19. Using a 25- or 100-µl syringe with a flat-tipped needle, load the protein sample(s) into one or more wells by carefully applying the sample as a thin layer at the bottom of the wells. Load control wells with molecular weight standards. Add an equal volume of 1× SDS sample buffer to any empty wells to prevent spreading of adjoining lanes.

    Preparing the samples at approximately the same concentration and loading an equal volume to each well will ensure that all lanes are the same width and that the proteins run evenly. If unequal volumes of sample buffer are added to wells, the lane with the larger volume will spread during electrophoresis and constrict the adjacent lanes, causing distortions.

    The samples will layer on the bottom of the wells because the glycerol added to the sample buffer gives the solution a greater density than the electrophoresis buffer. The bromphenol blue in the sample buffer makes sample application easy to follow visually.

20. Fill the remainder of the upper buffer chamber with additional 1× SDS electrophoresis buffer so that the upper platinum electrode is completely covered. Do this slowly so that samples are not swept into adjacent wells.

Run the gel

21. Connect the power supply to the cell and run at 10 mA of constant current for a slab gel 0.75 mm thick, until the bromphenol blue tracking dye enters the separating gel. Then increase the current to 15 mA.

    For a standard 16-cm gel sandwich, 4 mA per 0.75-mm-thick gel will run ~15 hr (i.e., overnight); 15 mA per 0.75-mm gel will take 4 to 5 hr. To run two gels or a 1.5-mm-thick gel, simply double the current. When running a 1.5-mm gel at 30 mA, the temperature must be controlled (10° to 20°C) with a circulating constant-temperature water bath to prevent "smiling" (curvature in the migratory band). Temperatures <5°C should not be used because SDS in the running buffer will precipitate. If the level of buffer in the upper chamber decreases, a leak has occurred.

22. After the bromphenol blue tracking dye has reached the bottom of the separating gel, disconnect the power supply.

    See Safety Considerations in the introduction.

Disassemble the gel

23. Discard electrode buffer and remove the upper buffer chamber with the attached gel sandwich.
24. Orient the gel so that the order of the sample wells is known, remove the sandwich from the upper buffer chamber, and lay the sandwich on a sheet of absorbent paper or paper towels.

RCU IASL / KENTRAL UNIVERSITY LIBRARY

25. Carefully slide one of the spacers halfway from the edge of the sandwich along its entire length. Use the exposed spacer as a lever to pry open the glass plate, exposing the gel.

26. Carefully remove the gel from the lower plate. Cut a small triangle off one corner of the gel so the lane orientation is not lost during staining and drying. Proceed with protein detection.

The gel can be stained with Coomassie blue or silver (UNIT 10.5), or proteins can be electroeluted, electroblotted onto a polyvinylidene difluoride (PVDF) membrane for subsequent staining or sequence analysis (UNIT 10.7), or transferred to a membrane for immunoblotting. If the proteins are radiolabeled (UNIT 3.3), they can be detected by autoradiography.

ELECTROPHORESIS IN TRIS-TRICINE BUFFER SYSTEMS

ALTERNATE PROTOCOL 1

Separation of peptides and proteins under 10 to 15 kDa is not possible in the traditional Laemmli discontinuous gel system (Basic Protocol 1). This is due to the comigration of SDS and smaller proteins, obscuring the resolution. Two approaches to obtain the separation of small proteins and peptides in the range of 5 to 20 kDa are presented: this Tris-tricine method that follows and a system using increased buffer concentrations (see Alternate Protocol 2). The Tris-tricine system uses a modified buffer to separate the SDS and peptides, thus improving resolution. Several precast gels are available for use with the tricine formulations (Table 10.1.3).

Additional Materials (also see Basic Protocol 1)

Separating and stacking gel solutions (Table 10.1.4)
2× tricine sample buffer (see recipe)
Peptide molecular-weight-standards mixture (Table 10.1.5)
Cathode buffer (see recipe)
Anode buffer (see recipe)
Coomassie blue G-250 staining solution (see recipe)
10% (v/v) acetic acid

Table 10.1.3 Vertical Format Precast Gel Compatibility

BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

Table 10.1.4 Recipes for Tricine Peptide Separation Gels[a]

SEPARATING AND STACKING GELS

Stock solution[b]	Separating gel	Stacking gel
30% acrylamide/0.8% bisacrylamide	9.80 ml	1.62 ml
Tris·Cl/SDS, pH 8.45	10.00 ml	3.10 ml
H_2O	7.03 ml	7.78 ml
Glycerol	4.00 g (3.17 ml)	—
10% (w/v) ammonium persulfate[c]	50 µl	25 µl
TEMED	10 µl	5 µl

Prepare separating and stacking gel solutions separately.

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (Table 10.1.1), Tris·Cl/SDS, pH 8.45 (see reagents, below), and H_2O. Add glycerol to separating gel only. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix, use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

ADDITIONAL REAGENTS USED IN GELS

Tris·Cl/SDS, pH 8.45 (3.0 M Tris·Cl 0.3% SDS)

Dissolve 182 g Tris base in 300 ml H_2O. Adjust to pH 8.45 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter, add 1.5 g SDS, and store at 4°C up to 1 month.

[a]The recipes produce 30 ml of separating gel and 12.5 ml of stacking gel, which are adequate for two gels of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the Tris-tricine buffer system of Schagger and von Jagow (1987).

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Best to prepare fresh.

1. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 1 to 11), using Table 10.1.4 in place of Table 10.1.1.
2. Prepare the sample (see Basic Protocol 1, step 12), but make the following changes for tricine gels. Substitute 2× tricine sample buffer for the 2× SDS sample buffer. Dilute an aliquot of the protein or peptide sample to be analyzed 1:1 (v/v) with 2× tricine sample buffer. Treat the sample at 40°C for 30 to 60 min prior to loading.

   If proteolytic activity is a problem, heating samples to 100°C for 3 to 5 min before loading the wells may be required (see Basic Protocol 1, annotation to step 12). Use the peptide molecular-weight-standards mixture for peptide separations (Table 10.1.5).
3. Load the gel and set up the electrophoresis apparatus (see Basic Protocol 1, steps 13 to 20) with the following alterations. Remove comb and, using the tricine-containing cathode buffer or water, rinse once and fill wells. Fill the lower buffer chamber with anode buffer, assemble the unit, and attach the upper buffer chamber. Fill the upper buffer chamber with cathode buffer and load the samples.
4. Connect the power supply to the cell and run 1 hr at 30 V (constant voltage) followed by 4 to 5 hr at 150 V (constant voltage). Use heat exchanger to keep the electrophoresis chamber at room temperature.

PGU IASL CENTRAL UNIVERSITY LIBRARY

Table 10.1.5 Molecular Weights of Peptide Standards for Polyacrylamide Gel Electrophoresis[a]

Peptide	Molecular weight
Myoglobin (polypeptide backbone)	16,950
Myoglobin 1-131	14,440
Myoglobin 56-153	10,600
Myoglobin 56-131	8,160
Myoglobin 1-55	6,210
Glucagon	3,480
Myoglobin 132-153	2,510

[a]Peptide standards are commercially available from Sigma.

5. After the tracking dye has reached the bottom of the separating gel, disconnect the power supply.

   See Safety Considerations in the introduction.

   Coomassie blue G-250 is used as a tracking dye instead of bromphenol blue because it moves ahead of the smallest peptides.

6. Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Stain proteins in the gel for 1 to 2 hr in Coomassie blue G-250 staining solution. Follow by destaining with 10% acetic acid, changing the solution every 30 min until background is clear (3 to 5 changes). For higher sensitivity, use silver staining as a recommended alternative (*UNIT 10.5*).

   Prolonged staining and destaining will result in the loss of resolution of the smaller proteins (<10 kDa). Proteins diffuse within the gel and out of the gel, resulting in a loss of staining intensity and resolution.

NONUREA PEPTIDE SEPARATIONS WITH TRIS BUFFERS

ALTERNATE PROTOCOL 2

A simple modification of the traditional Laemmli buffer system presented in Basic Protocol 1, in which the increased concentration of buffers provides better separation between the stacked peptides and the SDS micelles, permits reasonable separation of peptides as small as 5 kDa.

Additional Materials (also see Basic Protocol 1)

Separating and stacking gel solutions (Table 10.1.6)
2× SDS electrophoresis buffer (see recipe)
2× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table 10.1.1)

1. Prepare and pour the separating gel (see Basic Protocol 1, steps 1 to 6) using Table 10.1.6 in place of Table 10.1.1.

2. Prepare and pour the stacking gel (see Basic Protocol 1, steps 7 to 11), using 2× Tris·Cl/SDS, pH 8.8, rather than 1× Tris·Cl/SDS buffer, for rinsing the gel after removing the isobutyl alcohol overlay.

3. Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20) and substitute 2× SDS electrophoresis buffer for the 1× SDS electrophoresis buffer.

   Table 10.1.5 lists the standards for small protein separations.

BOURNS / CENTRAL UNIVERSITY LIBRARY

Table 10.1.6 Recipes for Modified Laemmli Peptide Separation Gels[a]

SEPARATING AND STACKING GELS

Stock solution[b]	Separating gel	Stacking gel
30% acrylamide/0.8% bisacrylamide	10.00 ml	0.65 ml
8× Tris·Cl, pH 8.8	3.75 ml	—
4× Tris·Cl, pH 6.8	—	1.25 ml
10% (w/v) SDS	0.15 ml	50 µl
H_2O	1.00 ml	3.00 ml
10% (w/v) ammonium persulfate[c]	50 µl	25 µl
TEMED	10 µl	5 µl

Prepare separating and stacking gel solutions separately.

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.1.1), 8× Tris·Cl, pH 8.8 (separating gel) or 4× Tris·Cl, pH 6.8 (stacking gel), 10% SDS (see reagents, below), and H_2O. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix; use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

ADDITIONAL REAGENTS USED IN GELS

4× Tris·Cl, pH 6.8 (0.5 M Tris·Cl)

Dissolve 6.05 g Tris base in 40 ml H_2O. Adjust to pH 6.8 with 1 N HCl. Add H_2O to 100 ml total volume. Filter the solution through a 0.45-µm filter and store at 4°C up to 1 month.

8× Tris·Cl, pH 8.8 (3.0 M Tris·Cl)

Dissolve 182 g Tris base in 300 ml H_2O. Adjust to pH 8.8 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter and store at 4°C up to 1 month.

10% (w/v) SDS

Mix 1 g SDS in 10 ml of H_2O. Use immediately.

[a]The recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the modified Laemmli peptide separation system of Okajima et al. (1993).

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Best to prepare fresh.

4. Run the gel (see Basic Protocol 1, steps 21 and 22).

Note that the separations will take ~25% longer than those using Basic Protocol 1. The increased buffer concentrations lead to faster transit through the stacking gel but lower mobility in the resolving gel.

5. Disassemble the gel (see Basic Protocol 1, steps 23 to 26).

If Coomassie blue staining is used, stain using the solutions outlined in UNIT 10.5 for 1 hr followed by destaining with several changes of 25% methanol/7% acetic acid. Prolonged staining will result in the loss of the smaller proteins.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

CONTINUOUS SDS-PAGE

With continuous SDS-PAGE, the same buffer is used for both the gel and electrode solutions. Although continuous gels lack the resolution of the discontinuous systems, they are extremely versatile, less prone to mobility artifacts, and much easier to prepare. The stacking gel is omitted.

Additional Materials (also see Basic Protocol 1)

Separating gel solution (Table 10.1.7)
2× and 1× phosphate/SDS sample buffer (see recipe)
1× phosphate/SDS electrophoresis buffer (see recipe)

1. Prepare and pour a single separating gel (see Basic Protocol 1, steps 1 to 4), except use solutions in Table 10.1.7 in place of those in Table 10.1.1 and fill the gel sandwich to the top. Omit the stacking gel. Insert the comb (see Basic Protocol 1, step 10) and allow the gel to polymerize 30 to 60 min at room temperature.

Table 10.1.7 Recipes for Separating Gels for Continuous SDS-PAGE[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in separating gel (%)[c]										
	5	6	7	8	9	10	11	12	13	14	15
30% acrylamide/ 0.8% bisacrylamide	2.5	3.00	3.50	4.00	4.50	5.00	5.50	6.00	6.50	7.00	7.50
4× phosphate/SDS, pH 7.2	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.25	6.75	6.25	5.75	5.25	4.75	4.25	3.75
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.1.1), 4× phosphate/SDS, pH 7.2, and H_2O. Degas under vacuum about 5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

ADDITIONAL REAGENTS USED IN GELS

4× phosphate/SDS, pH 7.2 (0.4 M sodium phosphate/0.4% SDS)

Mix 46.8 g $NaH_2PO_4 \cdot H_2O$, 231.6 g $Na_2HPO_4 \cdot 7\ H_2O$, and 12 g SDS in 3 liters H_2O.

Store at 4°C for up to 3 months.

[a]The recipes produce 15 ml of separating gel, which is adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the original continuous phosphate buffer system of Weber et al. (1972). The stacking gel is omitted.

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See Basic Protocol 1, annotation to step 3.

[d]Best to prepare fresh.

BOSTON CENTRAL UNIVERSITY LIBRARY

2. Mix the protein sample 1:1 with 2× phosphate/SDS sample buffer and heat to 100°C for 2 min.

   For large sample volumes or samples suspended in high ionic strength buffers (>50 mM), dialyze against 1× sample buffer prior to electrophoresis. Note that the precautions about proteases (see Basic Protocol 1, step 12) apply here.

3. Assemble the electrophoresis apparatus and load the sample (see Basic Protocol 1, steps 13 to 20), using the phosphate/SDS electrophoresis buffer and loading empty wells with 1× phosphate/SDS sample buffer.

4. Connect the power supply and start the run with 15 mA per 0.75-mm-thick gel until the tracking dye has entered the gel. Continue electrophoresis at 30 mA for 3 hr (5% gel), 5 hr (10% gel), 8 hr (15% gel), or until the dye reaches the bottom of the gel.

   Use temperature control if available to maintain the gel at 15° to 20°C. SDS will precipitate below 15°C in this system.

5. Disassemble the gel (see Basic Protocol 1, steps 23 to 26).

   Proteins in the gel may be stained using the protocols given in UNIT 10.5.

ALTERNATE PROTOCOL 4

CASTING AND RUNNING ULTRATHIN GELS

Ultrathin gels provide superb resolution but are difficult to handle. In this application, gels are cast on Gel Bond, a Mylar support material. Silver staining is recommended for the best resolution. Combs and spacers for gels <0.5 mm thick are not readily available for most protein electrophoresis units. However, by adapting combs and spacers used for DNA sequencing, casting gels from 0.2 to 0.5 mm thick is straightforward.

Additional Materials *(also see Basic Protocol 1)*

95% (v/v) ethanol
Gel Bond (FMC) cut to a size slightly smaller than the gel plate dimensions
Glue stick
Ink roller (available from art supply stores)
Combs and spacers (0.19 to 0.5 mm; sequencing gel spacers and combs can be cut to fit)

1. Wash gel plates with water-based laboratory detergent followed by successive rinses with hot tap water, deionized water, and finally 95% ethanol. Allow to air dry.

   Gel plates must be extremely clean for casting thin gels.

2. Apply a streak of adhesive from a glue stick to the bottom edge of the glass plate. Quickly position the Gel Bond with the hydrophobic side down (a drop of water will bead up on the hydrophobic surface). Apply pressure with Kimwipe tissue to attach the Gel Bond firmly to the plate. Last, pull the top portion of the Gel Bond back, place a few drops of water underneath, and roll flat with an ink roller.

   Make sure the Gel Bond does not extend beyond the edges of the upper and lower sealing surface of the plate. This will cause it to buckle on sealing. Reposition the Gel Bond if needed to prevent it from extending beyond the glass plate. Material may also be trimmed to fit flush with the plate edge.

3. Assemble the gel cassette according to the manufacturer's instructions (also see Basic Protocol 1, steps 1 and 2). Just prior to assembly, blow air over the surface of both the Gel Bond and the opposing glass surface to remove any particulate material (e.g., dust).

   Sequencing gel spacers can be easily adapted. First, cut the spacers slightly longer

RCU IASH CENTRAL UNIVERSITY LIBRARY

than the length of the gel plate. Position a spacer along each edge of the glass plate and assemble the gel sandwich, clamping in place. With a razor blade, trim the excess spacer at top and bottom to get a reusable spacer exactly the size of the plate.

4. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 3 to 9). In place of the Teflon comb, insert a square well sequencing comb cut to fit within the gel sandwich. Allow the stacking gel to polymerize 30 to 45 min at room temperature.

   Less solution is needed for ultrathin gels. For example, a 0.5-mm-thick gel requires 33% less gel solution than a 0.75-mm gel.

5. Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20).

   When preparing protein samples for ultrathin gels, 3 to 4 µl at 5 µg protein/µl is required for Coomassie blue R-250 staining, whereas 10-fold less is needed for silver staining.

6. Run the gel (see Basic Protocol 1, steps 21 and 22), except conduct the electrophoresis at 7 mA/gel (0.25-mm-thick gels) or 14 mA/gel (0.5-mm-thick gels) for 4 to 5 hr.

7. When the separation is complete, disassemble the unit and remove the gel (see Basic Protocol 1, steps 23 to 26). With a gloved hand, wash away the adhesive material under a stream of water before proceeding to protein detection.

   Either Coomassie blue or silver staining (UNIT 10.5) may be used, but silver staining produces particularly fine resolution with thin Gel Bond–backed gels. Compared to staining thicker (>0.75 mm) gels, thin (<0.75 mm) gels stain and destain more quickly. Although the optimum staining times must be empirically determined, all steps in Coomassie blue and silver staining procedures are generally reduced by half.

   Gloves are needed throughout these procedures to prevent contamination by proteins on the surface of skin.

CASTING MULTIPLE SINGLE-CONCENTRATION GELS

SUPPORT PROTOCOL 1

Casting multiple gels at one time has several advantages. All the gels are identical, so sample separation is not affected by gel-to-gel variation. Furthermore, casting ten gels is only slightly more difficult than casting two gels. Once cast, gels can be stored for several days in a refrigerator.

Additional Materials (also see Basic Protocol 1)

Separating and stacking gels for single-concentration gels (Table 10.1.8)
H_2O-saturated isobutyl alcohol

Multiple gel caster (Bio-Rad, Hoefer Pharmacia)
Extra plates and spacers
14 × 14–cm acrylic blocks or polycarbonate sheets
250- and 500-ml side-arm flasks (used in gel preparation)
Long razor blade *or* plastic wedge (Wonder Wedge, Hoefer Pharmacia)
Resealable plastic bags

Pour the separating gel

1. Assemble the multiple gel caster according to the manufacturer's instructions.

   With the Hoefer Pharmacia unit make sure to insert the large triangular space filler plug in the base of the caster. The plug is removed when casting gradient gels (see Support Protocol 2).

2. Assemble glass sandwiches and stack them in the casting chamber. Stack up to ten

BCU ARTS CENTRAL UNIVERSITY LIBRARY

Table 10.1.8 Recipes for Multiple Single-Concentration Polyacrylamide Gels[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in separating gel (%)[c]										
	5	6	7	8	9	10	11	12	13	14	15
30% acrylamide/ 0.8% bisacrylamide	52	62	72	83	93	103	114	124	134	145	155
4× Tris·Cl/SDS, pH 8.8	78	78	78	78	78	78	78	78	78	78	78
H_2O	181	171	160	150	140	129	119	109	98	88	78
10% (w/v) ammonium persulfate[d]	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
TEMED	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21

Preparation of separating gel

In a 500-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.1.1), 4× Tris·Cl/SDS, pH 8.8 (Table 10.1.1), and H_2O. Degas under vacuum about 5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix; use immediately.

STACKING GEL

In a 250-ml side-arm flask, mix 13.0 ml 30% acrylamide/0.8% bisacrylamide solution, 25 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.1.1), and 61 ml H_2O. Degas under vacuum about 5 min. Add 0.25 ml 10% ammonium persulfate and 50 µl TEMED. Swirl gently to mix. Use immediately. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

[a]The recipes produce about 300 ml of separating gel and 100 ml of stacking gel, which are adequate for ten gels of dimensions 1.5 mm × 14 cm × 14 cm. Volumes were measured using 1.5-mm spacers (or fewer gels). For thinner spacers or fewer gels, calculate volumes using the equation in the annotation to step 4. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in separating gel depends on the molecular size of the protein being separated. See Basic Protocol 1, annotation to step 3.

[d]Best to prepare fresh.

1.5-mm gels and fill in extra space with acrylic blocks or polycarbonate sheets to hold the sandwiches tightly in place. Make sure the spacers are straight along the top, right, and left edges of the glass plates and that all edges of the stack are flush.

The presence of loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis. Polycarbonate inhibits gel polymerization. Therefore, if polycarbonate sheets are placed in the caster before and after the set of glass sandwiches, the entire set will slide out as one block after polymerization. Placing polycarbonate sheets between each gel sandwich makes them easier to separate from one another after polymerization.

3. Place the front sealing plate on the casting chamber, making sure the stack fits snugly. Secure the plate with four spring clamps and tighten the bottom thumb screws.

4. Prepare the separating (resolving) gel solution (Table 10.1.8).

A 12-cm separating gel with a 4-cm stacking gel is recommended.

If fewer than ten gels are prepared (Table 10.1.8), use the following formula to estimate the amount of separating gel volume needed: Volume = gel number × height (cm) × width (cm) × thickness (cm) + 4 × gel number + 10 ml.

PCU IASLIC CENTRAL UNIVERSITY LIBRARY

5. Using a 100-ml disposable syringe with flat-tipped needle, inject the resolving gel solution down the side of one spacer into the multiple caster. A channel in the silicone plug distributes the solution throughout the whole caster. Avoid introducing bubbles by giving the caster a quick tap on the benchtop once the caster is filled.
6. Overlay the center of each gel with 100 µl H_2O-saturated isobutyl alcohol and let polymerize for 1 to 2 hr.
7. Drain off the overlay and rinse the surface with 1× Tris·Cl/SDS, pH 8.8. If the gels will not be used immediately, skip to step 12.

Pour the stacking gel

8. Prepare the stacking gel solution either singly (see Basic Protocol 1, step 8) or for all the gels at once (Table 10.1.8).

   The stacking gel solution should be prepared just before pouring the gel.

9. Fill each sandwich in the caster with stacking gel solution.
10. Insert a comb into each sandwich and let the gel polymerize for 2 hr.

    Insert the combs at a 45° angle to avoid trapping air underneath the comb teeth. Air bubbles will inhibit polymerization and cause dents in the wells and a distorted pattern of protein bands.

11. Remove the combs and rinse wells with 1× SDS electrophoresis buffer.

Remove the gels from the caster

12. Remove the gels from the caster and separate by carefully inserting a long razor blade or knife between each gel sandwich. A plastic wedge (Hoefer Pharmacia's Wonder Wedge) also works well.
13. Clean the outside of each gel plate with running water to remove the residual polymerized and unpolymerized acrylamide.
14. Overlay gels to be stored with 1× Tris·Cl/SDS, pH 8.8, place in a resealable plastic bag, and store at 4°C until needed (up to 1 week).

SEPARATION OF PROTEINS ON GRADIENT GELS

ALTERNATE PROTOCOL 5

Gels that consist of a gradient of increasing polyacrylamide concentration resolve a much wider size range of proteins than standard uniform concentration gels (see Critical Parameters and Troubleshooting). The protein bands, particularly in the low-molecular-weight range, are also much sharper. Unlike single-concentration gels, gradient gels separate proteins in a way that can be plotted easily to give a linear curve from 10 to 200 kDa. This facilitates molecular weight estimations.

The quantities given below provide separating gel solution sufficient for two 0.75-mm gels (~7 ml of each concentration) or one 1.5-mm gel (~14 ml of each concentration). Volumes can be adjusted to accommodate gel sandwiches of different dimensions.

Additional Materials (also see Basic Protocol 1)

Light and heavy acrylamide gel solutions (Table 10.1.9 and Table 10.1.10)
Bromphenol blue (optional; for checking practice gradient)
TEMED

Gradient maker (30 to 50 ml, Hoefer Pharmacia SG30 or SG50; *or* 30 to 100 ml, Bio-Rad 385)
Tygon tubing with micropipet tip

BCU PSI CENTRAL UNIVERSITY LIBRARY

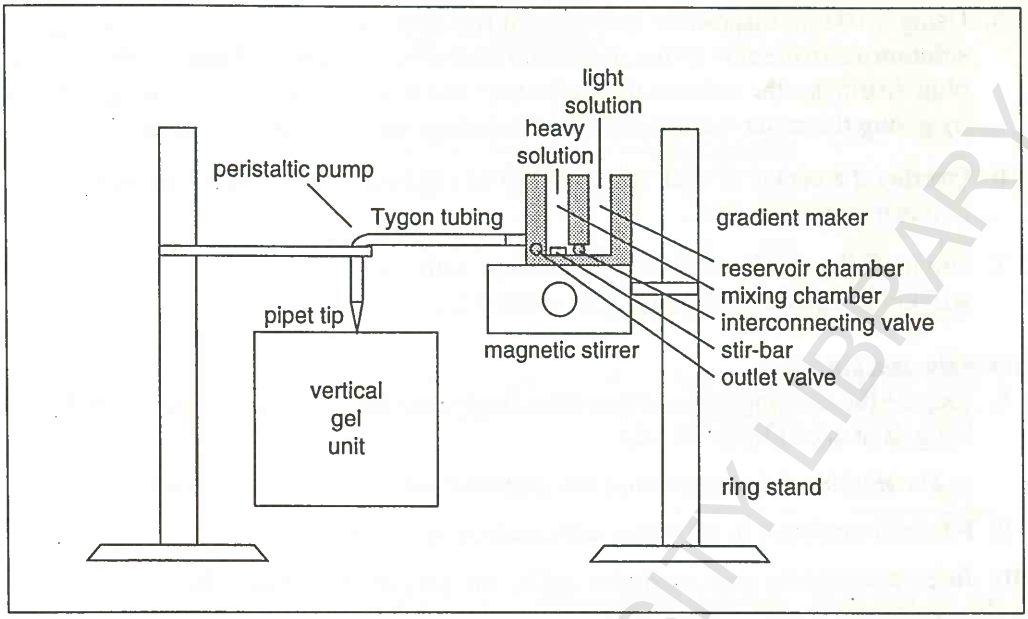

Figure 10.1.2 Gradient gel setup. A peristaltic pump, though not required, will provide better control.

Peristaltic pump (optional; Markson A-13002, A-34040, or A-34105 minipump)
Whatman 3MM filter paper

Set up the gradient maker and prepare the gel solutions

1. Assemble the magnetic stirrer and gradient maker on a ring stand as shown in Figure 10.1.2. Connect the outlet valve of the gradient maker to Tygon tubing attached to a micropipet tip that is placed over the vertical gel sandwich. If desired, place a peristaltic pump in line between the gradient maker and the gel sandwich.

   A peristaltic pump will simplify casting by providing a smooth flow rate.

2. Place a small stir-bar into the mixing chamber of the gradient maker (i.e., the chamber connected to the outlet).

3. Using the recipes in Table 10.1.9 and Table 10.1.10, prepare light and heavy acrylamide gel solutions. Do not add ammonium persulfate until just before use (step 7).

4. With the outlet port and interconnecting valve between the two chambers closed, pipet 7 ml of light (low-concentration) acrylamide gel solution into the reservoir chamber for one 0.75-mm-thick gradient gel.

   Recommended gradient ranges are 5% to 20% for most applications (to separate proteins of 10 to several hundred kilodaltons).

   A practice run with heavy and light solutions is recommended. Bromphenol blue should be added to the heavy solution to demonstrate linearity of the practice gradient.

5. Open the interconnecting valve briefly to allow a small amount (~200 µl) of light solution to flow through the valve and into the mixing chamber.

   The presence of air bubbles in the interconnecting valve may obstruct the flow between chambers during casting.

   Deaeration is not recommended for either the light or heavy solution. Omitting the deaeration will allow polymerization to proceed more slowly, letting the gradient establish itself in the gel sandwich before polymerization takes place.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Table 10.1.9 Light Acrylamide Gel Solutions for Gradient Gels[a]

Stock solution	Acrylamide concentration of light gel solution (%)[b]									
	5	6	7	8	9	10	11	12	13	14
30% acrylamide/ 0.8% bisacrylamide[c]	2.5	3.0	3.5	4.0	4.5	5.0	5.5	6.0	6.5	7.0
4× Tris·Cl/SDS, pH 8.8[c]	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.25	6.75	6.25	5.75	5.25	4.75	4.25
10% (w/v) ammonium persulfate	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05

[a]To survey proteins ≥10 kDa, 5-20% gradient gels are recommended. To expand the range between 10 and 200 kD, a 10-20% gel is recommended.

[b]Numbers in body of table are milliliters of stock solution. Deaeration is not required. Keep solution at room temperature prior to adding TEMED no longer than 1 hr.

[c]See Table 10.1.1 for preparation.

Table 10.1.10 Heavy Acrylamide Gel Solutions for Gradient Gels[a]

Stock solution	Acrylamide concentration of heavy gel solution (%)[b]										
	10	11	12	13	14	15	16	17	18	19	20
30% acrylamide/ 0.8% bisacrylamide[c]	5.0	5.5	6.0	6.5	7.0	7.5	8.0	8.5	9.0	9.5	10.0
4× Tris·Cl/SDS, pH 8.8[c]	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	5.0	4.5	4.0	3.5	3.0	2.5	2.0	1.5	1.0	0.5	0
Sucrose (g)	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25
10% (w/v) ammonium persulfate[b]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05

[a]Deaeration is not recommended for gradient gels.

[b]Numbers in body of table are milliliters of stock solution (except sucrose). Do not add the ammonium persulfate until just before use. The heavy acrylamide will polymerize, albeit more slowly, without the addition of TEMED. Keep the heavy solution on ice after adding ammonium persulfate.

[c]See Table 10.1.1 for preparation.

6. Add 7 ml of heavy (high-concentration) acrylamide gel solution to the mixing chamber.

   Keep the heavy solution on ice until use. Once the ammonium persulfate is added to the heavy solution, it will polymerize without TEMED, albeit more slowly; keeping the solution on ice prevents this. The gel solution will come to room temperature during casting. The higher the percentage of acrylamide, the more severe the problem of premature polymerization is.

7. Add specified amount of ammonium persulfate and ~2.3 µl TEMED per 7 ml acrylamide solution to each chamber. Mix the solutions in each chamber with a disposable pipet.

Form the gradient and cast the gel

8. Open the interconnecting valve completely.

   Some of the heavy solution will flow back into the reservoir chamber containing light solution as the two chambers equilibrate. This will not affect the formation of the gradient.

BOJAN CENTRAL UNIVERSITY LIBRARY

9. Turn on the magnetic stirrer and adjust the rate to produce a slight vortex in the mixing chamber.

10. Open the outlet of the gradient maker slowly. Adjust the outlet valve to a flow rate of 2 ml/min. If using a peristaltic pump, calibrate the flow rate with a graduated cylinder prior to casting the gel.

    Some adjustment of the flow rate may be necessary during casting. If the light solution is not flowing into the mixing chamber, a bubble may be caught in the interconnecting valve. Quickly close the outlet and cover the top of the reservoir chamber with a gloved thumb. Push down with the thumb to increase the pressure in the chamber and force the air bubble out of the center valve.

11. Fill the gel sandwich from the top. Place the pipet tip against one side of the sandwich so the solution flows down one plate only. The heavy solution will flow into the sandwich first, followed by progressively lighter solution.

12. Watch as the last of the light solution drains into the outlet tube and adjust the flow rate to ensure that the last few milliliters of solution do not flow quickly into the gel sandwich and disturb the gradient.

13. Overlay the gradient gel with H_2O-saturated isobutyl alcohol. Allow the gel to polymerize ~1 hr.

    In this gel system, the gel will polymerize from the bottom (i.e., heavy solution) up. Because polymerization is an exothermic reaction, heat can be felt evolving from the bottom of the gel sandwich during polymerization. A sharp optical discontinuity at the gel-overlay interface indicates that polymerization has occurred. In general, 1 hr is adequate for polymerization.

14. Remove the H_2O-saturated isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8. Cast the stacking gel (see Basic Protocol 1, steps 8 to 11).

    The gel can be covered with 1× Tris·Cl/SDS, pH 8.8, sealed in a plastic bag, and stored for up to 1 week.

Load and run the gel

15. Prepare the protein sample and protein molecular-weight-standards mixture (see Basic Protocol 1, steps 13 to 26). Load and run the gel.

    The gel can be stained with Coomassie blue or silver (UNIT 10.5).

16. After staining, dry the gels onto Whatman 3MM or equivalent filter paper.

    Gradient gels >0.75 mm thick require special handling during drying to prevent cracking. The simplest approach to drying gradient gels is to use thin gels; ≤0.75-mm gradient gels with ≤20% acrylamide solutions will dry without cracking as long as the vacuum pump is working properly and the cold trap is dry at the onset of drying. For gradient gels >0.75 mm thick, add 3% (w/v) glycerol to the final destaining solution to help prevent cracking. Another method is to dehydrate and shrink the gel in 30% methanol for up to 3 hr prior to drying. Then place the gel in distilled (Milli-Q-purified or equivalent) water for 5 min before drying.

PGU IASI / CENTRAL UNIVERSITY LIBRARY

CASTING MULTIPLE GRADIENT GELS

Casting gradient gels in a multiple gel caster has several advantages. In addition to the time savings, batch casting gives gels that are essentially identical. This is particularly important for gradient gels, where slight variations in casting technique can cause variations in protein mobility. The gels may be stored for up to 1 week after casting to ensure internal consistency from run to run during the week. Furthermore, gels with several ranges of concentrations (e.g., 5% to 20% and 10% to 20% acrylamide) can be cast and stored, giving much more flexibility to optimize separations.

Additional Materials (also see Alternate Protocol 5)

Plug solution (see recipe)
Light and heavy acrylamide gel solutions for multiple gradient gels (Table 10.1.11 and Table 10.1.12)
TEMED
H_2O-saturated isobutyl alcohol

Multiple gel caster (Bio-Rad, Hoefer Pharmacia)
Peristaltic pump (25 ml/min)
500- or 1000-ml gradient maker (Bio-Rad, Hoefer Pharmacia)
Tygon tubing

Set up system and pour separating gel

1. Assemble the multiple caster as in casting multiple single-concentration gels (see Support Protocol 1, steps 1 to 3), making sure to remove the triangular space filler plugs in the bottom of the caster.

   The plug is used only when casting single-concentration gels.

2. Set up the peristaltic pump (Fig. 10.1.3). Using a graduated cylinder and water, adjust the flow rate so that the volume of the gradient solution plus volume of plug solution is poured in ~15 to 18 min (~25 ml/min).

3. Set up the gradient maker. Close all valves and place a stir-bar in the mixing chamber, which is the one with the outlet port. Attach one end of a piece of Tygon tubing to the outlet of the gradient maker. Run the other end of the tubing through the peristaltic pump and attach it to the red inlet port at the bottom of the caster.

   Choose a gradient maker that holds no more than four times the total volume of the gradient solution to be poured (i.e., a 1000- or 500-ml gradient maker).

4. Prepare solutions for the gradient maker (Table 10.1.11 and Table 10.1.12).

5. Add the TEMED to both heavy and light solutions (54 µl/165 ml) and immediately pour the light (low concentration) solution into the mixing chamber (the one with the port). Open the mixing valve slightly to allow the tunnel to fill and to avoid air bubbles. Close the valve again and pour the heavy (high-concentration) acrylamide solution into the reservoir chamber.

6. Start the magnetic stirrer and open the outlet valve; then start the pump and open the mixing valve.

   In units for casting multiple gels, acrylamide solution flows in from the bottom. To use a multiple casting unit, the light solution is placed in the mixing chamber and the heavy in the reservoir. This is the reverse of casting a single gel (see Alternate Protocol 5). Thus, light solution enters the multiple caster first, followed by progressively heavier solution. Finally, the acrylamide solution is stabilized in the multiple caster with a

BCU INSTITUTE CENTRAL UNIVERSITY LIBRARY

Table 10.1.11 Light Acrylamide Gel Solutions for Multiple Gradient Gels[a,b]

Stock solution	Acrylamide concentration of light separating gel solution (%)[c]									
	5	6	7	8	9	10	11	12	13	14
30% acrylamide/0.8% bisacrylamide[d]	28	33	39	44	50	55	61	66	72	77
4× Tris·Cl/SDS, pH 8.8[d]	41	41	41	41	41	41	41	41	41	41
H_2O	96	91	85	80	74	69	63	58	52	47
10% (w/v) ammonium persulfate	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55

[a]To survey proteins ≥10 kDa, 5-20% gradient gels are recommended. To expand the range between 10 and 200 kDa, a 10-20% gel is recommended.

[b]Recipes produce ten 1.5-mm-thick gradient gels with 10 ml extra solution to account for losses in tubing.

[c]Numbers in body of table are milliliters of stock solution. Deaeration is not required. Keep solution at room temperature prior to adding TEMED no longer than 1 hr.

[d]See Table 10.1.1 for preparation.

heavy plug solution and allowed to polymerize (see step 8 and manufacturer's instructions).

7. When almost all the acrylamide solution is gone from the gradient maker, stop the pump and close the mixing valve. Tilt the gradient maker toward the outlet side and remove the last milliliters of the mix. Do not allow air bubbles to enter the tubing.

8. Add the plug solution to the mixing chamber and start the pump. Make sure that no bubbles are introduced. Continue pumping until the bottom of the caster is filled with plug solution to just below the glass plates; then turn off the pump. Clamp the tubing close to the red port of the casting chamber.

9. Quickly overlay each separate gel sandwich with 100 µl H_2O-saturated isobutyl alcohol. Use the same amount on each sandwich.

   Failure to use the same amount of overlay solution will cause the gel sandwiches to polymerize at different heights.

10. Drain off the overlay and rinse the surface of the gels with 1× Tris·Cl/SDS, pH 8.8.

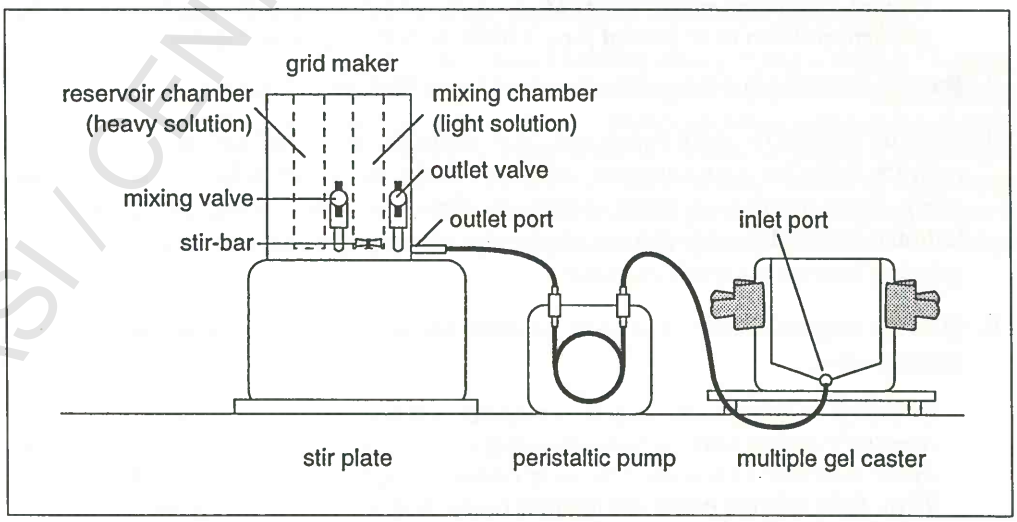

Figure 10.1.3 Setup for casting multiple gradient gels. Casting multiple gradient gels requires a peristaltic pump and a multiple gel caster. Gel solution is introduced through the bottom of the multiple caster.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

Table 10.1.12 Heavy Acrylamide Gel Solutions for Multiple Gradient Gels[a,b]

Stock solution	Acrylamide concentration of heavy gel solution (%)[c]										
	10	11	12	13	14	15	16	17	18	19	20
30% acrylamide/0.8% bisacrylamide[d]	55	61	66	72	77	83	88	94	99	105	110
4× Tris·Cl/SDS pH 8.8[d]	41	41	41	41	41	41	41	41	41	41	41
H_2O	55	50	44	39	33	28	22	17	11	5.5	0
Sucrose (g)	25	25	25	25	25	25	25	25	25	25	25
10% (w/v) ammonium persulfate	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55

[a]Deaeration is not recommended for gradient gels.

[b]Recipes produce 10 ml extra solution to account for losses in tubing.

[c]Numbers in body of table are milliliters of stock solution (except sucrose). Do not add the ammonium persulfate until just before use. The heavy acrylamide will polymerize, albeit more slowly, without the addition of TEMED. Keep the heavy solution on ice after adding ammonium persulfate.

[d]See Table 10.1.1 for preparation.

Pour stacking gel and remove gels from caster

11. Prepare and cast the stacking gel as in casting multiple single-concentration gels (see Support Protocol 1, steps 8 to 11).

12. Remove gels from the caster and clean the gel sandwiches (see Support Protocol 1, steps 12 and 13). Store gels, if necessary, according to the instructions for multiple single-concentration gels (see Support Protocol 1, step 14).

ELECTROPHORESIS IN SINGLE-CONCENTRATION MINIGELS

BASIC PROTOCOL 2

Separation of proteins in a small-gel format is becoming increasingly popular for applications that range from isolating material for peptide sequencing to performing routine protein separations. The unique combination of speed and high resolution is the foremost advantage of small gels. Additionally, small gels are easily adapted to single-concentration, gradient, and two-dimensional SDS-PAGE procedures. The minigel procedures described are adaptations of larger gel systems.

This protocol describes the use of a multiple gel caster. The caster is simple to use, and up to five gels can be prepared at one time with this procedure. Single gels can be prepared using adaptations in the manufacturer's instructions. A multiple gel caster is the only practical way to produce small linear polyacrylamide gradient gels (see Support Protocol 3).

Materials

Minigel vertical gel unit (Hoefer Pharmacia Mighty Small SE 250/280 *or* Bio-Rad Mini-Protean II) with glass plates, clamps, and buffer chambers
0.75-mm spacers
Multiple gel caster (Hoefer Pharmacia SE-275/295 *or* Bio-Rad Mini-Protean II multicasting chamber)
Acrylic plate (Hoefer Pharmacia SE-217 *or* Bio-Rad 165-1957) or polycarbonate separation sheet (Hoefer Pharmacia SE-213 *or* Bio-Rad 165-1958)
10- and 50-ml syringes
Combs (Teflon, Hoefer Pharmacia SE-211A series or Bio-Rad Mini-Protean II)
Long razor blade
Micropipet

BOYNTON / CENTRAL UNIVERSITY LIBRARY

Additional reagents and equipment for standard denaturing SDS-PAGE (see Basic Protocol 1)

Pour the separating gel

1. Assemble each gel sandwich by stacking, in order, the notched (Hoefer Pharmacia) or small rectangular (Bio-Rad) plate, 0.75-mm spacers, and the larger rectangular plate. Be sure to align the spacers properly with the ends flush with the top and bottom edge of the two plates when positioning the sandwiches in the multiple gel caster (Fig. 10.1.4).

   The protocol described is basically for the Hoefer Pharmacia system. For other systems, make adjustments according to the manufacturer's instructions. Alternatively, precast minigels can be purchased from a number of suppliers (see Table 10.1.3).

   The multiple casters from Hoefer Pharmacia have a notch in the base designed for casting gradient gels. A silicone rubber insert fills up this space when casting single-concentration gels. The Hoefer Pharmacia spacers are T-shaped to prevent slipping. The flanged edge of the spacer must be positioned against the outside edge of the glass plate. Placing a sheet of wax paper between the gel sandwiches will help separate the sandwiches after polymerization.

2. Fit the gel sandwiches tightly in the multiple gel caster. Use an acrylic plate or polycarbonate separation sheet to eliminate any slack in the chamber.

   Loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis.

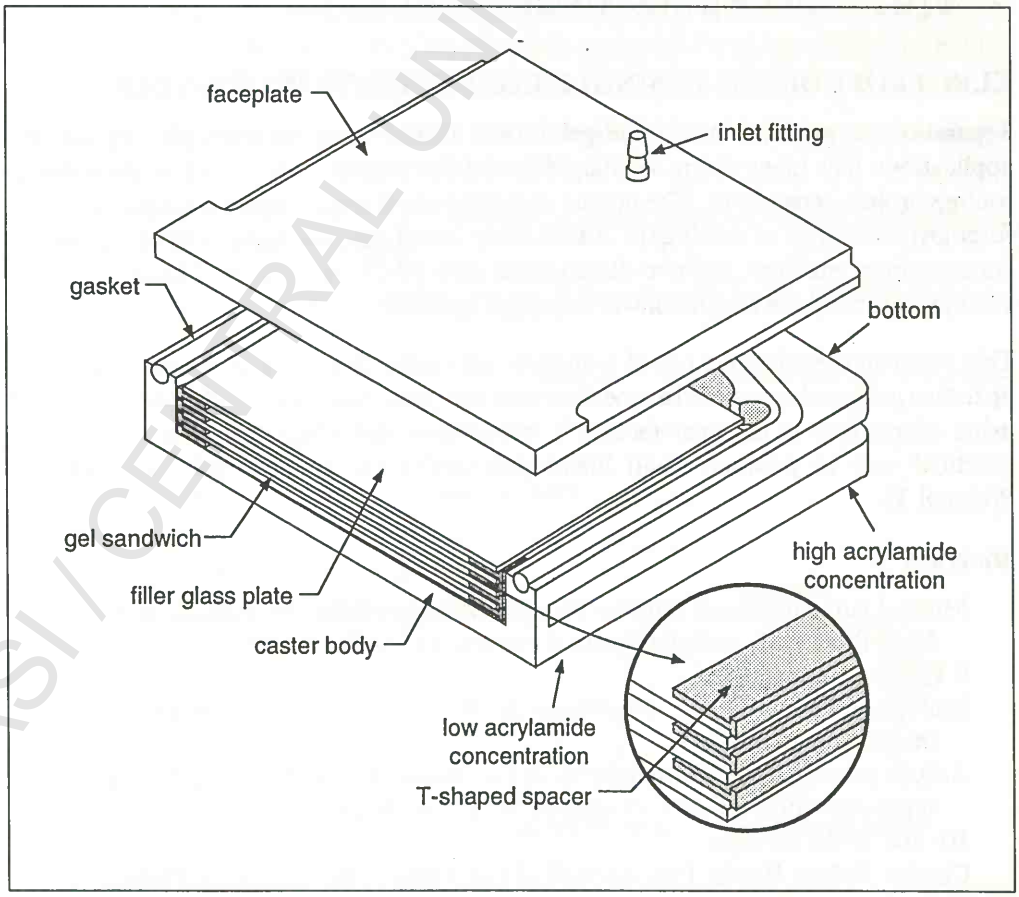

Figure 10.1.4 Minigel sandwiches positioned in the multiple gel caster. Extra glass or acrylic plates or polycarbonate sheets are used to fill any free space in the caster and to ensure that the gel sandwiches are held firmly in place.

ACU IASI / CENTRAL UNIVERSITY LIBRARY

3. Place the front faceplate on the caster, clamp it in place against the silicone gasket, and verify alignment of the glass plates and spacers.

4. Prepare the separating gel solution as directed in Table 10.1.1. For five 0.75-mm-thick gels, prepare ~30 ml solution (i.e., double the volumes listed).

   To compute the total gel volume needed, multiply the area of the gel (e.g., 7.3 × 8.3 cm) by the thickness of the gel (e.g., 0.75 mm) and then by the number of gels in the caster. If needed, add about 4 to 5 ml of extra gel solution to account for the space around the outside of the gel sandwiches.

   Do not add TEMED and ammonium persulfate until just before use.

5. Fill a 50-ml syringe with the separating gel solution and slowly inject it into the caster until the gels are 6 cm high, allowing 1.5 cm for the stacking gel.

6. Overlay each gel with 100 µl H_2O-saturated isobutyl alcohol. Allow the gels to polymerize for ~1 hr.

Pour the stacking gel

7. Remove the isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8.

   Stacking gels can be cast one at a time with the gel mounted on the electrophoresis unit, or all at once in the multiple caster.

8. Practice placing a comb in the gel sandwiches before preparing the stacking gel solution. Press the comb against the rectangular or taller plate so that all teeth of the comb are aligned with the opening in the gel sandwich, then insert into the sandwich. Remove combs after practicing.

9. Prepare the stacking gel solution (2 ml per gel) as directed in Table 10.1.1. Fill a 10-ml syringe with stacking gel solution and inject the solution into each gel sandwich.

10. Insert combs, taking care not to trap bubbles. Allow gels to polymerize 1 hr.

11. Remove the front faceplate. Carefully pull the gels out of the caster, using a long razor blade to separate the sandwiches.

    If the gels are left to polymerize for prolonged periods, they will be difficult to remove from the caster.

    The gels can be stored tightly wrapped in plastic wrap with the combs left in place inside a sealable bag to prevent drying for ~1 week. Without the stacking gel, the separating gel can be stored for 2 to 3 weeks. Keep gels moist with 1× Tris·Cl/SDS, pH 8.8, at 4°C. Do not store gels in the multiple caster.

Prepare the sample, load the gel, and conduct electrophoresis

12. Remove the combs and rinse the sample wells with 1× SDS electrophoresis buffer. Place a line indicating the bottom of each well on the front glass plate with a marker.

13. Fill the upper and lower buffer chambers with 1× SDS electrophoresis buffer. The upper chamber should be filled to 1 to 2 cm over the notched plate.

14. Prepare the protein sample and protein-standards mixture (see Basic Protocol 1, step 12).

15. Load the sample using a micropipet. Insert the pipet tip through the upper buffer and into the well. The mark on the glass plate will act as a guide. Dispense the sample into the well.

    For a complex mixture, 20 to 25 µg protein in 10 µl SDS sample buffer will give a strongly stained Coomassie blue pattern. Much smaller amounts (1 to 5 µg) are required for highly purified proteins, and 10- to 100-fold less protein amount in the same volume (e.g., 10 µl is required for silver staining).

BOCAS RATON CENTRAL UNIVERSITY LIBRARY

16. Electrophorese samples at 10 to 15 mA per 0.75-mm gel until the dye front reaches the bottom of the gel (~1 to 1.5 hr).

17. Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Proceed with detection of proteins.

SUPPORT PROTOCOL 3

PREPARING MULTIPLE GRADIENT MINIGELS

Polyacrylamide gradients not only enhance the resolution of larger format gels but also greatly improve protein separation in the small format. Casting gradient minigels one at a time is not generally feasible because of the small volumes used, but multiple gel casters make it easy to cast several small gradient gels at one time. The gels are cast from the bottom in multiple casters, with the light acrylamide solution entering first. This is the opposite of casting one gel at a time, in which the heavy solution enters from the top of the gel sandwich and flows down to the bottom.

Additional Materials (also see Basic Protocol 2)

Plug solution (see recipe)

Additional reagents and equipment for preparing gradient gels (see Alternate Protocol 5)

Set up the system and prepare the gel solutions

1. Assemble minigel sandwiches in the multiple gel caster as described for single-concentration minigels (see Basic Protocol 2, steps 1 to 3).

2. Set up the 30-ml gradient maker, magnetic stirrer, peristaltic pump (optional), and Tygon tubing as in Figure 10.1.3. Connect the outlet of the 30-ml gradient maker to the inlet at the base of the front faceplate of the caster.

   The monomer solution will be introduced through the inlet at the bottom of the front faceplate of the caster first, followed by progressively heavier solution.

3. Prepare light (Table 10.1.9) and heavy (Table 10.1.10) acrylamide gel solutions. Use ~12 ml of each solution for five 0.75-mm-thick minigels.

   Adjust volumes if a different thickness or number of gels is needed. Do not add ammonium persulfate until just before use. Deaeration is not recommended for gradient gels.

4. With the outlet and interconnecting valve closed, add the heavy solution to the reservoir chamber. Briefly open the interconnecting valve to let a small amount of heavy solution through to the mixing chamber, clearing the valve of air.

5. Fill the mixing chamber with light solution. Add 4 µl TEMED per 12 ml acrylamide solution to each chamber and mix with a disposable pipet.

Form the gradient and cast the gels

6. Turn on the magnetic stirrer. Open the interconnecting valve and allow the chambers to equilibrate. Then slowly open the outlet port to allow the solution to flow from the gradient maker to the multiple caster by gravity (a peristaltic pump may be used for better control). Adjust the flow rate to 3 to 4 ml/min.

   Faster flow rates are possible and will also produce good gradients. However, a fast flow increases the potential for introduction of bubbles into the caster.

7. Close the outlet port as the last of the gradient solution leaves the mixing chamber, just before air enters the outlet tube. Fill the two chambers with plug solution and slowly open the outlet once again.

PGU IAS / CENTRAL UNIVERSITY LIBRARY

8. Allow the plug solution to push the acrylamide in the caster up into the plates. Close the outlet when the plug solution reaches the bottom of the plates.

   A discontinuity between the bottom of the gels and the plug solution will be obvious.

9. Quickly add 100 µl H_2O-saturated isobutyl alcohol to each gel sandwich. Let the gels polymerize undisturbed for ~1 hr.

10. Prepare and pour the stacking gel (see Basic Protocol 2, steps 9 and 10).

Disassemble the system

11. Disconnect the gradient maker, place the caster in a sink, and remove the front faceplate. The plug solution will drain out from bottom of the caster.

12. Remove the gels (see Basic Protocol 2, step 11).

    Gradient minigels can be stored as described for single-concentration minigels (see Basic Protocol 2, step 11 annotation). For instructions on preparing, loading, and running the gels, see Basic Protocol 2, steps 12 to 17.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Anode buffer

121.1 g Tris base
500 ml H_2O
Adjust to pH 8.9 with concentrated HCl
Dilute to 5 liters with H_2O
Store at 4°C up to 1 month

Final concentration is 0.2 M Tris·Cl, pH 8.9.

Cathode buffer

12.11 g Tris base
17.92 g tricine
1 g SDS
Dilute to 1 liter with H_2O
Do not adjust pH
Store at 4°C up to 1 month

Final concentrations are 0.1 M Tris, 0.1 M tricine, and 0.1% (w/v) SDS.

Coomassie blue G-250 staining solution

200 ml acetic acid
1800 ml H_2O
0.5 g Coomassie blue G-250
Mix 1 hr and filter (Whatman no. 1 paper)
Store at room temperature indefinitely

The final solution is 0.025% (w/v) Coomassie blue G-250 in 10% (v/v) acetic acid.

Phosphate/SDS electrophoresis buffer

Dilute 500 ml of 4× phosphate/SDS, pH 7.2 (Table 10.1.7) with H_2O to 2 liters. Store at 4°C up to 1 month.

Final concentrations are 0.1 sodium phosphate (pH 7.2)/0.1% (w/v) SDS.

BOU IAST / CENTRAL UNIVERSITY LIBRARY

Phosphate/SDS sample buffer, 2× (for continuous systems)

0.5 ml 4× phosphate/SDS, pH 7.2 (Table 10.1.7)
0.2 g SDS
0.1 mg bromphenol blue
0.31 g DTT
2.0 ml glycerol
Add H_2O to 10 ml and mix

Final concentrations are 20 mM sodium phosphate, 2% (w/v) SDS, 0.001% (w/v) bromphenol blue, 0.2 M DTT, and 2% (v/v) glycerol.

Plug solution

0.125 M Tris·Cl, pH 8.8 (*APPENDIX 2E*)
50% (w/v) sucrose
0.001% (w/v) bromphenol blue
Store at 4°C up to 1 month

Recrystallized SDS (optional)

High-purity SDS is available from several suppliers, but for some sensitive applications (e.g., protein sequencing) recrystallization is useful. Commercially available electrophoresis-grade SDS is usually of sufficient purity for most applications.

Add 100 g SDS to 450 ml ethanol and heat to 55°C. While stirring, gradually add 50 to 75 ml hot H_2O until all SDS dissolves. Add 10 g activated charcoal (Norit 1, Sigma) to solution. After 10 min, filter solution through Whatman no. 5 paper on a Buchner funnel to remove charcoal. Chill filtrate 24 hr at 4°C and 24 hr at –20°C. Collect crystalline SDS on a coarse-frit (porosity A) sintered-glass funnel and wash with 800 ml –20°C ethanol (reagent grade). Repeat crystallization without adding activated charcoal. Dry recrystallized SDS under vacuum overnight at room temperature. Store in a desiccator over P_2O_5 in a dark bottle.

If proteins will be electroeluted or electroblotted for protein sequence analysis, it may be desirable to crystallize the SDS twice from ethanol/H_2O (Hunkapiller et al., 1983).

SDS electrophoresis buffer, 5×

15.1 g Tris base
72.0 g glycine
5.0 g SDS
H_2O to 1000 ml
Dilute to 1× or 2× for working solution, as appropriate

Do not adjust the pH of the stock solution, as the solution is pH 8.3 when diluted. Store at 0° to 4°C until use (up to 1 month).

SDS sample buffer, 2× (for discontinuous systems)

25 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.1.1)
20 ml glycerol
4 g SDS
2 ml 2-ME *or* 3.1 g DTT
1 mg bromphenol blue
Add H_2O to 100 ml and mix
Store in 1-ml aliquots at –70°C

To avoid reducing proteins to subunits (if desired), omit 2-ME or DTT (reducing agent) and add 10 mM iodoacetamide to prevent disulfide interchange.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

SDS sample buffer, 6× (for discontinuous systems)

7 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.1.1)
3.0 ml glycerol
1 g SDS
0.93 g DTT
1.2 mg bromphenol blue
Add H_2O to 10 ml (if needed)
Store in 0.5-ml aliquots at –70°C

Tricine sample buffer, 2×

2 ml 4× Tris·Cl/SDS, pH 6.8 (Table 10.1.1)
2.4 ml (3.0 g) glycerol
0.8 g SDS
0.31 g DTT
2 mg Coomassie blue G-250
Add H_2O to 10 ml and mix

Final concentrations are 0.1 M Tris, 24% (w/v) glycerol, 8% (w/v) SDS, 0.2 M DTT, and 0.02% (w/v) Coomassie blue G-250.

COMMENTARY

Background Information

Polyacrylamide gels form after polymerization of monomeric acrylamide into polymeric polyacrylamide chains and cross-linking of the chains by *N,N'*-methylenebisacrylamide. The polymerization reaction is initiated by the addition of ammonium persulfate, and the reaction is accelerated by TEMED, which catalyzes the formation of free radicals from ammonium persulfate. Because oxygen inhibits the polymerization process, deaerating the gel solution before the polymerization catalysts are added will speed up polymerization; deaeration is not recommended for the gradient gel protocols because slower polymerization facilitates casting of gradient gels.

Precast gels for commonly used vertical minigel and standard-sized SDS-PAGE apparatuses are available from several manufacturers (Table 10.1.3). Flatbed (horizontal) isoelectric focusing (IEF) and SDS-PAGE gels are not listed. Pharmacia supplies a range of horizontal gels for a variety of applications and should be consulted for further information. When using precast gels, pay strict attention to shelf life. In general, manufacturers overrate the shelf life, and the sooner the gels are used, the better. When reasonably fresh, precast gels provide excellent resolution that is as good or better than a typical gel cast in the laboratory.

The most widely used method for discontinuous gel electrophoresis is the system described by Laemmli (1970). This is the denaturing (SDS) discontinuous method used in Basic Protocol 1. A discontinuous buffer system uses buffers of different pH and composition to generate a discontinuous pH and voltage gradient in the gel. Because the discontinuous gel system concentrates the proteins in each sample into narrow bands, the applied sample may be more dilute than that used for continuous electrophoresis.

In the discontinuous system the sample first passes through a stacking gel, which has large pores. The stacking gel buffer contains chloride ions (called the leading ions) whose electrophoretic mobility is greater than the mobility of the proteins in the sample. The electrophoresis buffer contains glycine ions (called the trailing ions) whose electrophoretic mobility is less than the mobility of the proteins in the sample. The net result is that the faster migrating ions leave a zone of lower conductivity between themselves and the migrating protein. The higher voltage gradient in this zone allows the proteins to move faster and to "stack" in the zone between the leading and trailing ions. After leaving the stacking gel, the protein enters the separating gel. The separating gel has a smaller pore size, a higher salt concentration, and higher pH compared to the stacking gel. In the separating gel, the glycine ions migrate past the proteins, and the proteins are separated according to either molecular size in a denaturing gel (containing SDS) or molecular shape, size, and charge in a nondenaturing gel.

Proteins are denatured by heating in the presence of a low-molecular-weight thiol (2-ME or DTT) and SDS. Most proteins bind SDS in a constant-weight ratio, leading to identical

BOSTON UNIVERSITY LIBRARY

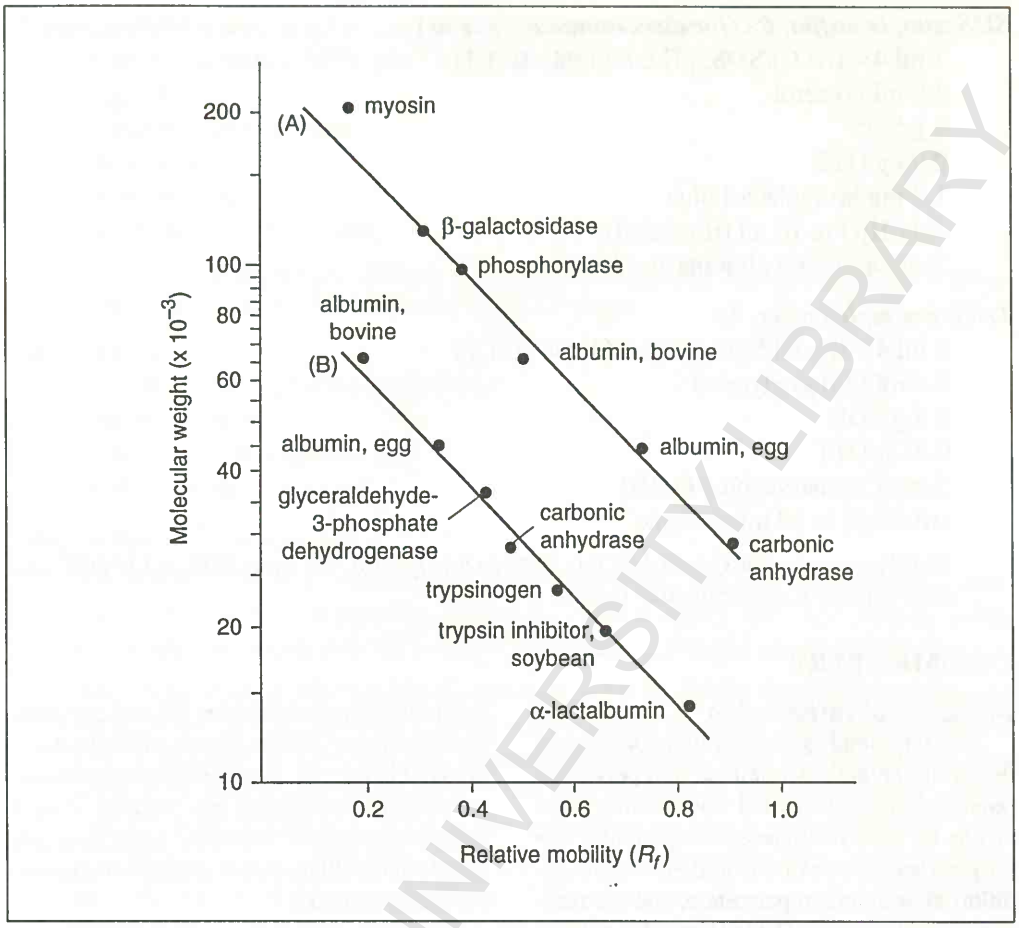

Figure 10.1.5 Typical calibration curves obtained with standard proteins separated by nongradient denaturing (SDS) discontinuous gel electrophoresis based on the method of Laemmli (1970). **(A)** Gel with 7% polyacrylamide. **(B)** Gel with 11% polyacrylamide. (Redrawn with permission from Sigma.)

charge densities for the denatured proteins. Thus, the SDS-protein complexes migrate in the polyacrylamide gel according to size, not charge. Most proteins are resolved on polyacrylamide gels containing from 5% to 15% acrylamide and 0.2% to 0.5% bisacrylamide (see Table 10.1.1). The relationship between the relative mobility and log molecular weight is linear over these ranges (Fig. 10.1.5). With the use of plots like those shown in Figure 10.1.5, the molecular weight of an unknown protein (or its subunits) may be determined by comparison with known protein standards (Table 10.1.2).

Basic Protocol 1 relies on denaturing proteins in the presence of SDS and 2-ME or DTT. Under these conditions, the subunits of proteins are dissociated and their biological activities are lost. A true estimate of a protein's molecular size can be made by comparing the relative mobility of the unknown protein to proteins in a calibration mixture (Fig. 10.1.5). Gradient gels (Alternate Protocol 5) simplify molecular-weight determinations by producing a linear relationship between log molecular weight of the protein and log % T over a much wider size range than single-concentration gels. Although percent acrylamide monomer is a more common measure of gel concentration, % T, the percentage of total monomer (acrylamide plus bisacrylamide) in the solution or gel, is used for molecular weight calculations in gradient gels. The % T is estimated assuming the acrylamide gradient is linear. For example, proteins in the gel shown in Figure 10.1.6 were separated in a 5% to 20% T acrylamide gradient. The % T of the point halfway through the resolving gel is 12.5% T. Simply plotting log molecular mass versus distance moved into the gel (or R_f) also produces a relatively linear standard curve over a fairly wide size range.

If two proteins have identical molecular sizes, they more than likely will not be resolved with one-dimensional SDS-PAGE, and two-di-

PCU IASRI CENTRAL UNIVERSITY LIBRARY

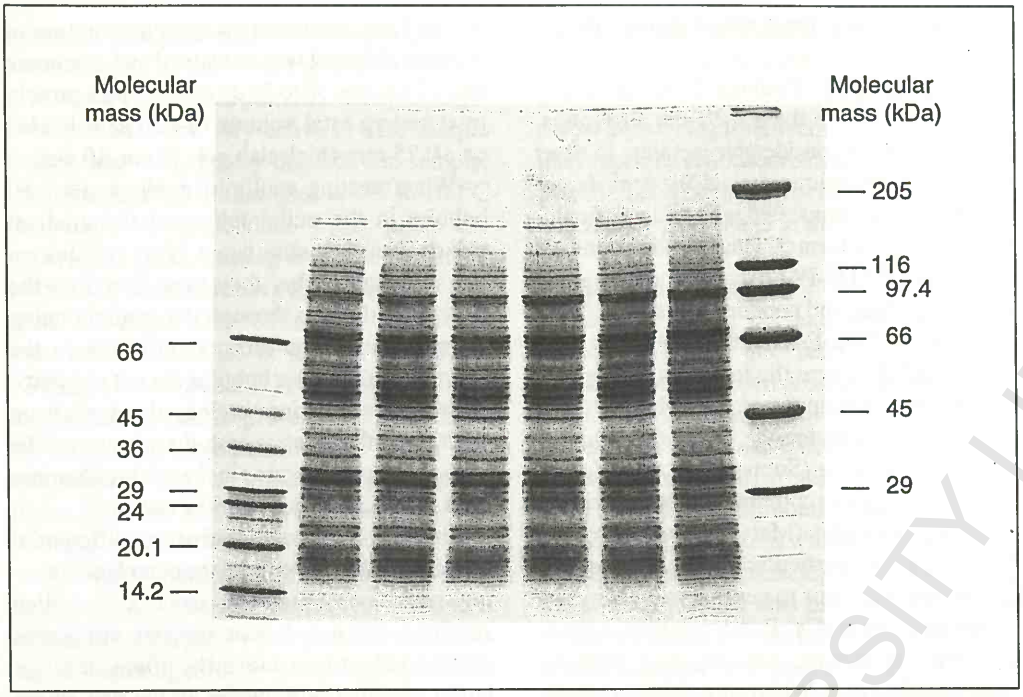

Figure 10.1.6 Separation of membrane proteins by 5.1% to 20.5% polyacrylamide gradient SDS-PAGE. Approximately 30 µl of 1× SDS sample buffer containing 30 µg of Alaskan pea (*Pisum sativum*) membrane proteins was loaded in wells of a 14 × 14–cm, 0.75-mm-thick gel. Standard proteins were included in the outside lanes. The gel was run at 4 mA for ~15 hr.

mensional SDS-PAGE should be considered (*UNIT 10.4*). Unusual protein compositions can cause anomalous mobilities during electrophoresis (see Critical Parameters and Troubleshooting), but similar-sized proteins of widely different amino acid composition or structure may still be resolved from one another using one-dimensional SDS-PAGE. Purified protein complexes or multimeric proteins consisting of subunits of different molecular size will be resolved into constituent polypeptides. Comparison of the protein bands obtained under nonreducing and reducing conditions provides information about the molecular size of disulfide cross-linked component subunits. The individual polypeptides can be isolated by electroelution (Smith, 1993) or electroblotting (*UNIT 10.8*), and the amino acid sequences can be determined.

Both the tricine (Schagger and von Jagow, 1987) and the modified Laemmli (Okajima et al., 1993) peptide separation procedures presented here (Alternate Protocols 1 and 2) are simple to set up and provide resolution down to 5 kDa. To separate peptides below 5 kDa, the tricine procedure must be modified by preparing a 16.5% T, 2.7% C resolving gel that uses a 10% T spacer gel between the stacking and resolving gel (Schagger and von Jagow, 1987). % C is the percentage of cross-linker (bisacrylamide) in the total monomer (acrylamide plus bisacrylamide).

Continuous electrophoresis, where the same buffer is used throughout the tank and gel, is popular because of its versatility and simplicity. The phosphate system described in Alternate Protocol 3 is based on that of Weber et al. (1972). Although unable to produce the high-resolution separations of the discontinuous SDS-PAGE procedures, continuous SDS-PAGE uses fewer solutions with one basic buffer and no stacking gel. Artifacts are also less likely to occur in continuous systems. Pepsin, for example, migrates anomalously on Laemmli-based discontinuous SDS-PAGE but has the expected mobility after electrophoresis in the phosphate-based continuous system described here. This is also true of cross-linked proteins.

Multiple gel casting (Support Protocols 1 to 3) is appropriate when gel-to-gel consistency is paramount or when the number of gels processed exceeds 5 a week. The variety of multiple gel casters, gradient makers, and inexpensive pumps available from major suppliers simplifies the process of casting gels in the laboratory. Alternatively, precast gradient gels

UNIVERSITY LIBRARY

are available for most major brands of gel apparatuses (Table 10.1.3).

Minigels (Basic Protocol 2) are generally considered to be in the 8 × 10–cm size range, although there is considerable variation in exact size. Every technique that is used on larger systems can be translated with little difficulty into the minigel format. This includes standard and gradient SDS-PAGE and separations for immunoblotting and peptide sequencing. Two-dimensional SDS-PAGE electrophoresis also adapts well, but here the limitation of separation area becomes apparent; for high-resolution separations, large-format gels are required. Gradient minigels (Support Protocol 3) are popular due to the combination of separation range and resolution (Matsudaira and Burgess, 1978). They are particularly useful for separation of proteins prior to peptide sequencing.

Mylar support (Gel Bond) provides a practical way of casting, running, and, staining extremely thin gels. When gels <0.75 mm thick are used, reagents have much better access both into and out of the gel, reducing staining time in both Coomassie blue and silver staining (*UNIT 10.5*). Double and broadened images caused by differential migration of the protein across the thickness of the gel are minimized, improving resolution.

Critical Parameters and Troubleshooting

If an electrophoretically separated protein will be electroeluted or electroblotted (*UNIT 10.8*) for sequence analysis, the highest-purity reagents available should be used. If necessary, SDS can be purified by recrystallization following the procedure given in Reagents and Solutions.

If the gels polymerize too fast, the amount of ammonium persulfate should be reduced by one-third to one-half. If the gels polymerize too slowly or fail to polymerize all the way to the top, fresh ammonium persulfate should be used or the amount of ammonium persulfate should be increased by one-third to one-half. The overlay should be added slowly down the spacer edge to prevent the overlay solution from crashing down and disturbing the gel interface.

After a separating gel is poured, it may be stored with an overlay of the same buffer used in the gel. Immediately prior to use, the stacking gel should be poured; otherwise, there will be a gradual diffusion-driven mixing of buffers between the two gels, which will cause a loss of resolution.

The protein of interest should be present in 0.2- to 1-μg amounts in a complex mixture of proteins if the gel will be stained by Coomassie blue. Typically, 30 to 50 μg of a complex protein mixture in a total volume of <20 μl is loaded on a 0.75-mm-thick slab gel (16 cm, 10 wells).

When casting multiple gradient gels, all bubbles in the outlet tubing of the gradient maker should be eliminated. If air bubbles get into the outlet tube, they may flow into the caster and then up through the gradient being poured, causing an area of distortion in the polymerized gel. Air bubbles are not so great a problem when casting single gradient gels from the top. As the gels are cast, the stirrer must be slowed so that the vortex in the mixing chamber does not allow air to enter the outlet.

Uneven heating of the gel causes differential migration of proteins, with the outer lanes moving more slowly than the center lanes (called smiling). Increased heat transfer eliminates smiling and can be achieved by filling the lower buffer chamber with buffer all the way to the level of the sample wells, by maintaining a constant temperature between 10° to 20°C, and by stirring the lower buffer with a magnetic stirrer. Alternatively, the heat load can be decreased by running at a lower current.

If the tracking dye band is diffuse, prepare fresh buffer and acrylamide monomer stocks. If the protein bands are diffuse, increase the current by 25% to 50% to complete the run more quickly and minimize band diffusion, use a higher percentage of acrylamide, or try a gradient gel. Lengthy separations using gradient gels generally produce good results (Fig. 10.1.6). Check for possible proteolytic degradation that may cause loss of high-molecular-weight bands and create a smeared banding pattern.

If there is vertical streaking of protein bands, decrease the amount of sample loaded on the gel, further purify the protein of interest to reduce the amount of contaminating protein applied to the gel, or reduce the current by 25%. Another cause of vertical streaking of protein bands is precipitation, which can sometimes be eliminated by centrifuging the sample or by reducing the percentage of acrylamide in the gel.

Proteins can migrate faster or slower than their actual molecular weight would indicate. Abnormal migration is usually associated with a high proportion of basic or charged amino acids (Takano et al., 1988). Other problems can occur during isolation and preparation of the protein sample for electrophoresis. Proteolysis of proteins during cell fractionation by endog-

FCU IAS CENTRAL UNIVERSITY LIBRARY

enous proteases can cause subtle band splitting and smearing in the resulting electrophoretogram (electrophoresis pattern). Many endogenous proteases are very active in SDS sample buffers and will rapidly degrade the sample; thus, first heating the samples to 70° to 100°C for 3 min is recommended.

In some cases, heating to 100°C in sample buffer will cause selective aggregation of proteins, creating a smeared layer of Coomassie blue–stained material at the top of the gel (Gallagher and Leonard, 1987). To avoid heating artifacts and also prevent proteolysis, the use of specific protease inhibitors during protein isolation and/or lower heating temperatures (70° to 80°C) have been effective (Dhugga et al., 1988).

Although continuous gels suffer from poor band sharpness, they are less prone to artifacts caused by aggregation and protein cross-linking. If streaking or aggregation appear to be a problem with the Laemmli system, then the same sample should be subjected to continuous SDS-PAGE to see if the problem is intrinsic to the Laemmli gel or the sample.

If the protein bands spread laterally from gel lanes, the time between applying the sample and running the gel should be reduced in order to decrease the diffusion of sample out of the wells. Alternatively, the acrylamide percentage should be increased in the stacking gels from 4% to 4.5% or 5% acrylamide, or the operating current should be increased by 25% to decrease diffusion in the stacking gel. Use caution when adding 1× SDS electrophoresis buffer to the upper buffer chamber. Samples can get swept into adjacent wells and onto the top of the well arm.

If the protein bands are uneven, the stacking gel may not have been adequately polymerized. This can be corrected by deaerating the stacking gel solution thoroughly or by increasing the ammonium persulfate and TEMED concentrations by one-third to one-half. Another cause of distorted bands is salt in the protein sample, which can be removed by dialysis (*APPENDIX 3B*), gel filtration (*UNIT 8.3*), or precipitation. Skewed protein bands can be caused by an uneven interface between the stacking and separating gels, which can be corrected by starting over and being careful not to disturb the separating gel while overlaying with isobutyl alcohol.

If a run takes too long, the buffers may be too concentrated or the operating current too low. If the run is too short, the buffers may be too dilute or the operating current too high.

If double bands are observed, the protein may be partially oxidized or partially degraded. Oxidation can be minimized by increasing the 2-ME concentration in the sample buffer or by preparing a fresh protein sample. If fewer bands than expected are observed and there is a heavy protein band at the dye front, increase the acrylamide percentage in the gel.

Anticipated Results

Polyacrylamide gel electrophoresis done under denaturing and reducing conditions should resolve any two proteins, except two of identical size. Resolution of proteins in the presence of SDS is a function of gel concentration and the size of the proteins being separated. Under nondenaturing conditions, the biological activity of a protein will be maintained.

Comparison of reducing and nonreducing denaturing gels can also provide valuable information about the number of disulfide cross-linked subunits in a protein complex. If the subunits are held together by disulfide linkages, the protein will separate in denaturing gels as a complex or as smaller sized subunits under nonreducing or reducing conditions, respectively. However, proteins separated on nonreducing denaturing gels appear more diffuse and exhibit less overall resolution than those separated on reducing gels.

Gradient gels provide superior protein-band sharpness and resolve a larger size range of proteins, making them ideal for most types of experiments in spite of being more difficult to prepare. Molecular-weight calculations are simplified because of the extended linear relationship between size and protein position in the gel. Increased band sharpness of both high- and low-molecular-weight proteins on the same gel greatly simplifies survey experiments, such as gene expression studies where the characteristics of the responsive protein are not known. Furthermore, the increased resolution dramatically improves autoradiographic analysis. Preparation of gradient gels is straightforward, although practice with gradient solutions containing dye is recommended. The gradient gels can be stored for several days at 0° to 4°C before casting the stacking gel.

Time Considerations

Preparation of separating and stacking gels requires 2 to 3 hr. Gradient gels generally take 5 min to cast singly. Casting multiple single-concentration gels requires an additional 10 min for assembly. Casting multiple gradient gels takes 15 to 20 min plus assembly time. It takes 4 to 5 hr to run a 14 × 14–cm, 0.75-mm

BOSTON UNIVERSITY LIBRARY

gel at 15 mA (70 to 150 V), and 3 to 4 hr to run a 0.75-mm gel at 20 mA (80 to 200 V). Overnight separations of ~12 hr require 4 mA per 0.75-mm gel. It takes 4 to 5 hr to run a 1.5-mm gel at 30 mA. Electrophoresis is normally performed at 15° to 20°C, with the temperature held constant using a circulating water bath. For air-cooled electrophoresis units, lower currents and thus longer run times are recommended.

It takes ~1 hr to run a 0.75-mm minigel at 20 mA (100 to 120 V). Separation times are not significantly different for gradient minigels.

One-Dimensional Isoelectric Focusing of Proteins in Slab Gels

Separation of proteins in complex mixtures for further analysis or purification can be achieved by isoelectric focusing (IEF), a special type of electrophoresis in which movement of proteins through pores in a polyacrylamide gel matrix is modulated by the presence of a pH gradient created by soluble ampholytes. The types of reagents and equipment used are similar to those needed for standard Laemmli sodium dodecyl sulfate (SDS) gels (*UNIT 10.1*) and IEF tube gels (*UNIT 10.4*). Use of IEF in the slab-gel format provides the advantage of permitting the analysis of large numbers of samples in a single experiment.

The Basic Protocol describes isoelectric focusing of polypeptides in urea-containing polyacrylamide slab gels. A pH gradient forms when ampholytes (small charged organic molecules) migrate through the gel in response to an electric field. Denaturing of proteins in special solubilizing buffer allows maximum exposure of amino acid side chains that contribute to a protein's isoelectric point (pI), as well as dissociation of multisubunit proteins. Separation on the basis of pI values produces bands of polypeptides that can be electrotransferred to suitable membranes for further analysis, for example, by staining (*UNIT 10.8*) or immunodetection. If samples have been radiolabeled, they can be visualized by fluorography. This unit contains support protocols detailing special conditions for application of denaturing IEF slab gels for electrotransfer (Support Protocol 1) and fluorography (Support Protocol 2) in which a scintillator is incorporated into the gel after completion of the run to facilitate detection of radioactively labeled polypeptides.

ISOELECTRIC FOCUSING IN SLAB GELS UNDER DENATURING CONDITIONS

BASIC PROTOCOL

The preparation and running of an IEF slab gel containing nonionic detergent and urea is presented. An acrylamide solution supplemented with urea, Triton X-100, and ampholytes is used to cast a slab gel; the stacking gel normally used in protein electrophoresis is omitted. Protein samples (preferably salt-free) are solubilized in buffer containing urea, 2-mercaptoethanol (2-ME), a nonionic detergent such as Triton X-100, and ampholytes before electrophoresis. A variety of electrophoresis units may be used with this protocol, but gel lengths of 15 to 20 cm and thicknesses of 0.75 to 1.0 mm are recommended. Thicker gels can be run, but consume correspondingly larger quantities of expensive ampholytes, and cannot be run at high power at the onset of the run.

Soluble ampholytes (Hoefer Pharmacia, Oxford Glycosystems, Serva) in the desired pH range are commercially available. The choice of pH range is dictated by the isoelectric points of the proteins to be resolved. This protocol results in a rather broad pH gradient (~pH 4.5 to 7.5) and can be modified as needed, provided the final ampholyte concentrations (~2% w/v) are maintained as indicated.

Materials

Urea (any high-grade urea will usually prove satisfactory)
10% (v/v) Triton X-100
Acrylamide stock solution (see recipe)
Ampholytes pH 5-7
Ampholytes pH 3.5-10
10% (w/v) ammonium persulfate (store 500-µl aliquots of freshly prepared stock at –20°C)

Copyright © 1995 by John Wiley & Sons, Inc.

BOSTON CENTRAL UNIVERSITY LIBRARY

TEMED (*N,N,N′-N′*-tetramethylenediamine)
20 mM H_3PO_4
Protein samples to be analyzed
IEF solubilization buffer (see recipe)
Overlay solution: IEF solubilization buffer diluted 1:3 (v/v) with H_2O
20 mM NaOH (freshly made, degassed immediately prior to use)

Electrophoresis apparatus (e.g., Studier type or equivalent) with glass plates, spacers, clamps, casting stand, and buffer chambers
Side-arm flask
Comb
Power supply (capable of delivering at least 1000 V and 10 W total power)
Hamilton syringe or mechanical pipet

CAUTION: Acrylamide is a neurotoxin; wear gloves when handling solutions.

Cast the isoelectric focusing gel

1. Prepare the electrophoresis apparatus by thoroughly cleaning glass plates. Assemble gel mold using spacers and clamps and mount in casting stand.

   Agarose (1% w/v) is a useful sealing agent. It is dispensed from a freshly boiled solution using a Pasteur pipet. Be sure that the hot agarose flows well between glass plates and spacer. Some minor spillage of agarose into the inside of the gel mold may be tolerated without affecting polymerization of the gel or quality of the separation.

   Most types of equipment for vertical slab gel electrophoresis can be used. Dimensions of gels are not specified, as these will differ widely between laboratories.

2. Prepare acrylamide gel solution in a side-arm flask; for 10 ml gel mix use the following:

   5.5 g urea (9.1 M final)
   2 ml 10% (v/v) Triton X-100 (2% v/v final)
   2 ml Milli-Q water
   1.35 ml acrylamide stock solution
   0.4 ml ampholytes pH 5-7
   0.1 ml ampholytes pH 3.5-10.

   To promote rapid dissolution of urea, the gel solution may be swirled in a 37°C water bath. Avoid overheating to minimize decomposition of urea.

   The total volume of the gel mix to be prepared is easily calculated from the dimensions of the gel and the thickness of the spacer. For a 200 × 150 × 1–mm gel, a total of 30 ml gel mix would be required; multiply quantities given above by three to obtain the appropriate amounts.

   The side-arm flask size (volume) should be at least 3× the volume of the amount of gel mix to be accommodated.

3. Degas solution briefly (up to 5 min).

   Because oxygen inhibits the polymerization process, it is important that the gel solution be deaerated before the polymerization catalysts are added.

4. Add 20 µl of 10% (w/v) ammonium persulfate and 10 µl TEMED to initiate polymerization. Mix well by swirling.

5. Pour gel all the way to the top of the glass plates.

   Wear gloves when handling unpolymerized gel solutions. Some of the gel mix will overflow from the mold. Remove spillage with tissue paper. By filling the mold to the

BOU IASI / CENTRAL UNIVERSITY LIBRARY

top, the insertion of the comb without causing bubbles to get trapped underneath the wells (step 6) is facilitated.

6. Insert comb, being careful to avoid air bubbles. Allow gel to polymerize ~45 min.

   The gel should be used shortly after polymerization is complete (the same day it is cast). In view of the decomposition of urea in aqueous solution, storage of poured gels is not recommended.

Perform the electrophoretic separation

7. Remove comb and place gel-plate sandwich in electrophoresis apparatus. Fill lower buffer chamber (anode) with 20 mM H_3PO_4.

8. Prepare protein samples to be analyzed in IEF solubilization buffer. Apply samples in gel wells. Fill any empty wells with a similar volume of IEF solubilization buffer.

   Samples may be applied with a Hamilton syringe or a mechanical pipet. The volume of the sample loaded is not particularly important, but it is recommended that no greater than 60% to 70% of the well's capacity be loaded so that overlay solution may be subsequently applied. Generally, sample volumes are <100 µl. Samples are loaded immediately adjacent to one another, without the need for empty lanes in between. Acrylamide teeth should be in good contact with both glass plates to eliminate the potential of spillover between wells. When in doubt, the integrity of the sample wells can be checked by first loading the overlay solution (which is colored); spillage from a freshly loaded well into an adjacent one indicates a faulty sample well, not to be used. If the wells are intact, samples can then be layered underneath the overlay using a Hamilton-type syringe.

   If unequal sample volumes are added to wells, the lane with the larger volume will spread during electrophoresis and constrict adjacent lanes, causing distortions. Preparing samples at approximately the same concentration and loading an equal volume in each well will ensure that all lanes are the same width and that the polypeptides run evenly. Fill any extra lanes (i.e., those not receiving a protein sample) with a similar volume of sample buffer, such that all wells are filled.

   The total amount of protein that may be loaded in a volume of 100 µl should not exceed 200 µg, and should be loaded over a total cross-section of 10 to 15 mm^2. The sample capacity of IEF gels is considerably greater than that of SDS-PAGE gels (UNIT 10.1), as it is an equilibrium separation method. The guideline given is recommended, but larger amounts of protein can in all likelihood be analyzed without serious loss of resolution. Samples should be salt-free, if possible, or of low ionic strength, to obtain reproducible separations. Immune complexes can be dissociated by the addition of IEF solubilization buffer. Most proteins in solution can be analyzed successfully when diluted with IEF solubilization buffer (4 parts buffer to 1 part sample). Samples that have been denatured in solubilization buffer for SDS-PAGE can likewise be diluted with IEF solubilization buffer and analyzed in parallel.

9. Apply overlay solution with a syringe or mechanical pipet, taking care not to disturb the sample layer.

   Use ~1/5 to 1/3 of the sample volume for the overlay. It is most convenient to add the tracking dye to the overlay solution, as this will generate a colored layer that separates sample from the upper reservoir electrolyte.

10. Using a Pasteur pipette, gently layer 20 mM NaOH over the samples, until the NaOH solution is flush with the top of the glass plate of the gel mold. Fill the upper reservoir with the remainder of the NaOH solution.

11. Connect power supply and apply voltage, starting at 20 V/cm. Limit voltage to 50 V/cm.

BOSTON UNIVERSITY LIBRARY

CAUTION: *The voltages and currents used during electrophoresis are dangerous and potentially lethal. Safety considerations are given in the introduction to UNIT 10.1.*

The cathode is at the top (NaOH-containing reservoir) and the anode is at the bottom (H_3PO_4-containing reservoir). The most convenient manner of running the gel is to use a power supply with a constant power setting and voltage limitation. The power is adjusted to a limit such that the desired starting voltage is obtained. Over the course of the run, the current will drop and the voltage will increase until the desired preset value is attained.

12. Run gel 13 to 16 hr (for a gel of a separating distance of ~20 cm).

    An overnight run is convenient. Over the course of the run, bromphenol blue included with samples will migrate the entire length of the gel and accumulate at the acidic end of the gel as a greenish-yellow band. When gels are run for longer times (>16 hr), no bromphenol blue may be discernible at all by the end of the run.

13. On termination of the run disconnect the power supply and disassemble the electrophoresis apparatus. Remove one of the glass plates from the gel-plate sandwich.

    The IEF gel will present a rippled appearance. The ripples correspond to positions of high local ampholyte concentrations that osmotically attract water. The ripple pattern is usually a good indicator of whether the gel ran straight and may allow one to gauge edge effects, "smiling" (curvature of migrating band), or the presence of samples with salt content drastically different from that of adjacent samples.

14. Process the gel, if desired, for staining (*UNIT 10.5*), electroblotting (see Support Protocol 1), or fluorography (see Support Protocol 2). Invert the glass plate with the gel still attached and hold it directly over the dish containing the appropriate solution. Using a spatula, peel off one corner of the gel, and continue loosening the gel until it begins to detach spontaneously from the glass plate. While holding the glass plate horizontally over the liquid-filled dish, minimize the distance that the gel will have to "fall" into the receptacle to reduce the risk of breakage.

SUPPORT PROTOCOL 1

ELECTROBLOTTING FROM DENATURING ISOELECTRIC-FOCUSING SLAB GELS

The Basic Protocol produces gels with separated polypeptides that can be subjected to standard electrotransfer procedures (*UNIT 10.7*). It is necessary, however, to remove the nonionic detergent (included in the IEF gel recipe) from the gel as it interferes with a number of commonly used staining protocols; the nonionic detergent also very significantly reduces the amount of protein transferred to membranes in electroblotting experiments. It is also necessary to bind SDS to the proteins. Both tasks are accomplished by repeated washings of the gel as follows: The gel is submerged in a shallow dish containing 50% methanol/1% (w/v) SDS/5 mM Tris·Cl (pH 8.0); the volume of wash solution should be 10× the volume of the gel. The gel is washed five times, 10 min each time, changing the solutions between washes. A convenient way to restrain the gel while decanting the used wash solution is to place paper towels or filter paper of a size that approximates that of the gel directly on the surface of the gel. Alternatively, liquid may be removed by aspiration; again, paper towels or filter paper may be used to hold the gel in the container. After the washes, the gel is ready for transfer as described in *UNIT 10.7*.

BCU IASRI CENTRAL UNIVERSITY LIBRARY

FLUOROGRAPHY OF DENATURING ISOELECTRIC-FOCUSING SLAB GELS

Slab gels containing separated polypeptides radiolabeled with ^{3}H, ^{14}C, or ^{35}S can be analyzed by fluorography. The use of the scintillant PPO (2,5-diphenyloxazole) is recommended to increase detectability of these weak β emitters and make the gels relatively easy to handle.

Materials

DMSO
DMSO/PPO solution (see recipe)
Polyacrylamide gel containing polypeptides of interest

Film cassette
Film
Intensifying screen

CAUTION: Solutions of PPO in DMSO readily permeate the skin, causing the PPO to precipitate subcutaneously. It is therefore imperative that gloves be worn at all times while handling DMSO/PPO solutions.

1. Fill a shallow dish with DMSO, using at least 10× the volume of the gel. Agitate for 20 min.
2. Remove DMSO by decantation or aspiration, and repeat step 1, using the same volume of DMSO.

   At this stage, the gel often presents an opaque appearance, with lines running perpendicular to the direction of the electrical field. We have not determined the identity of the material that forms this banding pattern, but it almost certainly relates to the distribution of the ampholytes. Like the "ripple" pattern alluded to in the Basic Protocol (step 13), it is a very good indicator of the quality of the separation and would reveal distortions due to overloaded lanes or high salt content in some of the samples.
3. Remove DMSO as in step 2, then add DMSO/PPO. Use at least 10× the volume of the gel. Agitate for 45 to 60 min.

   The DMSO/PPO solution may be reused multiple times and can be replenished by addition of the appropriate amount of PPO (assume that PPO consumed is equivalent to the gel volume). Spent DMSO/PPO solution may be diluted with water to precipitate remaining PPO. The PPO is then recovered by filtration and dried. In this manner, the (expensive) PPO can be used to maximum advantage.
4. Pour off and save DMSO/PPO. Add tap water (use at least 10× the gel volume, or as much as the container will allow) to precipitate the PPO in the gel, imparting mechanical strength to the gel. Agitate for 10 min.
5. Replace water. Wash at least two more times, replacing water at 20 min intervals.
6. Dry gel and place in film cassette. Cover with film, close cassette, and expose at –70°C.

   A brief (≤1 msec) exposure of the film to a flash of light from a photographic flash unit or stroboscope hypersensitizes the film, allowing a linear relationship to be drawn between the film image and the amount of radioactivity in the sample.

BCU ASTON CENTRAL UNIVERSITY LIBRARY

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Acrylamide stock solution: 30% (w/v) acrylamide, 1.6% (w/v) bisacrylamide

Use the recipe in Table 10.1.1, increasing the amount of bisacrylamide to 1.6 g per 100 ml final volume. Any high-quality electrophoresis-grade acrylamide should be satisfactory. It may be advisable to treat the solution with activated charcoal. Use 5 g charcoal (Merck) per 500 ml acrylamide stock solution and remove the charcoal by filtration. Filter the final solution through a 0.45-μm filter. Store ≤30 days at 4°C in the dark.

DMSO/PPO solution

Dissolve 220 g PPO in 800 ml DMSO (technical-grade DMSO may be used). Store at room temperature.

IEF solubilization buffer

5.7 g urea
2.0 ml 10% (v/v) Triton X-100
0.2 ml ampholytes pH 3.5-10
0.5 ml 2-mercaptoethanol
H_2O to 10 ml final volume

Bromphenol blue may be added to samples at a final concentration of 0.01% (w/v) to improve visibility of proteins during loading and overlay. Alternatively, it may be added to the overlay solution.

COMMENTARY

Background Information

Electrophoretic methods for separating polypeptides are powerful analytical tools. Separation according to size is achieved by electrophoresis in polyacrylamide matrices in the presence of sodium dodecyl sulfate (SDS; see *UNIT 10.1*). Separation of polypeptides according to charge is accomplished by isoelectric focusing: a pH gradient stabilized by an electric field allows the polypeptides to migrate until they reach their isoelectric point. The combination of separation according to charge in one dimension and separation according to molecular weight in the second dimension has become a widespread analytical method capable of resolving complex protein mixtures (see *UNIT 10.4*).

Separation in a single dimension is informative when the complexity of the polypeptide mixture to be resolved is small, or when methods for detecting the specific polypeptide of interest are available. For example, when a complex mixture of proteins is resolved by separation under nondenaturing conditions (*UNIT 10.3*), gel overlay methods that measure enzyme activity or ligand-binding activity can be used to detect the protein of interest. The most commonly used separation methods, however, involve prior denaturation of the protein mixture, so that multisubunit proteins dissociate and each polypeptide migrates as a single species, according to its mass or charge. In this case, specific detection of polypeptides is usually accomplished by transferring the resolved polypeptides to a suitable membrane (*UNIT 10.7*) and using antibodies to detect the polypeptide of interest (*UNIT 10.10*), or lectins to reveal the position of glycoproteins.

In many instances the complexity of the mixture of proteins to be resolved is reduced by prior purification. In some cases, for example, radiolabeled protein samples are subjected to immunoprecipitation, and the proteins thus recovered are resolved electrophoretically. Other methods of labeling (e.g., biotinylation) could be used, bearing in mind that the attachment of label may affect the charge of the protein or result in the introduction of charge heterogeneity in an otherwise homogeneous sample.

When examining the post-translational modifications on a single polypeptide backbone (e.g., by glycosylation, Chapter 12, or phosphorylation, Chapter 13), it may be advantageous to analyze the samples by isoelectric focusing instead of SDS-PAGE, especially if

BCU IASLIBRARY CENTRAL UNIVERSITY LIBRARY

the modifications in question result in a charge difference (e.g., addition of sialic acids to protein-bound glycans; phosphorylation; and sulfation). Such charge changes are often difficult to detect by SDS-PAGE, because whereas SDS-PAGE is sensitive to charge differences in proteins to be resolved, such changes affect mobility in an often unpredictable manner, or result in very minor differences in migration. The comparison of multiple samples by two-dimensional methods, although feasible, is clearly a rather cumbersome procedure with the inherent pitfalls of variation between individual separations.

The protocol described here for one-dimensional IEF is an adaptation of the method developed by O'Farrell (1975) for two-dimensional gel electrophoresis. In O'Farrell's technique, the IEF gel is cast in a glass tube, and later serves as the starting sample for the second-dimension gel. We have adapted gels of a composition similar to those described by O'Farrell to the slab-format gels. Most equipment currently in use for SDS-PAGE should be satisfactory (*UNIT 10.1*). No cooling of the electrophoresis unit is required, as long as the power applied to the gel is held within reasonable limits. The technique as described here allows high resolution of membrane proteins and has been used to detect isoelectric variants of membrane proteins not separable by size, to detect N-linked glycan modifications such as the addition of sialic acids, and to detect phosphorylated species of membrane proteins (Eichholtz et al., 1992; Benaroch et al., 1995). The method also lends itself to immunoblotting procedures, provided the high Triton X-100 concentrations in the gel are reduced and SDS is added by extensive washing of the gel in a methanol/SDS-containing solution. The method described is particularly useful when comparing polypeptides that may show only minute differences in charge: such differences would be more difficult to detect on two-dimensional separations, unless sophisticated methods are used to standardize gel pouring, electrophoresis, and workup of the gels (see Garrels, 1989). In addition, this method may be used to resolve short peptides, provided they can be detected (radiolabeled peptides).

Critical Parameters and Troubleshooting

It is important that the samples to be analyzed be salt-free, if possible. For immune complexes, this is easily accomplished by a final rinse of the complex adsorbed onto protein A–Sepharose, or some similar matrix, with water. Dissociation of the samples from the Sepharose is then achieved by addition of IEF solubilization buffer.

Staining of IEF gels as described in this protocol requires that the proteins are initially fixed in the gel using 20% (w/v) TCA (note that exposure of skin to TCA can cause blistering and other damage). This is followed by repeated washes in 10% (w/v) acetic acid/30% methanol. The gel can then be stained with most conventional SDS-PAGE stains (see *UNIT 10.5*).

Given the extreme variability of available electrophoresis equipment, one consideration is the size of the gel to be used. We have found a length of 15 to 20 cm to be satisfactory. Shorter gels may induce loss of the gel: the gel may simply slide from between the glass plates, as the combination of Triton and urea in the gel makes for poor adhesion to the glass plates. To avoid this, one may increase the surface area of the gel (pour larger gels), or assemble the gel mold with spacers such that the gel produced will taper towards the bottom (i.e., 1 cm narrower at the bottom than at the top).

Occasionally one may find that a gel has polymerized in an irregular fashion. Because the acrylamide gel serves as an anticonvection medium to stabilize the pH gradient, and does not contribute to resolution of the polypeptide mixture, such irregularities are usually inconsequential.

If the gel does not polymerize all the way to the top and hence no depressions of adequate size are present to form the sample wells, one may prepare a small batch of fresh gel solution and repour the top part separately. In this case, care should be taken to remove any remaining liquid from the top of the first gel, using blotting paper. The concentrations of ammonium persulfate and TEMED may be increased twofold to obtain rapid polymerization of the second, top layer. Any discontinuity in the gel that results from this procedure is unlikely to affect the separation. In this manner, an initially defective gel can be rescued with minimal loss of costly ampholytes.

Samples in SDS-PAGE solubilization buffer may be used for IEF, provided the same amount of buffer is present in each lane of the gel. Try to keep the amount of SDS sample buffer to be loaded as low as possible (30 µl or less). Dilute these samples with IEF solubilization buffer as much as the capacity of the sample well will allow (preferably more than a twofold dilution), and make sure that every sample well in the gel will receive the same

SCANNED BY RAE INTERNATIONAL LIBRARY

amount of SDS sample buffer (including lanes that will not receive protein samples).

Polypeptides that are rather basic will be poorly resolved on the gradients specified in this protocol. This may be compensated, but only in part by using ampholytes of a higher pH range. Although so-called nonequilibrium IEF gels, in which the samples are loaded at the acidic end of the gel and the run is terminated before equilibrium has been reached, have been successful when run in glass tubes, we have generally not been successful in adapting slab gels to nonequilibrium IEF conditions, except for runs of very short duration to resolve peptides (Heemels et al., 1993).

When using equipment that can be cooled, care should be taken not to cool the gels to the point where urea comes out of solution in the gel. Nonetheless, it is recommended that the temperature of the gel not be allowed to rise over 40°C (i.e., warm to the touch). Even though the high concentration of ampholytes in the gel is likely to scavenge most of the decomposition products, decomposition of urea in aqueous solution accelerates at higher temperatures and is a cause for concern (i.e., results in carbamylation of proteins).

For fluorography of gels, the use of the DMSO/PPO protocol is recommended, because the final product, the PPO-impregnated gel, is easier to handle and less fragile than gels processed using commercially available fluorography reagents such as EN^{3}HANCE (DuPont NEN) and similar products.

Anticipated Results

For representative examples of the types of separation that can be achieved using these protocols, the reader is referred to Eichholtz et al. (1992) and Benaroch et al. (1995).

Time Consideration

Preparing the gel mix, pouring the gel, and completing the polymerization process can be accomplished in <2 hr. Gels ~20 cm in length are conveniently electrophoresed overnight. Because the separation is essentially taken to equilibrium, variations in running time have minor impact on the resolution actually achieved. Runs should not be extended beyond 18 hr, however, as cathodic drift may begin to seriously affect the pH gradient in the basic portion of the gel. The time required for electroblotting will depend somewhat on the conditions used, but preparation of the gel for transfer should take 1 hr. The entire fluorography procedure requires 2.5 to 3 hr, not including drying of the gel, which can take 0.5 to 1 hr depending on the equipment used.

One-Dimensional Electrophoresis Using Nondenaturing Conditions

Nondenaturing or "native" electrophoresis—i.e., electrophoresis in the absence of denaturants such as detergents and urea—is an often-overlooked technique for determining the native size, subunit structure, and optimal separation of a protein. Because mobility depends on the size, shape, and intrinsic charge of the protein, nondenaturing electrophoresis provides a set of separation parameters distinctly different from mainly size-dependent denaturing sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE; *UNITS 10.1 & 10.4*) and charge-dependent isoelectric focusing (IEF; *UNITS 10.2 & 10.4*). Two protocols are presented below. Continuous PAGE (Basic Protocol) is highly flexible, permitting cationic and anionic electrophoresis over a full range of pH. The discontinuous procedure (Alternate Protocol) is limited to proteins negatively charged at neutral pH but provides high resolution for accurate size calibration.

CONTINUOUS ELECTROPHORESIS IN NONDENATURING POLYACRYLAMIDE GELS

BASIC PROTOCOL

Separation of proteins by nondenaturing electrophoresis requires the same type of equipment used for denaturing slab gels (*UNIT 10.1*) and is adaptable to a range of gel sizes (e.g., from 7.3 × 8.3–cm minigels to 14 × 16–cm full-size gels) and matrix types (e.g., single-concentration and gradient gels). This protocol outlines straightforward procedures for making acrylamide solutions, casting separating gels (stacking gels are omitted), loading samples, and conducting electrophoresis. Continuous systems, although flexible, do not give the high-resolution separation found in discontinuous systems (see Alternate Protocol).

Separation in a continuous system (i.e., in which the same buffer is used for preparing acrylamide solutions and filling electrophoresis chambers) is governed by pH, and this protocol describes four types of buffers useful over discrete ranges from pH 3.7 to pH 10.6. Use of unadjusted acetic acid gel buffer can extend the range to pH 2.0. The choice of pH and thus the buffer system depends on the protein being studied (i.e., its isoelectric point) and often must be determined empirically. In general, the system should be between pH 5.0 and 8.0 for optimal results. Extremes of pH can lead to precipitation or denaturation of the protein. Acrylamide concentrations are empirically determined, but the higher the percent acrylamide, the sharper the protein bands.

It is important to include native protein standards in the electrophoresis runs. Several manufacturers supply standards for isoelectric focusing that are also suitable for native electrophoresis. The standards have a range of isoelectric points and will carry a net positive, negative, or zero charge depending on the pH of the gel system. Alternatively, Sigma supplies a standard kit that is useful for calculating molecular weights under neutral pH, nondenaturing conditions. The samples and standard proteins, should be used at concentrations of ~1 to 2 μg/μl.

Materials

4× acetic acid gel buffer (200 mM acetic acid, pH 3.7 to 5.6; see recipe)
4× phosphate gel buffer (400 mM sodium phosphate, pH 5.8 to 8.0; see recipe)
4× Tris gel buffer (200 mM Tris·Cl, pH 7.1 to 8.9; see recipe)
4× glycine gel buffer (200 mM glycine, pH 8.6 to 10.6; see recipe)
300 mM sodium sulfite (0.38 g in 10 ml H_2O; used in acetic acid gel preparation)
Protein samples to be analyzed
Native protein standards

Electrophoresis buffer: appropriate 4× gel buffer diluted to 1× with H_2O

75-ml side-arm flask (used in gel preparation)

Additional reagents and equipment for gel electrophoresis (*UNIT 10.1*) and staining proteins in gels (*UNIT 10.5*)

Prepare the gel

1. Assemble the glass-plate sandwich of the gel electrophoresis unit and secure it to the casting stand.

   Either single-concentration or gradient gels can be used in the minigel or standard-size format. Gradient gels will enhance the band sharpness of the separated proteins.

2. Prepare acrylamide solutions according to the recipes in Table 10.3.1, Table 10.3.2, Table 10.3.3, or Table 10.3.4, adding the ammonium persulfate and TEMED just before use.

   Deaeration of the solution before the polymerization catalysts are added will speed polymerization by removing inhibitory oxygen, but is not generally required. The pH used depends on many factors. The most important are the pI values of both the protein of interest and any contaminants, as well as protein mobility and protein solubility. Determining which pH and thus which buffer system to use is largely empirical. However, extremes of pH (<4.0 and >9.0) can lead to denaturation and should be avoided. Prior knowledge of the pI of a protein (UNITS 10.2 & 10.4) allows determination of the net charge under the separation conditions (i.e., if gel pH < protein pI, the protein

Table 10.3.1 Recipes for Acetic Acid Nondenaturing Polyacrylamide Gels[a]: pH range 3.7 to 5.6[b]

TEMED[f]	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.1.1), 300 mM sodium sulfite, 4× acetic acid gel buffer (see Reagents and Solutions), and H_2O. If desired to speed polymerization, degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

[b]The pH range can be extended to ~2.0 (the pH of acetic acid) by using unadjusted acetic acid in place of 4× acetic acid gel buffer, although there is little buffering capacity at this pH.

[c]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[d]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

[e]Must be freshly made. Sodium sulfite is needed for efficient polymerization at acid pH.

[f]Added just before polymerization.

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.1.1), 4× phosphate gel buffer (see Reagents and Solutions), and H_2O. If desired, degas under vacuum ~5 min to speed polymerization. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

[d]Must be freshly made.

[e]Added just before polymerization.

will have a net positive charge; if gel pH > protein pI, the protein will be negatively charged).

3. Pour gel to 2 cm from the top of the gel mold and insert the comb. Avoid trapping air bubbles under the comb teeth.

   Air bubbles will cause small semicircular depressions in the well and lead to distortions in the protein banding pattern.

4. Allow gel solution to polymerize 1 to 2 hr.

   Polymerization is indicated by a sharp optical discontinuity around the wells.

Prepare samples and load the wells

5. Solubilize the protein sample to be analyzed using 5% (w/v) sucrose in water or dilute (1 to 5 mM) gel buffer if possible. Also prepare native protein standards.

   The concentration of protein will vary depending on the sample complexity and detection method. For Coomassie blue staining of highly enriched samples such as the standards, use 1 to 2 mg/ml (1 to 2 μg/μl). For more complex mixtures, use 5 to 10 mg/ml (5 to 10 μg/μl). Load 10- to 100-fold less for silver staining. In general, samples should be loaded in a minimum volume, preferably 10 to 20 μl for 0.75- and 1.5-mm-thick gels, respectively. With thin gels, this means using a more concentrated protein sample.

6. Remove comb carefully and rinse wells with electrophoresis buffer (appropriate 4× gel buffer diluted to 1×).

   Rinsing with electrophoresis buffer is needed to remove residual unpolymerized acrylamide monomer, which will continue to polymerize after comb removal, creating uneven wells that may interfere with sample loading.

10% (w/v) ammonium persulfate[d]	0.2	0.2	0.2	0.2	0.2	0.2	0.2
TEMED[e]	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 10.1.1), 4× Tris gel buffer (see Reagents and Solutions), and H_2O. If desired, degas under vacuum ~5 min to speed polymerization. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

[d]Must be freshly made.

[e]Added just before polymerization.

7. Fill wells with electrophoresis buffer. If desired, prerun gel.

The gel can be prerun at this point to remove any charged material such as ammonium persulfate from the gel prior to loading the sample. Assemble the electrophoresis unit and fill the buffer chambers with electrophoresis buffer. Run the gel at 300 V until the current no longer drops. This should take ~30 min. Disassemble the unit, discard the buffer, and proceed to the next step.

8. Carefully load up to 10 µl (0.75-mm gels) or 20 µl (1.5-mm gels) sample per lane as a thin layer at the bottom of the wells. Load control wells with native protein standards. Add an equal volume of electrophoresis buffer to any empty wells to prevent spreading of adjoining lanes.

Mobility (R_f) markers require special consideration in nondenaturing gel systems. For cationic systems, cytochrome c (pI ~9 to 10, 5 to 10 µg/lane) works well as an R_f marker. Bromphenol blue (10 µg/ml) is a suitable marker for anionic systems. The marker should be included in the solubilization buffer with the sample.

Perform the separation

9. Assemble the gel unit, fill the upper and lower buffer chambers with electrophoresis buffer, and connect the unit to the power supply. Set current to 30 mA for a 1.5-mm-thick gel (15 mA for a 0.75-mm-thick gel).

If the protein is negatively charged under the separation conditions, then the standard SDS-PAGE electrode polarity should be used (proteins will migrate to the anode or positive electrode). If the protein is positively charged, then the electrodes should be reversed at the power supply (i.e., red high-voltage cable to the black output and black high-voltage lead to the red output) so the positively charged protein migrates to the negative cathode.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

[d]Must be freshly made.

[e]Added just before polymerization.

10. Continue electrophoresis until the R_f marker reaches the bottom of the gel.

For minigels, electrophoresis will take 1 to 2 hr. Standard gels require 4 to 6 hr runs.

11. Turn off power supply, disassemble the unit, and remove gel from sandwich.

12. Stain the gel according to *UNIT 10.5*.

NATIVE DISCONTINUOUS ELECTROPHORESIS AND GENERATION OF MOLECULAR WEIGHT STANDARD CURVES (FERGUSON PLOTS)

ALTERNATE PROTOCOL

One straightforward approach to discontinuous native electrophoresis is to leave out the SDS and reducing agent (DTT) from the standard Laemmli SDS-PAGE protocol (*UNIT 10.1*). The gels are prepared as described in *UNIT 10.1* except that the sample buffer contains no SDS or DTT (samples are not heated), and the gel and electrophoresis solutions are prepared without SDS. This protocol illustrates the separation of standard proteins at four different concentrations of acrylamide and how the results are used to construct a molecular weight standard curve (Ferguson plot) without the need for SDS. By plotting relative mobility against %T (percentage weight per volume of acrylamide plus bisacrylamide in the gel), the presence of isoforms and multimeric proteins can also be detected.

Materials

4× Tris·Cl, pH 8.8 (1.5 M Tris·Cl; *APPENDIX 2E*)
4× Tris·Cl, pH 6.8 (0.5 M Tris·Cl; *APPENDIX 2E*)
Protein sample of interest
2× Tris/glycerol sample buffer (see recipe)

RCU IASH / CENTRAL UNIVERSITY LIBRARY

Native protein standards (e.g., Sigma nondenatured protein molecular weight kit)
Tris/glycine electrophoresis buffer (see recipe)

1. Assemble the glass-plate sandwich of the gel electrophoresis unit and place it in the casting stand.
2. Prepare and cast the gels, using 4× Tris·Cl, pH 8.8, for the separating gel and 4× Tris·Cl, pH 6.8, for the stacking gel instead of the SDS-containing counterparts (Table 10.1.1). Prepare a minimum of four separate gels at different acrylamide concentrations.

   A typical range of concentrations is from 5% to 12.5% (e.g., 5%, 7.5%, 10%, 12.5% acrylamide). As with SDS-PAGE, typical gel thickness ranges from 0.75 to 1.5 mm. The 0.75-mm-thick gels are recommended because they offer a combination of fast staining and high resolution.

3. Mix protein sample of interest 1:1 with 2× Tris/glycerol sample buffer to attain a 1 to 2 µg/µl final concentration. Also prepare native protein standards. Remove comb, rinse wells, and load 10 to 20 µl per well for Coomassie brilliant blue staining, and 1 to 2 µl for silver staining.

   Some proteins must be dissolved in 50 mM NaCl or water to become fully solubilized prior to mixing with the sample buffer (Sigma, 1986).

4. Assemble gel electrophoresis unit, using Tris/glycine electrophoresis buffer to fill both lower and upper buffer chambers. Connect power supply and conduct electrophoresis.

   Conditions for separation are the same as for discontinuous SDS-PAGE (i.e., 30 mA for 1.5-mm-thick gels, 15 mA for 0.75-mm-thick gels). For standard-size gels the separation takes 4 to 5 hr; for minigels, 1 to 2 hr is required. Alternatively, standard gels can be run at 4 to 6 mA/gel overnight.

5. After the bromphenol blue R_f marker has reached the bottom of the gel, fix and stain the proteins in the gels according to *UNIT 10.5*. Estimate relative mobilities of the proteins.

   An example of a stained gel is shown in Figure 10.3.1. A minimum of four gel concentrations is recommended. In Figure 10.3.1, Sigma native molecular weight standards were separated on 5%, 7.5%, 10%, and 12.5% acrylamide gels (5.1%, 7.7%, 10.3%, and 12.8% T, respectively).

6. Plot log R_f against gel concentration (% T) (Fig. 10.3.2). Determine the slope of K_r using linear regression.
7. Plot $-\log K_r$ of the curves from step 6 against log molecular weight of the standards (Fig. 10.3.3). Determine the slope using linear regression.
8. Estimate the size of the standards and unknowns from the generated curve (Ferguson plot).

   Use the curve generated by linear regression to estimate the predicted size of the standard for comparison to the actual size stated by the supplier. This indicates the accuracy of the curve. The $-\log K_r$ value (y) of the unknown is then used to predict the molecular weight (x).

RGU IASI/CENTRAL UNIVERSITY LIBRARY

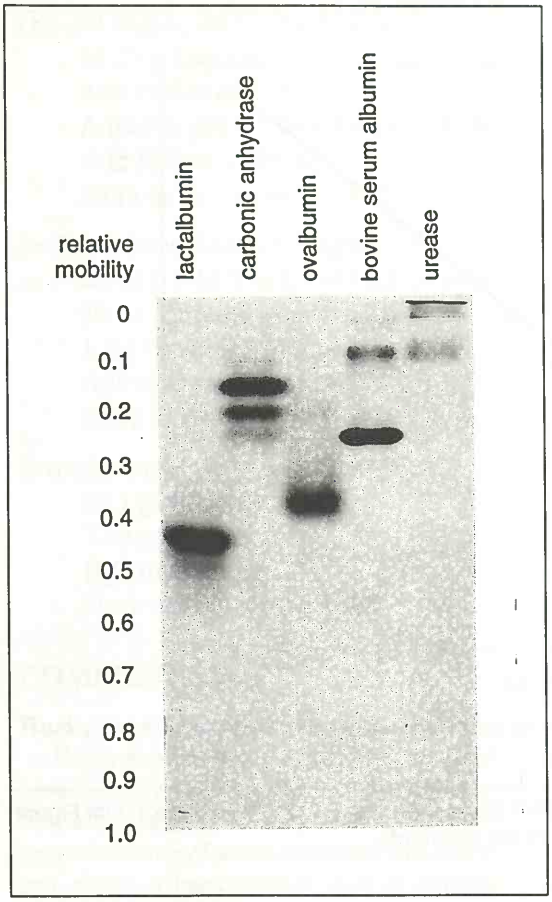

Figure 10.3.1 Separation of native protein standards under nondenaturing conditions by discontinuous polyacrylamide gel electrophoresis at 12.8% T. Approximately 20 µg protein was loaded per lane on a 1.5-mm-thick, 16-cm-long gel. The gel and samples were prepared according to the Alternate Protocol and were electrophoresed 16 hr at 6 mA. Proteins were stained with Coomassie blue.

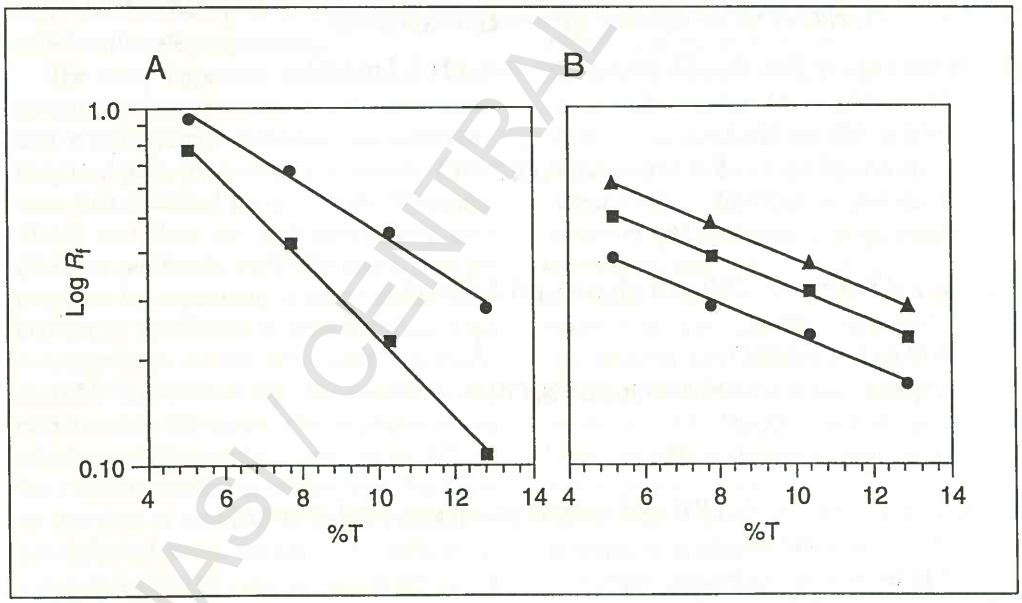

Figure 10.3.2 Effect of %T on the relative mobility of several native proteins. The relative mobility (R_f) of the standard proteins shown in Figure 10.3.1 was determined at four different gel concentrations and plotted as log R_f against %T. See text for details. (**A**) BSA monomer (squares) and dimer (circles); (**B**) carbonic anhydrase isoforms.

BOKHARI / CENTRAL UNIVERSITY LIBRARY

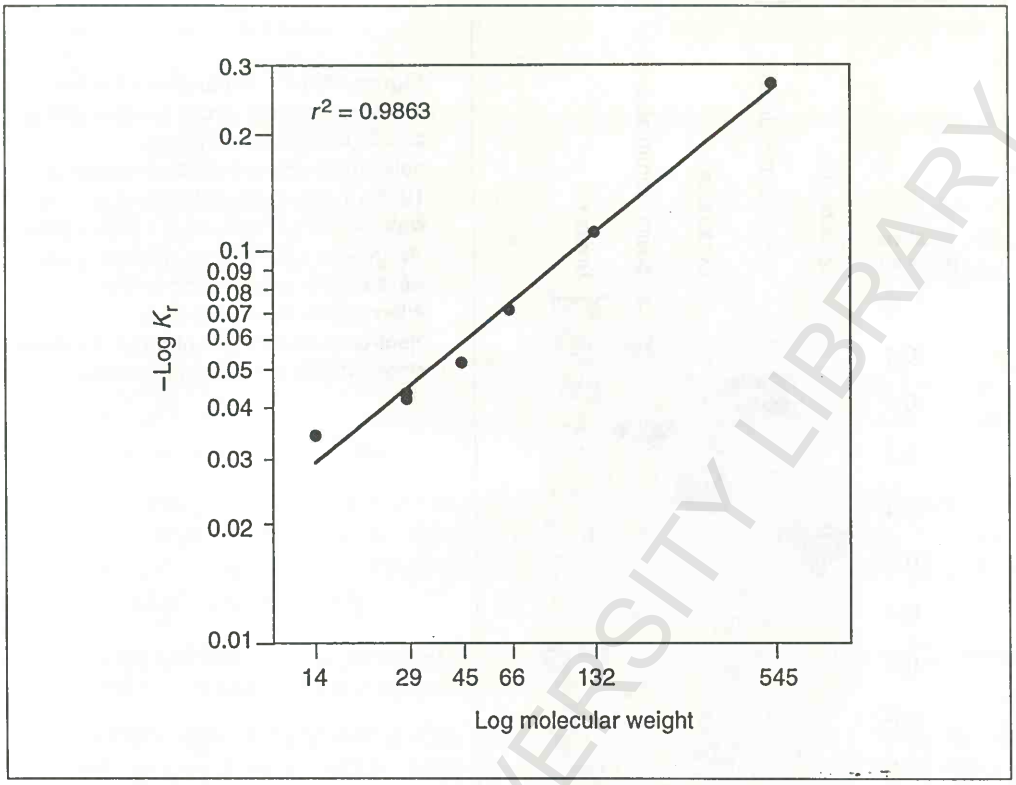

Figure 10.3.3 Native molecular weight standard curve. The –log slope of the line (K_r) from Figure 10.3.2 is plotted against log molecular weight of the standards.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Acetic acid gel buffer, 4× (200 mM acetic acid, pH 3.7 to 5.6)

11.49 ml glacial acetic acid
Add to 500 ml H_2O
Adjust to pH 3.7 to 5.6 with 1 M NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Glycine gel buffer, 4× (200 mM glycine, pH 8.6 to 10.6)

15.01 g glycine
Add to 500 ml H_2O
Adjust to pH 8.6 to 10.6 with 1 M NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Phosphate gel buffer, 4× (400 mM sodium phosphate, pH 5.8 to 8.0)

55.2 g $NaH_2PO_4 \cdot H_2O$
Add to 500 ml H_2O
Adjust to pH 5.8 to 8.0 with 1 M NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

BOU IASL / JEN E LUNIVERSITY LIBRARY

Tris gel buffer, 4× (200 mM Tris·Cl, pH 7.1 to 8.9)

24.23 g Tris base
Add to 500 ml H_2O
Adjust to pH 7.1 to 8.9 with 1 M HCl
Add H_2O to 1000 ml
Store up to 1 month at 4°C

2× Tris/glycerol sample buffer

25 ml 0.5 M Tris·Cl, pH 6.8 (*APPENDIX 2E*)
20 ml glycerol
1 mg bromphenol blue
Add H_2O to 100 ml and mix
Store in 1-ml aliquots up to 6 months at –70°C

Tris/glycine electrophoresis buffer

15.1 g Tris base
72.0 g glycine
H_2O to 5000 ml
Store up to 1 month at 4°C

COMMENTARY

Background Information

Under nondenaturing conditions, in which protein activity, native charge, and conformation are sustained, electrophoretic separation depends on many factors, including size, shape, and charge. Characteristics such as intrinsic molecular weight (i.e., in the absence of denaturation), the number of isoforms, and the presence of multimeric proteins can be determined with nondenaturing electrophoresis (often called native electrophoresis).

The most important application of nondenaturing electrophoresis is in the determination of native protein size (Alternate Protocol). Ferguson plots (reviewed by Andrews, 1986) were first described for starch gels (Ferguson, 1964) and then for polyacrylamide gels (Hedrick and Smith, 1968). Ferguson plots are prepared by separating proteins under nondenaturing conditions at several different gel concentrations. As the acrylamide concentration (%T) is increased, the relative mobility (R_f) of the protein decreases. This is plotted as log relative mobility (on the *y* axis) versus %T (on the *x* axis) to produce a straight line. The slope of this line is referred to as the retardation coefficient (K_r) and measures how effectively a protein is slowed by the increase in %T. Large proteins will be retarded much more significantly than small proteins with increasing gel concentration, with the size of the protein being proportional to the slope of the curve. Once the K_r plots for several size standards are generated (Fig. 10.3.2), the K_r values are plotted against the molecular weight of the standard proteins using a log-log graph (Fig. 10.3.3). The retardation coefficient also depends on a large number of other variables including temperature, pH, buffer type, ionic strength, and %C (percent bisacrylamide cross-linker). All these factors should be kept constant for a given experiment.

In addition to estimated size, other types of information are available from the Ferguson plots (Rodbard and Chrambach, 1971; Andrews, 1986). For example, if two components differ in size but have the same charge per unit size (e.g., for a multimeric protein with identical subunits), curves similar to those illustrated by BSA monomer and dimer (Fig. 10.3.2A) will result. Note that when the curve is extrapolated back to 0% T, it is evident that the monomer and the dimer have similar free solution mobilities. Furthermore, as the acrylamide concentration is increased, the separation between the two also increases. However, if two proteins have similar sizes but different amounts of charge, the curves will be parallel on the log plot. This is illustrated by the carbonic anhydrase isoforms (Fig. 10.3.2B). In this example, optimal separation of the isoforms occurs at the lower concentrations of acrylamide as this is a log plot.

Further applications of nondenaturing electrophoresis include preparative purification. The pH of the gel determines the net charge on the protein. Below its isoelectric point (pI) a protein will have a net positive charge, whereas above its pI it will have a net negative charge. In general, most proteins will be positively charged at pH 2.0 to 4.0; above pH 8.0, most

B. C. U. „M. EMINESCU" IAŞI
CHILIE

proteins will be negatively charged. As these general guidelines imply, the majority of proteins have isoelectric points between pH 4.0 and 8.0. There are, however, many exceptions. A protein with a highly acidic isoelectric point (e.g., pepsin, with a pI of 2.2) will remain negatively charged at a pH down to its pI. Although a full range of pH options are given, extremes of pH (<4.0 and >9.0) should be avoided, if possible, to minimize denaturation or inactivation. By picking an appropriate electrophoresis pH, it is possible to ensure that the protein of interest will be either positively or negatively charged so that it can be selectively run into the gel, excluding a large proportion of contaminants that have the opposite or no charge. Furthermore, the pH conditions determine the mobility and can be adjusted to ensure a difference in mobility between the protein of interest and contaminants.

Continuous gel systems (Basic Protocol) offer the most flexibility in terms of separation design. The pH can be tailored so that a given protein has a net positive, neutral, or negative charge. Depending on the polarity of the gel, the protein can then be excluded from or electrophoresed into the gel. Discontinuous gels have a fixed pH and gel polarity. For the nondenaturing Laemmli gel presented in the Alternate Protocol, the proteins of interest should have an isoelectric point of ≤7.0 in order to be negatively charged so that they move into the gel. Other more basic and more acidic discontinuous gel systems can be found in Hames (1990) and Schägger (1994).

Critical Parameters

The success of a gel separation under nondenaturing conditions depends on many factors, and two of the most important are protein solubility and isoelectric point. The protein must be soluble at the pH and the ionic strength of the gel, and it must be charged at that pH in order to move into the gel. If the protein experiences a pH below its isoelectric point, then it will have a net positive charge and will move to the negative electrode. Note that this is the reverse of typical SDS-PAGE. If the protein experiences a pH above its isoelectric point, it will have a net negative charge and will migrate to the positive electrode.

Solubility is a complex issue. Membrane-associated and other hydrophobic proteins are difficult to separate by nondenaturing electrophoresis (Schägger, 1994). Nonionic detergents at concentrations up to 1% and solubilizing reagents such as urea (4 to 8 M) can be used, but these reagents, especially urea, are likely to alter the protein's conformation and most likely the isoelectric point by exposing previously hidden charged groups. If detergent or urea must be included for solubilization, the minimum required to solubilize the protein should be used. Schägger (1994) lists several nonionic detergents suitable for solubilization. Among the more popular are octylglucoside and CHAPS. In general, detergents should be used near the critical micelle concentration (CMC; 0.001% to 1%, depending on the detergent).

The gel concentration has a dramatic effect on resolution and should be optimized in order to achieve the best separation and band sharpness. In general, increasing the %T will improve band sharpness.

Troubleshooting

Gel polymerization at acid pH can be problematic, and sodium sulfite is needed for efficient polymerization (Andrews, 1986). Both the ammonium persulfate and the sodium sulfite must be freshly made, and the highest quality reagents available should be used. Furthermore, the gel solutions should be at room temperature for effective polymerization.

If the protein does not enter the gel and no stained material is present at the well surface, try reversing the polarity of the electrode. If material concentrates at the top of the gel, try lowering the acrylamide concentration. Stained material at the top of the gel may also indicate poor solubilization, and increasing the ionic strength of the solubilization buffer or adding a small amount of urea and/or nonionic detergent may be required.

Anticipated Results

Proteins will resolve depending on their solubility and native charge at the chosen pH. Ideally, a distinct band representing the protein of interest will be visible. If the band is diffuse, then increasing the gel concentration or using a gradient gel will improve resolution. If the band is not visible, then the protein may be at its isoelectric point or may have moved out of the gel because it had the wrong charge. Continuous gel systems, although more versatile, will give lower resolution than discontinuous gels. Detergents or other solubilizing agents such as urea may be needed to fully solubilize and resolve the protein. Once the conditions that resolve the protein are determined, Ferguson plots will give indications of multiple subunit structure, native size, and potential isoform relationships.

Time Considerations

Separations will be complete when the tracking dye or protein reaches the bottom of the gel. For minigels, this generally takes 1 to 2 hr, using 15 or 30 mA for 0.75- or 1.5-mm-thick gels, respectively. Standard-format gels require 4 to 5 hr at 15 or 30 mA for 0.75- or 1.5-mm-thick gels, respectively. Standard-format gels can also run overnight at 4 to 6 or 8 to 12 mA for 0.75- or 1.5-mm-thick gels, respectively.

Two-Dimensional Gel Electrophoresis

Two-dimensional gel electrophoresis combines two different electrophoretic separating techniques in perpendicular directions to provide a much greater separation of complex protein mixtures than either of the individual procedures. The most common two-dimensional technique uses isoelectrofocusing (IEF) in a tube gel (see Basic Protocol 1) followed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) in a perpendicular direction (Basic Protocol 3). This combination of isoelectric point (pI) and size separation is the most powerful tool for protein separations currently available. After staining, proteins appear on the final two-dimensional gel as round or elliptical spots instead of the rectangular bands observed on one-dimensional gels. Although the total separating power of large-format two-dimensional gels is estimated to be as high as 5000 spots per gel, in practice a single two-dimensional separation of a complex mixture such as a whole-cell or tissue extract may produce 1000 to 2000 well-resolved spots when a sensitive detection method is used.

The most common IEF procedures are based on the use of soluble ampholytes, which are relatively small organic molecules with various isoelectric points and buffering capacities. The pH gradient for IEF gels is produced when the soluble ampholytes migrate in the gel matrix until they reach their isoelectric point. Because stable pH gradients outside the pH 3.0 to 8.0 range are difficult to create, alternative protocols using nonequilibrium conditions are required to resolve proteins with pI values below 3.0 to 4.0 (see Alternate Protocol 1 for acidic proteins) or above 8.0 (see Alternate Protocol 2 for basic proteins). One of the more important limitations of soluble ampholytes is the difficulty in obtaining highly reproducible pH profiles, especially when very narrow pH ranges are needed.

An increasingly attractive alternative to soluble ampholytes is the use of immobilized pH gradient (IPG) gels (see Basic Protocol 2). In this system, the buffering side chains are covalently incorporated into the acrylamide matrix, and any pH range and curve shape can be generated by pouring a gradient gel using two solutions that differ in ampholyte composition rather than acrylamide concentration. As with tube gels, the initial electrophoresis is followed by a second separation using SDS-PAGE in a perpendicular direction (see Basic Protocol 4). The use of IPG gels has recently increased, for at least three major reasons: many of the technical problems associated with their use have been solved or substantially minimized, reproducible premade IPG gels are now commercially available, and lately strong interest has arisen in using two-dimensional gels for proteome analysis studies (analyzing and comparing the complete protein profiles of cell lines, tissue samples, or single-celled organisms).

Another common two-dimensional electrophoresis format is a nonreducing/reducing electrophoretic separation (see Alternate Protocol 3), which provides useful information about intersubunit disulfides or protein-protein complexes that have been cross-linked using a bifunctional chemical cross-linker containing a disulfide bond within the linker region.

This unit also includes support protocols describing pI standards and pH profile measurements (see Support Protocol 1), casting Immobiline gels (see Support Protocol 3), preparation of tissue culture cells and solid tissues for isoelectricfocusing (see Support Protocols 4 and 5), preparation of molecular weight standards for two-dimensional gels (see Support Protocol 6), and two-dimensional protein databases (see Support Protocol 7).

NOTE: High-purity water (e.g., Milli-Q water or equivalent) is essential for all solutions. For cautions relating to electricity and electrophoresis, see Safety Considerations in the introduction to *UNIT 10.1*.

HIGH-RESOLUTION EQUILIBRIUM ISOELECTROFOCUSING IN TUBE GELS

This protocol describes the preparation of broad-range first-dimension gels using soluble ampholytes that resolve proteins with pI values between approximately 3.0 and 8.0, and is based on the original procedure described by O'Farrell (1975). The procedure presented here refers specifically to 3-mm IEF tube gels (first-dimension) combined with 1.5-mm-thick 16 × 16–cm (size of separating gel) second-dimension gels (see Basic Protocol 3) and may be easily adapted to a variety of different gel sizes (see Table 10.4.1). A 3-mm IEF gel has a total protein capacity of ~500 µg for complex protein mixtures such as whole-cell extracts. The maximum capacity of any single protein spot is ~0.5 to 5 µg, depending on the solubility of the protein near its isoelectric point and the separation distance from any near neighbors.

In this protocol, gels are cast and prefocused before the sample is loaded. The proteins are then separated according to isoelectric point, and the gels are extruded from the tubes and stored. Measuring pH profiles in IEF gels is a convenient and accurate method for determining pI (see Support Protocol 1). To provide optimal reproducibility, multiple gels should be cast and run simultaneously. This is especially important for comparative studies involving complex mixtures of proteins.

The IEF gels may be cast either by pouring the gel solution into the gel tubes (steps 3a to 7a) or by using hydrostatic pressure (steps 3b to 7b). Pouring the gel solution into the gel tubes is convenient for 3-mm-diameter IEF gels and requires only a minimal excess of reagents. Because the gels are cast using a long needle and syringe, for narrower gels, where the needle does not fit inside the gel tube, casting using hydrostatic pressure is more appropriate. This method requires a larger excess of reagents and special casting cylinders. Many types of ampholytes are readily available from different suppliers to form the desired pH profiles. As ampholytes may vary significantly in their performance, careful selection of the appropriate ampholytes is usually necessary (see Commentary).

Materials

Chromic acid, in acid-resistant container
Urea (ultrapure)
30% acrylamide/0.8% bisacrylamide (see recipe)
20% (w/v) Triton X-100 (see recipe)
Ampholytes (e.g., pH 3-10/2D; ESA)
TEMED (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)
2.5% (w/v) ammonium persulfate (see recipe; prepare immediately before use)
8 M urea (see recipe; prepare immediately before use)
0.1 M orthophosphoric acid (H_3PO_4; see recipe)
0.1 M NaOH (*APPENDIX 2E*; make fresh daily)
Lysis buffer (see recipe)
Protein samples to be analyzed
Equilibration buffer (see recipe)
2-Mercaptoethanol

Isoelectrofocusing apparatus (e.g., Protean II xi 2D from Bio-Rad or equivalent) with glass tubes, casting stand, buffer chambers, rubber grommets, and plugs
37°C water bath
110°C oven
10-ml syringe equipped with filter capsule (0.22 or 0.45 µm, e.g., Costar µStar LB)
10-ml syringe equipped with blunt needle [e.g., 20-G × 6 in. (15 cm) or 18-G × 6 in. (15 cm)]

BCU IASL - CENTRAL UNIVERSITY LIBRARY

Large glass cylinder sealed at bottom with Parafilm (optional, for hydrostatic pressure casting method only)
2000-V power supply
60-ml syringe
Metal or plastic scoop
Dry ice pellets

Wash tubes and prepare the gel mixture

1. Remove the glass tubes from a chromic acid–filled container. Extensively wash the tubes with water, using high-purity water for the last wash. Dry the tubes at least 1 hr in an oven at 110°C and store them at room temperature, covered with aluminum foil.

   To prevent gels from sticking to the glass tubes, gel tubes have to be very clean. Satisfactory results are obtained by storing the tubes in chromic acid between uses and washing them shortly before use. Because drying the tubes requires at least 1 hr, cleaning steps should be performed the day before gels will be cast.

   CAUTION: *Chromic acid is highly corrosive; follow supplier's precautions carefully.*

2. Prepare the gel solution by mixing:

   16.9 g urea
   4.0 ml of 30% acrylamide/0.8% bisacrylamide
   3.0 ml of 20% (w/v) Triton X-100
   7.5 ml water
   3.0 ml ampholytes.

   Briefly warm the mixture in a 37°C water bath to solubilize urea if needed.

   To minimize decomposition of urea, never warm any solutions containing urea above 37°C, use ultrapure urea, and prepare solutions immediately before use.

   Choice of ampholyte composition is one of the key factors determining the quality of isoelectrofocusing separations. Substantial differences in performance, resolution, and shape of the pH gradient formed may be observed with different combinations of ampholytes and with ampholytes from different suppliers. ESA's ampholytes (pH 3-10/2D) are suited for most applications and give reproducible results.

   Although purity of all reagents is important, the purity of urea and choice of ampholytes are among the most critical factors for the quality and performance of isoelectrofocusing. Most commercially available reagents marketed specifically for two-dimensional gel electrophoresis should be suitable, although individual lots of reagents from any supplier may provide variability and/or unacceptable results.

Cast gels by pouring

3a. Wrap one end of each glass tube with Parafilm and mount the tube in a casting stand. Mark all the tubes to indicate the desired gel height.

   For reproducible results, all gels should be the same height.

4a. Filter the gel solution using a 10-ml syringe equipped with a syringe-tip filter capsule. Briefly degas the gel solution (~5 min) either by sonication or under vacuum. Then add 42.5 µl TEMED and 187.5 µl of 2.5% (w/v) ammonium persulfate solution to the filtered gel mixture and swirl gently to mix.

5a. Using a 10-ml syringe with a blunt needle, fill each glass tube with gel solution to the desired height. Make sure there are no air bubbles trapped in the gel.

   A needle is the best choice for casting gels if tubes of 3-mm inner diameter are used. For narrower tubes, the use of hydrostatic pressure is more appropriate (see steps 3b to 7b,

BOSTON CENTRAL UNIVERSITY LIBRARY

below). For long gels the needle can be extended by inserting a piece of capillary polyethylene tubing over the needle tip. The amount of gel solution described in step 2 is sufficient for sixteen 3-mm tube gels that are 16 cm long.

6a. Immediately overlay each gel with ~50 µl of 8 M urea.

A pipettor with a capillary pipet tip is a convenient tool for overlaying with urea. Avoid mixing the overlay and gel solutions. Polymerization starts to occur ~15 min after the addition of TEMED and ammonium persulfate. It is essential that the gels be poured and overlaid before significant polymerization has occurred.

7a. Let the gels polymerize at least 3 hr prior to use.

Urea decomposes at a substantial rate at room temperature; therefore, the gels should be used the same day they are cast.

Cast gels using hydrostatic pressure

3b. Place a rubber band around the gel tubes so they form a tight bundle. Place the bundle inside a larger glass cylinder that is sealed at the bottom with several layers of Parafilm. All tubes must be precisely vertical.

The dimensions of the larger cylinder depend on the dimensions and number of gel tubes. Excessive space will require more gel solution to cast the gels.

4b. Filter the gel solution using a 10-ml syringe and filter capsule. Degas the gel solution briefly (~5 min) either with sonication or under vacuum. Add 42.5 µl TEMED and 187.5 µl of 2.5% ammonium persulfate solution and swirl.

5b. Pipet the gel solution into the bottom of the glass cylinder. Gently run water down the outside of the tube bundle using a wash bottle. Keep adding water until the gel mix reaches the desired height.

Hydrostatic pressure will force the gel solution into the tubes. Sufficient gel solution must be used to obtain the desired gel height while avoiding forcing any water into the tubes. The volume of gel solution required can be estimated as follows: number of gels × 3.14 × (tube internal radius in cm)^2 × height in cm + ~10 ml to keep a safe level of gel mix at the bottom of the casting cylinder. As water is less dense than the gel solution, the water level will be slightly higher than the level of gel solution inside the tubes.

6b. Overlay the gels with 8 M urea.

Urea decomposes at a substantial rate at room temperature; therefore, the gels should be used the same day they are cast.

7b. Let the gels polymerize at least 3 hr prior to use.

Mount the gels in the electrophoresis unit

8. Prepare the lower electrode solution by degassing the proper amount of 0.1 M H_3PO_4 under vacuum with stirring for at least 5 min. Fill the bottom electrophoresis chamber.

The amount of phosphoric acid depends on the length of the gel tubes and the type of electrophoresis unit. The solution should cover the entire gel for good heat dissipation. Approximately 3 liters are required for Protean II xi 2D electrophoresis units.

9. Remove the gel tubes from the casting stand, remove the Parafilm from the tube bottoms, and inspect gels for irregularities or trapped air bubbles. Discard imperfect gels. If using gels cast with hydrostatic pressure, remove the bundle of tubes en bloc, cut off excess acrylamide with a razor blade, and then rinse away remaining acrylamide particles from the outside of each tube.

10. Place a rubber grommet on the top of the tube. Approximately 5 mm of the tube should be visible above the upper edge of the grommet.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

11. Mount the tube with the grommet in the upper reservoir and plug any unused holes.

After the tube is seated, its lower end must be submerged in the lower electrode solution. Be sure to remove any air bubbles trapped at the bottom of the tube by shaking or tapping the tube gently. Alternatively, with some units bubbles can be dislodged by raising and lowering the tubes or by using a long curved needle and syringe.

Prefocus the gels

12. Prepare the 0.1 M NaOH upper electrode solution by degassing under vacuum with stirring for at least 5 min.

The amount of upper electrode solution necessary depends on the type of electrophoresis chamber. If a Bio-Rad Protean II xi 2D apparatus is used, 1 liter of 0.1 M NaOH is sufficient for both prefocusing and the separation.

13. Remove the 8 M urea overlay from the top of the gels using a Pasteur pipet and place ~50 µl lysis buffer on the top of each gel.

14. Overlay lysis buffer with the degassed 0.1 M NaOH to fill the gel tubes. Avoid mixing of NaOH with the lysis buffer.

15. Pour the degassed 0.1 M NaOH into the upper chamber, making sure that all the gel tubes are covered with the electrode solution. Check carefully for leaks and air bubbles, then place lid on apparatus.

16. Connect the electrodes to a power supply by the red (+) lead to the lower chamber and the black (–) lead to the upper chamber.

The voltages and currents used during electrophoresis are dangerous and potentially lethal. Safety considerations are given in the Electricity and Electrophoresis section of UNIT 10.1.

17. Prefocus for 30 min using 500 V constant voltage.

Load the samples

18. Turn off power supply (see Safety Considerations in *UNIT 10.1*), disconnect leads, and remove lid. Using a 60-ml syringe, remove the electrode solution (0.1 M NaOH) from the upper chamber.

19. Remove the electrode solution and the overlay solution from each tube. Be careful not to damage the gel surface.

20. Place ~50 µl lysis buffer on the top of each gel. Wait at least 2 min.

21. Remove the lysis buffer from the tubes.

Rinsing the gels with lysis buffer removes any residual NaOH and protects the samples against exposure to high pH.

22. Load protein samples to be analyzed and carefully overlay each sample with ~50 µl lysis buffer diluted with water 8:2 (v/v). Avoid mixing the buffer with the sample.

The overlay solution protects samples from direct contact with the strong base used as an upper electrode solution. Dilution of the lysis buffer with water is necessary to decrease the density so the overlay does not mix with the sample.

A 3-mm-i.d. × 16-cm-long IEF gel has a total protein capacity of ~500 µg for whole-cell extracts and other complex protein mixtures. The maximum capacity for any single protein spot is ~0.5 to 5 µg, depending on its solubility near its isoelectric point and the separation distance from any near neighbors. Preparation of relatively pure protein samples for isoelectrofocusing is generally straightforward. The sample usually may be prepared in one of the following ways: dialyze into any compatible low-ionic-strength buffer, lyophilize in a volatile or compatible low-ionic-strength buffer and dissolve in lysis buffer, or

BOLIVAR CENTRAL UNIVERSITY LIBRARY

precipitate the protein using trichloroacetic acid (TCA) and redissolve in lysis buffer. For preparing extracts from cultured cells and from tissue samples, see Support Protocol 4 and Support Protocol 5, respectively.

The minimum sample concentration of protein or radioactivity has to be sufficient for the desired detection method. For complex protein mixtures such as tissue or cell extracts, a 500-µg total load is recommended for Coomassie blue staining (UNIT 10.5) or electroblotting (UNIT 10.7) for subsequent structural analysis, a 50-µg total protein load should be sufficient for silver staining (UNIT 10.5) or immunoblotting, and no less than 100,000 counts/gel is recommended for proteins labeled with ^{3}H, ^{14}C, or ^{35}S for autoradiography purposes. Sample volumes should be <150 µl for 3-mm gels and <40 µl for 1.5-mm gels. This implies at least a 5 µg/µl protein concentration in the sample for gels to be stained with Coomassie blue.

23. Carefully fill all tubes with 0.1 M NaOH. Avoid mixing the NaOH solution with the overlay solution and the sample.

24. Fill the upper reservoir with 0.1 M NaOH. Be sure that all gel tubes are covered with the solution.

Run the gels

25. Connect the electrodes to a power supply with red (+) to the lower chamber and black (–) to the upper chamber.

26. Focus for a total of 12,000 Vhr.

Unlike other electrophoretic techniques, in IEF the volt-hour is the most common unit describing the "time" of isoelectrofocusing. The initial voltage is usually set according to the desired number of volt-hours in a way that is convenient for the operator (i.e., so that the separation will run overnight), but it should not be <400 V. The upper voltage limit is restricted by heat released in the gels during isoelectrofocusing. At constant voltage the current will be the highest during the first hour of separation. The initial current will be strongly influenced by the ionic strength of the samples loaded onto the gels. An initial voltage of <800 V is recommended for 3-mm gels loaded with samples containing less than 100 mM salts/buffers; the voltage could be increased to 1200 V after ~1 hr, if cooling is used. The current is a derivative of voltage and is never preset for isoelectrofocusing purposes. Some power supplies allow preprogramming the desired number of volt-hours and continuously adjust voltage and current during the isoelectrofocusing procedure (constant power). The total number of volt-hours is a major factor that affects separation in the first dimension. Optimal focusing time will vary for different ampholyte combinations, but 12,000 Vhr is a reasonable value for most systems. To achieve a total of 12,000 Vhr set the power supply to 667 V for 18 hr. These conditions are convenient for an overnight separation and do not require use of a cooling unit. Higher voltages can be used but may cause overheating of gels unless a highly efficient cooling system is employed. The maximum practical voltage decreases with increased gel tube inner diameter. Focusing for too long may cause cathodic drift and result in a shifted pH profile in the gel, whereas focusing for a short time will decrease resolution.

Extrude and store gels

27. Turn off power supply and carefully disconnect leads. Detach the lid and remove the NaOH solution from the upper reservoir of the electrophoresis chamber using a 60-ml disposable plastic syringe.

28. Remove one gel tube at a time from the chamber.

29. Using a 10-ml syringe equipped with a blunt needle, slowly and carefully inject water between the gel and glass tube. Start from the bottom of the tube, then repeat the procedure from the top. The gel should slide out of the glass tube.

It is convenient to let the gel slide from the glass tube onto a metal or plastic scoop, which facilitates transfer of the gel into a storage vial. It is relatively easy to break the gel during

BCU IAS / CENTRAL UNIVERSITY LIBRARY

extrusion, and practicing on several unused gels is recommended. To extrude smaller-diameter gels, use water pressure generated by a syringe connected to the gel tube with Tygon tubing. If clean, unscratched glass tubes are used, extrusion should be easy.

30. Using the scoop, slide the gel into a 4.5-ml cryovial containing 3 ml equilibration buffer and 50 µl 2-mercaptoethanol. Close the vial, incubate exactly 5 min at room temperature, then freeze by placing the tube horizontally on top of dry ice pellets. Do not move or agitate the tube while the sample is freezing.

The IEF gels may be run on a second-dimension gel immediately (see Basic Protocol 3), or can be stored at −80°C for many weeks. Even when the second-dimension is to be run immediately, extruded gels should be frozen after a carefully controlled incubation time at room temperature, such as the 5 min cited above for 3-mm-i.d. gels, to minimize diffusion of proteins out of the IEF gel. This short incubation before freezing will allow glycerol to diffuse into the gel. Too short an incubation or agitation during freezing can result in gel breakage. The total incubation time in equilibration buffer (sum of the time prior to freezing and after thawing) is critical and should be carefully controlled. Insufficient incubation time in equilibration buffer will not allow sufficient time for SDS to diffuse into the gel and saturate sites on the proteins. Excessive incubation times can result in appreciable protein losses due to diffusion out of the highly porous IEF gel.

CONDUCTING pH PROFILE MEASUREMENTS

SUPPORT PROTOCOL 1

Standards with different isoelectric points can help in evaluating the performance of a specific system and determining the effective pH range in the isoelectrofocusing gel. Many pI standards are commercially available from different suppliers. It is most useful to separate a mixture of standard proteins that is prepared from several individual proteins or purchased as a preformulated kit. This mixture should be run in parallel with experimental samples on a separate reference gel. It is generally not recommended to run pI standards together in the same gel with samples because of possible interference with migration and identification of proteins of interest. Instead of analyzing standard proteins, a more precise evaluation of the pH profile can be made by directly measuring the pH throughout the gel using either a surface pH electrode or the following procedure.

1. Prepare and focus one or two gels (see Basic Protocol 1, steps 1 to 26) without any sample in parallel with experimental samples.
2. Prepare 20 to 40 glass test tubes each containing 1 ml high-purity, degassed water for each gel that will be used to measure the pH gradient (measurements on duplicate gels are recommended).

   The number of tubes required per gel equals twice the gel length (in cm).

3. After electrofocusing is completed, extrude the blank gels (see Basic Protocol 1, steps 27 to 29). Briefly rinse the gels with water.

   After extrusion, gel surfaces may be contaminated with electrode solutions. Rinsing with water is essential for obtaining reliable pH profiles.

4. Place the gel on a glass plate with a plastic ruler below the plate. Cut the gel into 0.5-cm pieces using a sharp razor blade.
5. Place each gel piece in a test tube containing 1 ml water.

   Do not mix the order of samples because each gel piece represents a single pH profile data point.

6. Place all test tubes on a shaker and shake gently for 1 hr at room temperature.
7. Read the pH of each solution and plot the pH profile as a function of the distance from the top of the gel.

BOC IASI CENTRAL UNIVERSITY LIBRARY

ALTERNATE PROTOCOL 1

NONEQUILIBRIUM ISOELECTROFOCUSING OF VERY ACIDIC PROTEINS

Basic Protocol 1 is sufficient for separating proteins with isoelectric points greater than ~3.0 to 3.5. For very acidic proteins, however, a nonequilibrium system is needed. The major features of this method are utilization of a shorter focusing time (without reaching equilibrium), a modified ampholyte mixture, and different electrode solutions.

Additional Materials (also see Basic Protocol 1)

10% (w/v) ammonium persulfate (prepare immediately before use)
Concentrated sulfuric acid (used in lower chamber electrode solution)
Ampholytes, pH 2-11 (used in upper chamber electrode solution)

To analyze very acidic proteins, follow Basic Protocol 1 with these exceptions in the indicated steps:

2. When preparing the gel solution, use the following mixture of ampholytes: 2.4 ml ampholytes pH 2.5-4 and 0.6 ml ampholytes pH 2-11.

4. Following the procedure for casting gels by pouring, add 100 µl of 10% ammonium persulfate solution, swirl, add 42.5 µl TEMED, and swirl again.

   Gel mixtures containing entirely or predominantly very acidic or very basic ampholytes are generally difficult to polymerize. Use of an increased ammonium persulfate concentration and adherence to the proper order of adding the reagents should ensure polymerization.

8. Prepare the bottom chamber electrode solution by adding 4.5 ml concentrated sulfuric acid to 3 liters water. Degas at least 5 min.

Omit steps 12 to 19 (do not prefocus the gels).

20. Remove the 8 M urea (polymerization overlay solution) and place ~50 µl lysis buffer on top of each gel. Wait at least 2 min, then remove the lysis buffer.

23. Carefully fill all tubes with the upper chamber electrode (anode) solution prepared by mixing pH 2-11 ampholytes with water in a 1:40 ratio.

24. Fill the upper buffer chamber (anode) with the solution described in step 23.

    Iminodiacetic acid (10 mM) may be a more economical alternative anode solution.

26. Focus for a total of 4000 Vhr.

ALTERNATE PROTOCOL 2

NONEQUILIBRIUM ISOELECTROFOCUSING OF BASIC PROTEINS

In general, most equilibrium IEF gel systems using soluble ampholytes produce pH gradients that do not exceed pH 8.0 on the basic end, yet many proteins have higher pI values. For this reason samples containing very basic proteins are usually focused using a nonequilibrium system. In an equilibrium system, proteins are loaded on the basic end of the gel and migrate toward the acidic end until they reach a pH equal to their pI. In nonequilibrium systems, the sample is loaded on the acidic end of the gel, and focusing is terminated after a relatively short time (fewer volt-hours).

To run nonequilibrium IEF gels, follow the procedure previously described (see Basic Protocol 1) with these alterations in the indicated steps:

8. Use 0.1 M NaOH as the lower electrode solution.

   Electrode solutions and electrodes are reversed in this procedure relative to equilibrium isoelectrofocusing.

BCU IAS CENTRAL UNIVERSITY LIBRARY

Omit steps 12 to 19 (do not prefocus the gels).

20. Remove the 8 M urea (polymerization overlay solution) and place 50 µl lysis buffer on top of each gel. Wait at least 2 min, then remove the lysis buffer.

23. After loading the samples and overlaying with lysis buffer diluted with water 8:2 (v/v) as in Basic Protocol 1, use 0.1 M H_3PO_4 instead of NaOH to fill all gel tubes.

24. Use 0.1 M H_3PO_4 as the upper electrode solution.

25. Reverse the connection of electrodes—i.e., connect the red (+) lead to the upper chamber and the black (–) lead to the lower chamber.

26. Focus for a total of 3000 to 5000 Vhr.

The optimal number of volt-hours depends on the nature of the sample and the ampholytes used. The values recommended above may need to be adjusted empirically.

ISOELECTROFOCUSING USING IMMOBILIZED pH GRADIENT GEL STRIPS

BASIC PROTOCOL 2

In immobilized pH gradient (IPG) gels, the ampholytes are covalently linked to the acrylamide matrix, which facilitates production of highly reproducible gradients as well as very narrow pH gradients for optimal resolution of minor charge differences. A variety of precast gels and all the necessary equipment are commercially available from Hoefer Pharmacia. Equipment and chemicals are also available for the user to cast gels in the laboratory (see Support Protocol 3), although precast gels are likely to suffice for the majority of applications. Narrow strips of precast IEF gels (Immobiline DryStrips) may be used to achieve a first-dimension separation for two-dimensional gel electrophoresis, and broader precast slab gels (Immobiline DryPlates) can be used to compare multiple samples after IEF separation only (see Support Protocol 2 and Table 10.4.3). In this protocol, precast Immobiline DryStrips from Hoefer Pharmacia are rehydrated overnight using the reswelling cassette (one to twelve sample strips may be handled at a time); samples are applied using sample cup holders and gel strips are isoelectrofocused overnight. This procedure has been adapted from instruction booklets provided by Hoefer Pharmacia with Immobiline Dry Strip Kits and with the Immobiline DryStrip reswelling tray. Since there is a greater selection of pH ranges for premade Immobiline DryPlates than DryStrips, it is sometimes convenient to cut DryPlates into strips prior to rehydrating the gel to obtain narrower pH ranges where needed. See Basic Protocol 4 for details concerning preparing and running the second-dimension gel.

Wear gloves throughout the procedure and handle the Immobiline DryStrips with forceps where feasible to prevent extraneous protein contamination of the gels and gel solutions. Thoroughly clean all equipment with a mild laboratory detergent solution, rinse well with Milli-Q water, and allow to dry before using. Solutions containing 10 M urea may be heated *briefly* to 30° to 40°C to aid in solubilization.

Materials

Urea (ultrapure)
CHAPS or Triton X-100
Pharmalyte 3-10, 4-6.5, and/or 8-10.5 soluble ampholytes (see Table 10.4.1; Hoefer Pharmacia)
Ampholine pH 6-8 (Hoefer Pharmacia)
DTT (dithiothreitol)
Bromphenol blue
Precast Immobiline DryStrips (Hoefer Pharmacia)

B.C.U. „M. EMINESCU" IAŞI
CHIMIE

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

Table 10.4.1 Rehydration Solutions for Immobiline DryStrips[a]

Component	Final conc.	DryStrip type		
		3-10L	3-10NL	4-7L
Ultrapure urea	9 M[b]	2.7 g	2.7 g	2.7 g
CHAPS[c]	2%	0.1 g	0.1 g	0.1 g
Pharmalyte pH 3-10	1:50	100 µl		
Pharmalyte pH 4-6.5			50 µl	100 µl
Pharmalyte pH 8-10.5			25 µl	
Ampholine pH 6-8			25 µl	
DTT	0.3%	75 mg	75 mg	75 mg
Bromphenol blue	Trace	A few grains	A few grains	A few grains
Milli-Q water		To 5 ml	To 5 ml	To 5 ml

[a]Rehydration solutions should be prepared fresh immediately before use and should be filtered using a 0.2-µm filter. Minimize total time the solution is at room temperature prior to use to minimize decomposition of urea. If the reswelling tray is used, ~250 or 400 µl rehydration solution is required per 11- or 18-cm DryStrip, respectively.

[b]Urea concentrations between 8 M and 10 M are typically used. Higher concentrations promote better protein solubility during isofocusing while increasing the risk of urea crystallization. If 10 M urea is used, extra care should be taken to minimize evaporation and the temperature should be maintained at 20°C or slightly higher at all times to avoid crystallization of the urea.

[c]The optimal detergent and detergent concentration should be empirically determined. Other common alternatives are Triton X-100 and octyl-glucoside. The detergent used must be nonionic or zwitterionic to avoid high current and consequent overheating during isoelectrofocusing.

DryStrip cover fluid (Hoefer Pharmacia)
Immobiline DryStrip kit (Hoefer Pharmacia) including:
- Cathode electrode
- Anode electrode
- Sample cup bar
- Tray
- Sample cups
- Immobiline strip aligner
- IEF electrode strips
- Sample application pieces
- Instruction manual

Protein sample to be analyzed
Lysis buffer (see recipe)

Immobiline DryStrip reswelling tray (Hoefer Pharmacia)
Forceps
Filter paper
Glass plate
Flatbed electrophoresis unit (Hoefer Pharmacia Multiphor II or equivalent)
Recirculating cooling water bath
Power supply (minimum capacity of 3000 to 3500 V)
Petri dishes

Additional reagents and equipment for protein detection by staining (*UNIT 10.5*) and/or for electroblotting (*UNIT 10.7*, optional)

BCU IASI - CENTRAL UNIVERSITY LIBRARY

Rehydrate the Immobiline DryStrip(s)

1. Prepare an appropriate rehydration solution for the type of DryStrips to be used as described in Table 10.4.1 (~400 µl rehydration solution per 18-cm DryStrip).

   The urea concentration in the rehydration solution should be 8 to 10 M, and 2% CHAPS or another appropriate detergent (zwitterionic or nonionic) such as Triton X-100, NP-40, or n-octylglucoside should be included in the rehydration solution to aid in sample solubility. The optimal detergent and detergent concentration may vary with type of sample and should be determined empirically.

   One possible method of loading large sample volumes onto IPG gels is to add the sample directly to the rehydration solution. However, this sample loading method is not typically recommended since it tends to result in poor and variable protein loading into the gel. During rehydration of the gel, proteins are only poorly adsorbed into the gel matrix, apparently as a result of charge repulsion effects caused by the highly charged gel matrix.

   Solutions containing urea should be filtered using a 0.2-µm filter before use.

2. Slide the protective lid off the reswelling tray and level the tray by adjusting the leveling feet until the leveling bubble is centered.

3. For an 18-cm gel, pipet 350 to 400 µl of rehydration solution into a slot of the reswelling tray. Move the pipet along the length of the well while adding the solution to spread it evenly throughout the length of the slot. Avoid excessive air bubble formation while pipetting this solution.

4. Remove the protective cover from the Immobiline DryStrips and gently place them, gel side down, into the prepared slot.

   To facilitate their removal after rehydration, the strips should be oriented with their pointed ends at the sloped end of the slots in the rehydration tray. Be careful not to trap any air bubbles under the gel strips.

5. Overlay each strip with 2 to 3 ml of DryStrip cover fluid to prevent evaporation and urea crystallization. Slide the protective lid into place and allow gels to rehydrate overnight (~16 hours) at room temperature.

   Shorter rehydration times may not completely and reproducibly rehydrate the gels. Do not substantially exceed 16 hr as extensive incubation, especially rehydrating gels over a weekend, increases potential problems due to evaporation and subsequent urea crystallization. In addition, long incubation times increase the extent of urea decomposition, which will increase the risk of amino group modification on proteins by the cyanate produced from urea decomposition.

6. After the overnight rehydration, slide the lid off the reswelling tray. Place a forceps tip into the slight depression under each strip and remove the strip. Gently blot any excess oil or moisture from the plastic backing of the rehydrated strips with filter paper. A damp piece of filter paper may also be used to blot the surface of the gel. Some of the paper may adhere to the gel and should be gently peeled away. The gel is now ready to be placed in the strip aligner on the cooling plate of the electrophoresis unit.

   Do not allow the gel to dehydrate prior to placing it on the cooling plate in step 11. (Steps 7 to 10 should be completed prior to removing the strips from the reswelling tray.)

Run the first dimension

7. Level the Multiphor II electrophoresis unit, then connect it to a circulating cooling water bath. Allow it to cool to 15°C for 1 to 2 hr to ensure even cooling. Do not cool below 15°C to prevent precipitation of urea in the gels.

BOSTON UNIVERSITY MEDICAL LIBRARY

8. Pipet ~5 ml DryStrip cover fluid onto the surface of the Multiphor II cooling plate. Position the Immobiline DryStrip tray on the cooling plate oriented with the red (+, anodic) electrode at the top, near the cooling tubes.

Avoid large air bubbles between the cooling plate and the tray (small bubbles should not cause a problem).

9. Connect the red and black electrode leads on the tray to their respective positions on the Multiphor II unit. Pour 10 ml of DryStrip cover fluid into the tray. Place the Immobiline DryStrip aligner on top of the oil, groove side up.

Avoid getting oil on top of the strip aligner. The possible presence of small air bubbles under the strip aligner is not important.

10. Cut two electrode strips to a length of 11 cm (regardless of the number of DryStrips used). Place the electrode strips onto a clean glass plate and soak each one with 0.5 ml Milli-Q water. Blot with a Kimwipe or tissue paper to remove excess water.

The electrode strips should be evenly soaked and just damp after blotting. Excessive water could cause sample streaking.

11. Transfer the strips from step 6 to adjacent grooves in the aligner tray. Position the rounded (acidic) end of each strip near the top of the tray at the red electrode (anode) near the cooling tubes, and the square end at the bottom of the tray near the black electrode (cathode). Be sure that the edges of all gel strips at the anode end are lined up evenly.

12. Place the blotted electrode strips from step 9 on top of the gel surface of the DryStrips near the anode and cathode ends of the gel. Position the red (anode) and black (cathode) electrodes on top of the electrode strips at their respective ends.

After the electrodes have been pressed down on top of the electrode strips, check that the gel strips have not shifted position.

13. Push the sample cups onto the sample cup bar. Place the sample cup bar near the anode end of the gel so that the small spacer arm just touches the electrode and the sample cups are nearest to the electrode, but do not allow the cups to touch the gel.

The sample cups should face the nearest electrode. The acidic end of the gel can usually be used for sample application; however, the optimal loading position may need to be determined empirically for different types of samples. At high protein concentrations and/or at non-optimal pH, samples may precipitate in the gel at the loading position.

14. Position one sample cup above each gel strip and push down to ensure good contact between the bottom of the sample cup and the gel strip. Make sure the gel strips have not shifted position.

15. Pour 70 to 80 ml of DryStrip cover fluid into the tray (it will cover the gels). If oil leaks into the sample cups, adjust the cups to stop leakage. When there is no leakage into the sample cups, add enough cover fluid to the tray to completely cover the sample cups (~150 ml).

16. Pipet protein samples (in lysis buffer) into the sample cups by underlaying. The sample should sink to the bottom of the cup. Check for leakage of the sample out of the sample cup.

Samples should either be lyophilized and then solubilized in lysis buffer, or diluted 9 parts lysis buffer to 1 part sample. The maximum volume each sample cup holds is 100 µl. The complexity of the sample, the sample solubility at the loading concentration and pH used, the thickness of the second-dimension gel, and the detection method to be employed should be considered when deciding how much protein to load. As a starting reference, typical

BCU IASI CENTRAL UNIVERSITY LIBRARY

loading ranges for 1.0- to 1.5-mm-thick 18-cm × 18-cm gels would be ~5 to 20 ng per major spot for silver staining and ~1 to 5 µg per major spot for Coomassie blue staining. When very complex samples are used such as whole cell extracts, total protein loads are likely to be ~20 to 100 µg for silver staining and ~200 to 1000 µg for Coomassie blue staining. The salt concentration in samples should be kept <50 mM and, if the sample contains SDS, the final SDS concentration should be <0.25%.

17. Place the lid on the Multiphor II unit and connect the leads to a power supply. Focus the gels with constant voltage for 2 to 3 hr at 500 V followed by 12 to 16 hr at 3500 V for a total of 40 to 60 kVhr. Refer to the user manual for exact recommended voltage conditions for each type of Immobiline DryStrip.

The optimal number of Vhr will depend upon the pH range of the Immobiline Strip used, the type of sample, and the sample load and volume; therefore, the optimal Vhr should be empirically determined for different applications.

18. When isoelectrofocusing is complete, disconnect the power supply and remove the cover from the Multiphor II unit. Remove the electrodes, electrode strips, and sample cup bar from the tray.

If gels are to be run in the second dimension immediately after isofocusing, steps 1 to 3 of Basic Protocol 4 should be completed prior to terminating isofocusing.

19. Using forceps, remove the DryStrips from the tray. If the gels are to be run in the second dimension immediately, place in a petri dish with the support film along the wall of the dish and proceed directly to equilibration of the gel (see Basic Protocol 4, step 4). Alternatively, gels may be stored sealed in a plastic bag at −80°C until ready to run the second-dimension gel.

Gels may be stored at least 2 to 3 months at −80°C. Do not place in the equilibration buffers required for the second dimension prior to storage.

ELECTROPHORESIS ON IMMOBILIZED pH GRADIENT GELS

SUPPORT PROTOCOL 2

In this protocol, after precast IEF gels (Immobiline DryPlates) from Hoefer Pharmacia are rehydrated, samples are loaded and subjected to isoelectrofocusing. Gels are typically run at 2500 to 3500 V and require focusing times of 2 to 7 hr. Protein samples may be detected by conventional methods such as Coomassie blue or silver staining (*UNIT 10.5*). Isoelectric points can be determined with the use of pI calibration proteins; alternatively, because the gradient is linear, one can measure the migration distance across the gel and estimate the pI at each location. As noted in Basic Protocol 2, Immobiline DryPlates can be cut into 3-mm-wide strips to use as the first dimension of two-dimensional gels, since DryPlates are available in narrower pH ranges than DryStrips. DryPlates can also be used as described in this protocol to simultaneously separate multiple samples in a single dimension. Applications of this method include initial screening of samples to determine the optimal pH gradient prior to running more time-consuming two-dimensional gels, prescreening fractions from a chromatographic purification step prior to running two-dimensional gels, and evaluation of charge heterogeneity of purified proteins.

Additional Materials (also see Basic Protocol 2)

Precast DryPlate gel (Hoefer Pharmacia)
Repel-Silane (Hoefer Pharmacia)
Paraffin oil
Protein samples to be analyzed
Reswelling Cassette kit (Hoefer Pharmacia) including:
125 × 260 × 3–mm glass plate with 0.5-mm U frame
125 × 260 × 3–mm glass plate

continued

BOSTON UNIVERSITY LIBRARY

Silicone tubing
Pinchcock
Clamps
20-ml syringe
Roller (Hoefer Pharmacia)
Whatman no. 1 filter paper

Flatbed electrophoresis unit (Hoefer Pharmacia Multiphor II)
10° *or* 15°C cooling water bath
Electrode strips
Sample applicator strip or sample application pieces
Power supply (minimum capacity 3000 to 3500 V)

Additional reagents and equipment for protein detection by staining (*UNIT 10.5*) and for electroblotting (*UNIT 10.7*; optional)

Rehydrate the gel

1. Remove precast gel from packaging. If the entire gel is not needed, cut off the required number of lanes and reseal the unused gel. Mark the polarity of the gel section to be used by cutting a small triangle off the anode corner. Handle the gel by the support film only.

   It is critical that the lanes are cut from the gel in the proper orientation to preserve the pH gradient (see Fig. 10.4.1), and polarity must be indicated for proper orientation of electrodes later in the procedure.

2. Use the Reswelling Cassette to rehydrate the gel. Connect silicone tubing through hole in the bottom corner of the U-frame plate, seal with silicone glue, and connect the pinchcock to the other end of the tubing. Place a glass plate on a clean flat surface and wet with a few drops of water. Place the gel on the plate, gel side up. Gently roll with a clean rubber roller to remove any air bubbles.

3. Cover the plate and gel with the plate fitted with the U frame.

   The U-frame plate should be coated with a thin layer of Repel-Silane to prevent the gel from sticking to the plate.

4. Place clamps around the edges of the plates, making sure the seal is tight.

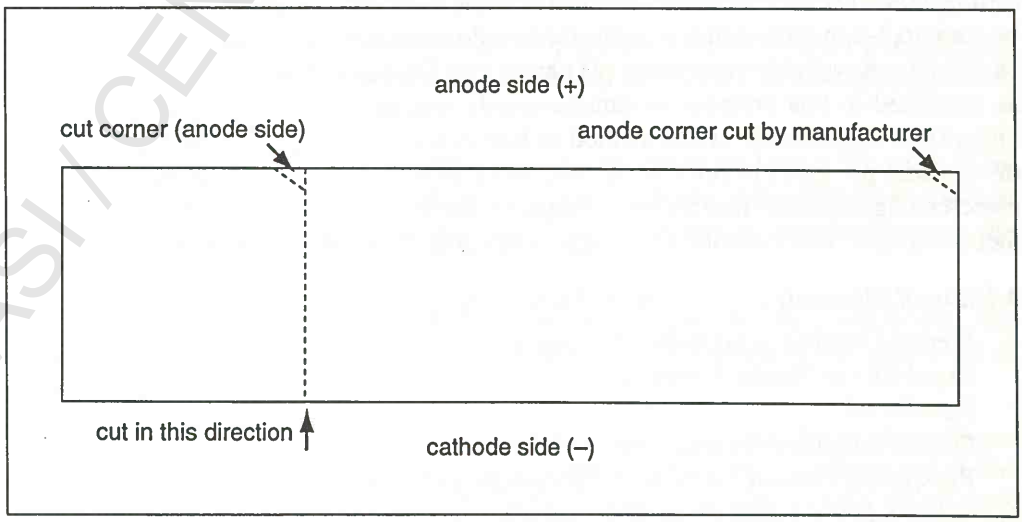

Figure 10.4.1 Marking orientation of a precast IPG gel when only a portion of the gel is used.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

5. Slowly fill the cassette with the desired rehydration solution using a 20-ml syringe connected to the silicone tubing and let stand for the recommended amount of time. Precool electrophoresis unit 1 to 2 hr prior to electrophoresis (see step 9).

   Reswelling with water for 2 to 3 hr is normally sufficient. If using additives such as urea, Triton, glycerol, or reducing agents, allow the gel to rehydrate overnight. Additives can be used to improve solubility of proteins near their isoelectric point. Reducing reagents such as 2-mercaptoethanol or DTT are used to reduce disulfide bonds.

6. When gel has been allowed to rehydrate completely, remove the clamps and gently pry the plates apart.

7. Moisten a piece of filter paper with water and place on top of the gel, then layer with a piece of dry filter paper.

8. Gently blot the gel by rolling over the dry filter paper with the rubber roller to remove excess water. The gel is now ready to be placed on the cooling plate.

   Do not let the gel dehydrate prior to placing it on the cooling plate in step 11.

Run the gel

9. Connect the flatbed electrophoresis unit to a recirculating cooling water bath. Allow to cool to 10°C for 1 to 2 hr to ensure even cooling. If the gel has been rehydrated in the presence of urea, do not cool below 15°C so that urea does not precipitate.

10. Pipet 2 to 3 ml paraffin oil onto the surface of the cooling plate.

11. Position the gel on the cooling plate, being careful not to trap air bubbles between the gel and the plate. Orient the gel so that the polarity of the gel matches the polarity of the cooling plate.

12. Soak two electrode strips with ~3 ml water, then blot to remove excess water.

13. Lay a blotted electrode strip along each long edge of the gel. Cut off the ends of the electrode strip so that it does not extend beyond the edge of the gel.

14. Load protein samples to be analyzed onto the gel. Use an applicator strip for sample volumes between 5 and 20 µl (make sure contact between the strip and the gel is uniform). Use sample application pieces for sample volumes >20 µl. Remove the application pieces halfway through focusing. For sample volumes of 2 to 10 µl, samples may be spotted directly on the gel without using applicator strips. See manufacturer's instructions for further details.

    An important experimental consideration is the position in the pH gradient where the sample is applied. The acidic end of the gel can usually be used for sample application; however, the optimal loading position may need to be determined empirically for different types of samples. At high protein concentrations and/or at nonoptimal pH's, samples may precipitate in the gel at the loading position.

    Samples should contain <50 mM salt or buffer components; greater concentrations will cause local overheating of the gel. If possible, salt-free samples should be solubilized or dialyzed in the rehydration buffer.

15. Align the electrodes with the electrode strips, put the safety lid in place, and connect the apparatus to the power supply. Conduct electrophoresis at 3000 V.

    Broad-range IPG gels, such as Immobiline DryPlate, pH 3-10, should be run at ~3000 V for 2 to 4 hr. Narrower-range gels are also run at 3000 V but may require a focusing time of 4 to 7 hr.

BOTANY LIBRARY UNIVERSITY OF FLORIDA

16. After removing gels from the electrophoresis apparatus, detect proteins using any conventional staining technique such as Coomassie blue or silver staining.

17. Preserve the gels by sealing in a plastic bag or by drying for a permanent record. Alternatively, electrotransfer the proteins on the gel to a membrane.

To dry a gel, presoak it first in a preservation solution. For silver-stained gels, use a solution of 5% to 10% (w/v) glycerol/30% (v/v) ethanol; for Coomassie blue–stained gels, use a solution of 5% to 10% (w/v) glycerol/16% (v/v) ethanol/8% (w/v) acetic acid. After soaking the gel, place it on a glass plate gel side up, cover with a cellophane sheet soaked in preservation solution, and allow to dry at room temperature.

For electrotransfer (UNIT 10.7), use film remover to remove the plastic support film from the gel. Electrotransfer of proteins to a polyvinylidene difluoride (PVDF) membrane using a Multiphor II NovaBlot transfer kit (Hoefer Pharmacia) is recommended. Transferring IPG gels requires special procedures; see the transfer kit manual for instructions.

SUPPORT PROTOCOL 3

CASTING AN IMMOBILINE GEL

An alternative to precast IPG gels is the use of Hoefer Pharmacia Immobilines to cast immobilized pH gradient gels with customized pH gradients and ranges, including very narrow pH ranges, to improve separation of proteins with small charge differences. This protocol describes the general procedure of casting custom-made Immobiline gels. The Reswelling Cassette used in Basic Protocol 2 for rehydrating gels is employed for casting the gels, which are polyacrylamide gels poured with a gradient of Immobilines following instructions provided by Hoefer Pharmacia application note 324.

Additional Materials (also see Support Protocol 2)

GelBond PAG film (Hoefer Pharmacia)
Immobiline solutions (Hoefer Pharmacia)
2.5% (v/v) glycerol

Gradient maker
Orbital shaker

Additional materials and equipment for rehydrating immobilized pH gradient gels (see Basic Protocol 2)

Cast the gel

1. Coat the plate with the U frame with Repel-Silane to prevent the gel from sticking to the glass plate.

2. Place a glass plate on a clean, flat surface and wet with several drops of water. Cover with a sheet of GelBond PAG film, hydrophilic side up. Use the roller to remove any air bubbles trapped between the film and the glass plate.

3. Place the plate with the U frame on top of the GelBond PAG film. Clamp the plates together on three sides.

4. Mix the Immobiline solutions following the instructions provided by Hoefer Pharmacia application note 324 to prepare the desired pH range. Cast the pH gradient gel using a gradient maker.

Once the catalysts have been added to the gel solution, it is important to work quickly to ensure that the gradient is poured before polymerization occurs. See UNIT 10.1 for instructions for using gradient makers.

5. Do not disturb the gel during the first 10 min to allow the gradient to stabilize. Allow the gel to polymerize 1 hr in a 50°C oven.

BCU IASI/ CENTRAL UNIVERSITY LIBRARY

Dry and store the gel

6. Allow the gel to cool to room temperature, then disassemble the cassette. Cut off a small corner to label the anode end of the gel.
7. Wash the gel 2 to 3 hr with 200 to 300 ml water. Use an orbital shaker and change the water two or three times.

   At this stage the gel may be used immediately (if no additives are needed) or dried as described in steps 8 to 10.
8. Wash the gel 30 min to 1 hr with 200 to 300 ml of 2.5% (v/v) glycerol.
9. Place the gel on a glass plate (gel side up) in a dust-free environment and allow to dry at room temperature overnight.
10. Store the dried gel in a sealed plastic bag at –20°C for up to 2 months.

    The gels may be rehydrated when needed (see Support Protocol 2).

PREPARING TISSUE CULTURE CELL EXTRACTS FOR ISOELECTROFOCUSING

SUPPORT PROTOCOL 4

Preparation of samples for isoelectrofocusing containing relatively pure proteins is generally straightforward (see Basic Protocol 1, step 22). In contrast, complex samples such as whole-cell extracts, tissue extracts, or subcellular fractions are more difficult to prepare for successful isoelectrofocusing. Solubility limitations both prior to isoelectrofocusing and during focusing restrict analysis of these complex samples to protocols that include nonionic detergents and urea (see Basic Protocol 1). In addition, the presence of DNA and RNA in crude cell extracts further complicates isoelectrofocusing. The protocol presented below is suitable for preparing samples from cell cultures and is based on quantities compatible with silver staining or Coomassie blue staining. If smaller cell numbers and high-sensitivity detection methods such as autoradiography are used, volumes and quantities should be adjusted as needed.

In this protocol the cells are harvested and washed in phosphate-buffered saline (PBS) with proteolysis inhibitors, then lysed in Tris/SDS buffer using sonication, after which the total protein concentration is determined in the lysate. The lysate is further treated with a mixture of DNase and RNase, and additional SDS and reducing agent are added. At this stage, the samples can be stored at –80°C for an extended time or, after addition of urea and lysis buffer, may be loaded directly onto prefocused IEF gels. Filtration of the final sample prior to loading onto the IEF gel is essential for quality of isoelectrofocusing.

Materials

Cell culture flasks containing cells of interest
PBS with proteolysis inhibitors (PBS/I buffer; see recipe)
Dry ice/ethanol (optional, for freezing samples)
Tris/SDS buffer (see recipe)
BCA protein assay kit (Pierce)
DNase and RNase solution (see recipe)
20% (w/v) SDS (*APPENDIX 2E*)
2-Mercaptoethanol
Urea (ultrapure)
Lysis buffer (see recipe)
50-ml centrifuge tube
Centrifuge with rotor (e.g., Beckman JS-4.2), 4°C

ROYAL CENTRAL UNIVERSITY LIBRARY

1- to 2-ml cryovials
Microcentrifuge, 4°C
Sonicator with microtip
0.2-µm microcentrifuge filter units (e.g., Millipore Ultrafree-MC filter units)

Harvest and wash the cells

1. Place cell culture flasks containing cells of interest on ice.
2. Rapidly wash cells three times with 2 to 6 ml PBS/I buffer. Keep the flasks on ice.

   The required volume of PBS/I buffer depends on the flask size. For example, use 2 ml for a 25-cm^2 tissue culture flask and 6 ml for a 75-cm^2 tissue culture flask.
3. Add 2 to 6 ml PBS/I buffer to the flask, scrape the cells using a cell scraper, and transfer the suspension to a 50-ml centrifuge tube. Repeat this step with another 2 to 6 ml buffer to ensure complete transfer of the cells.

   Cells grown in suspension are washed in an analogous manner using repetitive centrifugation.
4. Collect the cells by centrifuging 15 min at 2600 × *g* (3000 rpm in Beckman JS-4.2 rotor), 4°C.
5. Discard the supernatant and resuspend the cells in a small volume of PBS/I buffer.
6. Transfer the cell suspension to a labeled cryovial.

   The weight of the empty cryovial can be determined prior to use if the wet weight of the cell pellet is desired as a reference value rather than cell number, radioactivity, or another criterion.
7. Microcentrifuge the cells 15 min at maximum speed, 4°C.
8. Remove and discard the supernatant using a pipettor or Pasteur pipet. Weigh the vial containing the cell pellet. Record the wet weight of the cell pellet (in mg).
9. Freeze the cell pellet in a dry ice/ethanol mixture (optional).

   Frozen cells can be stored at –80°C for at least several months.

Prepare the cell pellets for isoelectrofocusing

10. Retrieve cell pellets from –80°C storage if samples were frozen.
11. Add 400 µl Tris/SDS buffer per 50 to 100 mg cell pellet wet weight. Keep the cells on ice at all times.

    The total amount of protein in the pellet is roughly 5% of the wet pellet weight.
12. Sonicate the sample three times for 3 sec using a sonicator with a microtip at medium power. Keep the samples on ice during sonication.

    Use pulse sonication or wait at least 5 min between sonications. Minimizing heat generation is essential because substantial proteolysis can occur if the sample warms appreciably. If additional sonication is necessary (i.e., if the sample is not homogeneous), let the sample cool down on ice before the next series of sonications.
13. Run a BCA protein assay to determine the protein concentration if sample will be loaded on that basis. For maximum accuracy use the same amount of Tris/SDS buffer in standards as in experimental samples.
14. Prepare labeled cryovials to store aliquots of the sample, if desired. Precool vials on ice prior to making aliquots.

    The amount of protein per aliquot depends on the anticipated future uses of the sample, as repeated freezing and thawing should be avoided. About 500 µg/gel whole-cell extract is

BCU IASI / CENTRAL UNIVERSITY LIBRARY

a maximum load for preparative purposes using 3-mm gels (i.e., isolation of proteins for sequencing or other structural work). Approximately 50 µg/gel is an appropriate load for silver staining. The final protein concentration after completion of the protocol (steps 15 to 20) will equal the concentration found by protein assay divided by 1.1, owing to the addition of reagents after the protein assay step.

15. Add 20 µl DNase and RNase solution per 400 µl Tris/SDS buffer used for sonication (step 11). Incubate 10 min on ice.

16. Add 20 µl of 20% SDS solution and 5 µl of 2-mercaptoethanol per 400 µl Tris/SDS buffer used in step 11. Incubate 5 min at 37°C.

17. Quickly divide samples into previously prepared cryovials and immediately freeze aliquots using a dry ice/ethanol bath. Store at −80°C. Samples stored at −80°C are stable ≥1 year.

    Work quickly to minimize potential proteolysis.

    This step may be omitted if the samples are to be loaded on IEF gels immediately. Generally, the total amount of sample greatly exceeds the amount required for an IEF gel, and freezing aliquots is beneficial. To avoid potential reproducibility problems, all samples should be processed identically.

Prepare the samples for isoelectrofocusing

18. If cell extracts were frozen, thaw samples and immediately add dry urea to 9 M final concentration.

    The amount of urea (in mg) equals 0.83 times the sample volume (in µl). For example, use 83 mg urea per 100 µl sample. The final volume of the sample (with urea added) equals 1.6 times the initial volume (160 µl in the same example).

19. Add an equal volume of lysis buffer (160 µl in the above example) and warm briefly if necessary to dissolve urea.

20. Filter samples using a 0.2-µm microcentrifuge filter unit by microcentrifuging at maximum speed, room temperature, until the entire sample has passed through the filter. Load the desired volume onto the IEF gel.

    If a 500-µg total protein load per 3-mm gel is desired (a practical maximum load for most whole-cell extracts), the protein concentration determined during the protein assay has to be ≥5 µg/µl. If the sample is less concentrated, the sample volume required will be too large for a 3-mm IEF gel. Alternatively, sample loads can be based on cell numbers, radioactivity, or any other appropriate reference (see Basic Protocol 1, step 22).

PREPARING PROTEINS IN TISSUE SAMPLES

SUPPORT PROTOCOL 5

Tissue samples are usually solubilized in lysis buffer using homogenization. After centrifugation, the protein sample can be loaded onto the first-dimension gel. In general, much higher sample-to-sample variability is expected when tissue samples are analyzed.

Materials

Tissue samples
Lysis buffer (see recipe)

Dounce homogenizer or equivalent
Ultracentrifuge and rotor (e.g., Beckman Ti70), 2°C

1. Place tissue sample in a Dounce homogenizer, add ~2 ml lysis buffer per 100 mg tissue, and homogenize the sample on ice (e.g., 3 to 5 strokes).

2. Let the mixture stand a few minutes, then transfer to an appropriately sized ultracentrifuge tube depending on total sample volume.

POLYTECHNIC UNIVERSITY LIBRARY

3. Centrifuge 2 hr at 100,000 × *g* (e.g., 33,000 rpm in a Beckman Ti70 rotor for 100,000 × *g*), or 1 hr at 200,000 × *g* 2°C.
4. Divide the supernatant into aliquots and freeze at −80°C or immediately load an appropriate volume onto the IEF gel.

BASIC PROTOCOL 3

SECOND-DIMENSION ELECTROPHORESIS OF IEF TUBE GELS

Second-dimension gels are identical to those described in *UNIT 10.1* except for sample loading, which requires a broad, flat well. A broad well can be cast using an appropriate two-dimensional comb if the second-dimension gel thickness is slightly larger than that of the first-dimension gel. Alternatively, when the second-dimension gel is being cast, water can be layered over the entire surface of the gel to produce a flat surface that will accommodate the first-dimension gel.

Narrow analytical isoelectrofocusing gels (≤1.5 mm) that fit between the glass plates of the second-dimension gel do not generally require a stacking gel, although a stacking gel may improve resolution under some circumstances. Stacking gels are essential when first-dimension gels >1.5 mm are loaded on reduced-thickness second-dimension gels, for example, when 3-mm first-dimension gels are loaded on 1.5-mm second-dimension gels. To ensure the best reproducibility, casting multiple second-dimension gels in a multigel casting stand is strongly recommended. This is especially important when gradient gels are used for the second-dimension and/or critical comparisons of multiple samples are planned.

This protocol describes all the specific steps required for successfully casting and running the second-dimension gel. The use of beveled plates and an agarose overlay is especially important when 3-mm IEF gels are loaded onto 1.5-mm second-dimension gels.

Materials

2% (w/v) agarose (see recipe)
Equilibration buffer (see recipe)
Isoelectrofocusing gels containing protein samples to be analyzed (see Basic Protocol 1)
Piece of agarose containing molecular weight standards (see Support Protocol 6)

Beveled glass plates
Boiling water bath
Metal or plastic scoop

Additional reagents and equipment for linear and gradient Laemmli gels (*UNIT 10.1*)

Cast the second-dimension gels

1. Assemble the glass-plate sandwich of an electrophoresis apparatus, using a beveled plate for the shorter side of the gel sandwich.

   A beveled plate provides more space for a thicker IEF gel and will accommodate a first-dimension gel that is at least 1 to 2 mm larger than the thickness of the second-dimension gel.

2. If the thickness of the first-dimension gel exceeds that of the second-dimension gel, pour a separating gel of the desired acrylamide concentration and immediately overlay with water to produce a smooth surface. The separating gel height should be a minimum of 2 cm below the top of the beveled plate to accommodate the stacking gel.

BCU IASI CENTRAL UNIVERSITY LIBRARY

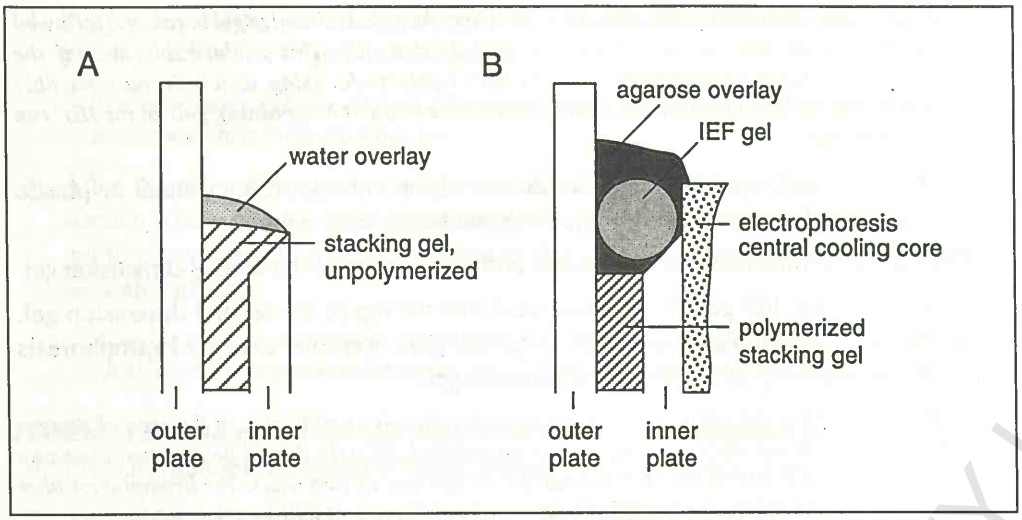

Figure 10.4.2 Casting the second-dimension gel and loading the IEF gel. (**A**) The stacking gel solution should reach to the upper edge of the beveled plate, and then the gel solution has to be overlaid with a minimum volume of water. The water will stay on the surface because of surface tension. (**B**) After polymerization, the gel is mounted on the central cooling core of the electrophoresis unit, and the equilibrated IEF gel is placed on top of the polymerized stacking gel. Excess buffer is removed, and the IEF gel is overlaid with hot agarose/equilibration buffer mixture. After the agarose solidifies, the upper electrophoresis chamber is filled with buffer.

3. After the separating gel has polymerized (a sharp interface between the polymerized gel and the water overlay will reappear), remove the overlay, rinse the gel surface with water, and pour the stacking gel. The stacking gel solution should reach to the top of the bevel. Immediately overlay the stacking gel solution with a minimum amount of water, which will adhere owing to the surface tension (see Fig. 10.4.2A).

   A water overlay of the stacking gel provides a smooth surface and better contact between the IEF gel and second-dimension gel. A small volume of water has to be used to avoid lowering the upper edge of the stacking gel below the edge of the beveled plate. The stacking gel height must be between 1.5 and 2 cm. The solution is filled to the top of the bevel so that after the slight shrinkage that occurs during polymerization the top of the polymerized gel will be near the bottom of the bevel (see Fig. 10.4.2B).

Load the isoelectrofocusing gels onto the second-dimension gels

4. Assemble second-dimension gels in an electrophoresis chamber. Do not pour electrophoresis buffer into the upper chamber.

5. Melt 2% (w/v) agarose in a boiling water bath and add an equal volume of equilibration buffer for use in step 11. Keep agarose/equilibration buffer in the boiling water bath until step 11 is completed.

6. Retrieve isoelectrofocusing gels containing protein samples to be analyzed from storage. Incubate cryotubes containing frozen IEF gels in a 37°C water bath for 15 min for a 3-mm tube gel. A 5- to 7-min incubation is sufficient for 1.5-mm or thinner IEF gels. Do not agitate during thawing, as vigorous agitation of a partially thawed gel can break the gel.

   During this thawing/equilibration step, SDS in the equilibration solution in which the gels were frozen diffuses into the gel matrix and binds to proteins in the IEF gel. The length of incubation in the equilibration buffer is critical because insufficient saturation of proteins with SDS will contribute to vertical streaks on staining. On the other hand, extended incubation in equilibration buffer will result in excessive loss of proteins owing to diffusion of protein out of the gel, which is especially critical for thin IEF gels. For this reason, it is recommended that after extrusion from the IEF tube IEF gels be initially incubated for

BOWMAN-CENTRAL UNIVERSITY LIBRARY

5 min to allow adequate diffusion of glycerol into the gel to minimize gel breakage, followed by freezing on dry ice (see Basic Protocol 1, step 30). This is desirable even if the second-dimension gel will be run directly after isoelectrofocusing, as it is the most feasible way of precisely controlling the equilibration time while the remaining gels in the IEF run are extruded.

7. Pour the gel and equilibration solution out of the cryovial onto a metal or plastic scoop. Carefully remove excess equilibration buffer with a pipet.
8. Place a few milliliters of electrophoresis buffer on the top of the second-dimension gel.
9. Slowly slide the IEF gel off the scoop and onto the top of the second-dimension gel. Remove all air bubbles trapped between the gels. Remove excess electrophoresis buffer from the top of the second-dimension gel.

   The basic end of the gel may be placed on either the left or right side of the second-dimension gel. However, once a convention is established, all gels should be oriented the same way. The acidic end of the IEF gel can be recognized in two ways: the bromphenol blue will usually be yellow, and a bulge (increased gel diameter) will be present.

10. Place a piece of agarose containing molecular weight standards (see Support Protocol 6) beside the basic side of the IEF gel (optional).

    Note that when molecular weight standards are used, the isoelectrofocusing gel has to be shorter than the width of the second-dimension gel.

11. Carefully overlay the IEF gel (and the gel piece with standard proteins) with the hot agarose/equilibration buffer mixture (~2 ml/gel) prepared in step 5. Let the agarose solidify.

    The agarose prevents the IEF gel from shifting position and ensures good contact between the IEF and second-dimension gels.

12. Carefully pour electrophoresis buffer into the upper reservoir, taking care to avoid disturbing the agarose-covered IEF gel.
13. Connect electrodes and run the gels.

    See UNIT 10.1 for electrophoresis conditions.

BASIC PROTOCOL 4

SECOND-DIMENSION ELECTROPHORESIS OF IPG GELS

In this protocol, vertical gel electrophoresis is used as the second dimension for IPG gels in an analogous manner to the protocol described for the second dimension of IEF tube gels (see Basic Protocol 3). One difference is the use of second-dimension gel spacers or gel apparatus that will accommodate an 18-cm-long Immobiline DryStrip; Bio-Rad offers a conversion kit to increase the gel width from 16 cm to 18 cm, and Hoefer Pharmacia offers the Iso-Dalt gel system. The use of beveled plates is not necessary as the 0.5-mm strips are narrower than the second-dimension gel (1.0 or 1.5 mm thick). Another change involves a two-step equilibration of the strips prior to electrophoresis.

Additional Materials (also see Basic Protocol 3)

DryStrip equilibration solutions 1 and 2 (see recipes; prepare fresh in step 4)
Immobiline IPG DryStrip with focused protein (see Basic Protocol 2)
Platform shaker

Cast the second-dimension gel

1. Assemble the glass-plate sandwich of an electrophoresis apparatus, using gel plates wide enough to accommodate an 18-cm-long DryStrip gel.

   Beveled plates are not necessary. If the spacers are not wide enough to accommodate an 18 cm gel, the ends of the gel strip may be trimmed away from the IPG gel so that it will fit on top of the second dimension; however, some very basic or acidic proteins may be lost.

BCU IAS/CENTRAL UNIVERSITY LIBRARY

2. Pour a separating gel of the desired acrylamide concentration and immediately overlay with water to produce a smooth surface.

The separating gel should be a minimum of ~2.5 cm below the top of the inner plate to accommodate a 2-cm stacking gel.

3. After the separating gel has polymerized, remove the water overlay, rinse the gel surface with water to remove any unpolymerized acrylamide, and pour the stacking gel to a height of 0.5 cm from the top of the plate. Overlay with water to produce a smooth surface.

A water overlay provides a smooth surface for better contact between the Immobiline DryStrip and the second dimension gel. The stacking gel height should be ~2 cm.

Load the Immobiline IPG DryStrip gel onto the second-dimension gel

4. Prepare Immobiline DryStrip equilibration solutions 1 and 2 (see recipe).

5. Assemble the second-dimension gels in a electrophoresis chamber. Do not pour electrophoresis buffer into the upper chamber.

6. Melt 2% (w/v) agarose in a boiling water bath. Mix a solution of 1 part 2% agarose to 2 parts equilibration solution 2.

Keep agarose/equilibration buffer mixture in boiling water bath until step 11 is completed.

The agarose prevents the IPG DryStrip from shifting position and ensures good contact between the IEF and second-dimension gels.

7. Using forceps, remove the IPG gels from the electrophoresis tray after isoelectrofocusing is complete or from the –80°C freezer (see Basic Protocol 2, step 19) and place each strip in a separate petri dish with the support film side of the strip facing the petri dish wall. Add 15 ml of DryStrip equilibration buffer 1. Cover and place on a platform shaker for 10 min.

Strips may be run in the second dimension immediately after isofocusing or after storage at –80°C. If the strips have been stored at –80°C, remove them from the freezer, then place in petri dish as stated and continue with the equilibration procedure.

8. Discard equilibration buffer 1 and add 15 ml of equilibration buffer 2. Cover and place on a platform shaker for 10 min.

9. Dampen a piece of filter paper and place on a glass plate. Remove the DryStrips from equilibration buffer 2. Place each strip on its edge on the filter paper to remove any excess buffer.

Strips should not be left in this position for >10 min, or spot sharpness may be affected.

10. Add a small amount of SDS electrode buffer along the glass plate above the second-dimension gel. Place the DryStrip gel in the well with the gel facing out and the basic side to the left. Push the DryStrip down so that it is firmly in contact with the stacking gel of the second-dimension gel. Remove excess running buffer.

11. Overlay the IPG gel strip with the agarose/equilibration buffer (from step 6) and allow agarose to solidify.

12. Carefully pour electrophoresis buffer into the upper reservoir, taking care to avoid disturbing the agarose-embedded IPG DryStrip.

13. Connect electrodes and run the gels.

See UNIT 10.1 for electrophoresis conditions and UNIT 10.5 for gel staining conditions.

BOUVIA SCIENTRA UNIVERSITY LIBRARY

PREPARING MOLECULAR WEIGHT STANDARDS FOR TWO-DIMENSIONAL GELS

Molecular weight markers are usually necessary for the identification of proteins or as references to describe experimental proteins on two-dimensional gels. In many cases, molecular weight markers are required only at the beginning of a project. Once the system is established, common proteins in the sample (e.g., actin or tubulin) provide sufficient references for molecular weight identification on subsequent gels. To minimize any differences in migration of the molecular weight standards and isoelectrofocused proteins, the standard proteins should be loaded on the second-dimension gel in the same manner as the IEF gel. This protocol describes the preparation of standards in solidified agarose. The agarose pieces may be stored at –80°C for at least a year and provide a convenient source of standards for the second-dimension gel. The procedure described is recommended for 3-mm IEF gels. Narrow standards in solidified agarose (made in tubes ≤1.5 mm in diameter) can be prepared by the same method, but extrusion of the thinner agarose gel without breaking is more difficult. The protocol supplies molecular weight markers containing ~2.5 µg of each standard suitable for Coomassie blue staining or 0.25 µg of each standard for silver staining.

Materials

Molecular weight standards (Table 10.1.2)
1× SDS sample buffer (*UNIT 10.1*)
2% (w/v) agarose (see recipe)

Boiling water bath
Glass tubes (3-mm inner diameter)
Plastic or metal tray

1. Prepare 3 ml molecular weight standards in 1× SDS sample buffer using 250 µg of each standard.

   The stated amount is appropriate for Coomassie blue staining of gels. If silver staining is planned, use 25 µg of each standard.

2. Mix the standards with 2 ml of 2% (w/v) agarose melted in a boiling water bath.
3. Prepare clean glass tubes by wrapping one end with Parafilm. Pour the hot mixture into the tubes and let the agarose solidify.
4. Carefully extrude the agarose from the tubes.
5. Cut agarose rods into 5-mm pieces using a razor blade.
6. Freeze all pieces separately on a plastic or metal tray using dry ice.
7. Collect frozen pieces in a plastic bottle and store at –80°C. The standards may be stored ≥1 year.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

DIAGONAL GEL ELECTROPHORESIS (NONREDUCING/ REDUCING GELS)

ALTERNATE PROTOCOL 3

Protein subunit compositions and cross-linked protein complexes can be analyzed by two-dimensional gel electrophoresis using separation under nonreducing conditions in the first dimension followed by reduction of disulfide bonds and separation under reducing conditions in the second dimension. Most proteins will migrate equal distances in both dimensions, forming a diagonal pattern. Proteins containing interchain disulfide bonds will be dissociated into individual subunits and can be resolved in the second-dimension gel.

The approach is similar to that described for two-dimensional gel electrophoresis (see Basic Protocol 3) except, in this protocol, the first-dimension gels are nonreducing (i.e., 2-mercaptoethanol or dithiothreitol is omitted from sample buffer) SDS-denaturing gels instead of isoelectrofocusing gels. Use of 1.2-mm tube gels for the first-dimension separation and 1.5-mm slab gels for the second-dimension run is recommended.

Additional Materials (also see Basic Protocol 3)

Separating and stacking gel solutions (see Table 10.1.1)
1× SDS sample buffer *without* reducing agents (*UNIT 10.1*)
Reducing buffer (see recipe)
1.5% (w/v) agarose in reducing buffer (see recipe; optional, for securing first-dimension gel on second-dimension gel)
Two-dimensional comb (optional)

Additional reagents and equipment for casting tube gels (see Basic Protocol 1), SDS-PAGE (*UNIT 10.1*), and protein staining (*UNIT 10.5*)

Pour and run the first-dimension gel

1. Clean and dry 1.2-mm glass gel tubes for the first-dimension gel (see Basic Protocol 1, step 1).

2. Prepare a separating gel solution with the desired percentage acrylamide (Table 10.1.1); omit the stacking gel for the first dimension.

   Stacking gels can usually be avoided in the first dimension by keeping sample volumes small (i.e., ≤10 µl).

   Less than 200 µl of gel solution is required to cast a single 1.2-mm tube gel 12 cm in length. Adjust the amounts from Table 10.1.1 accordingly.

3. Cast the first-dimension polyacrylamide gels in 1.2-mm tubes using a syringe with a long needle (see Basic Protocol 1, step 5a). Overlay with water and allow the gels to polymerize.

4. Prepare samples in 1× SDS sample buffer without any reducing reagents (i.e., no 2-mercaptoethanol or DTT). Load the samples and electrophorese until the tracking dye is ~1 cm from the bottom of the tube.

Reduce sample and run the second-dimension gel

5. Extrude the gel from the tube (see Basic Protocol 1, steps 27 to 29).

6. Place the extruded gel in a test tube containing 5 ml reducing buffer. Equilibrate 15 min at 37°C with gentle agitation.

7. Cast the second-dimension separating and stacking gels (see Basic Protocol 3, steps 1 to 3), making sure that the top of the stacking gel is at least 5 mm below the top of

BOSTON CENTRAL UNIVERSITY LIBRARY

the short glass plate. Layer water across the entire stacking gel or use a two-dimensional comb.

Most two-dimensional gel combs have a separate small well for a standard or reference sample.

The use of beveled plates (see Basic Protocol 3, steps 1 to 3) is not essential but is still preferred because it will facilitate loading of the first-dimension gel. In this procedure, the first-dimension gel will fit between the glass plates if 1.2-mm tubes are used for the first dimension and 1.5-mm gels are used for the second dimension.

8. Load the first-dimension gel onto the second-dimension gel. Remove any air bubbles trapped between the gels.

   If the first-dimension gel does not remain securely in place, it can be embedded using 1.5% (w/v) agarose in reducing buffer.

9. Carefully pour electrophoresis buffer into the upper electrophoresis chamber and electrophorese using voltages and times appropriate for the gel type selected.

   Parameters for electrophoresis are given in UNIT 10.1.

SUPPORT PROTOCOL 7

USING TWO-DIMENSIONAL PROTEIN DATABASES

Computerized image acquisition and manipulation constitute the only practical method for systematic qualitative and quantitative evaluation of complex protein patterns from different samples that are to be compared by high-resolution two-dimensional gel analysis. Examples of experimental applications include comparisons of tumor cells or tissues with appropriate normal controls and comparisons of a single cell line under different experimental conditions.

There are currently a number of commercially available image acquisition/computer systems specifically designed for comparing two-dimensional gels and storing associated information in a database (*UNIT 10.12*). The systems include both hardware and the necessary software for comparing different gels and producing databases containing the two-dimensional protein patterns, with options for annotating specific spots and producing quantitative comparisons among large numbers of different samples. With most systems, images can be acquired from either stained gels or autoradiographs. The equipment used to obtain two-dimensional gel images includes laser scanners, video cameras, and phosphoimagers. After image acquisition, software running on a microcomputer or workstation is used to refine the image, detect spots, and match spots between different gels.

It is essential that very high-quality, reproducible gels be used for computerized comparisons. The greatest dynamic range in protein abundance for a single two-dimensional gel can be obtained using autoradiography (*UNIT 10.12*) or phosphoimaging. With these methods, up to several thousand spots can be compared and tracked. A representative reference gel or a composite image can be stored and used as a reference for future experiments.

Information related to each spot on the two-dimensional pattern, including the quantity of protein in the indicated spot on different gels used in the comparison, can be archived and updated. Other known information related to a specific spot can also be added to the investigator-built database, including the pI, molecular weight, amino acid composition, sequence, and/or identity of the protein and any other important attributes correlated with the indicated spot. A number of research groups, including those of Garrels and Celis (Garrels, 1989; Garrels and Franza, 1989; Celis et al., 1991), have extensively characterized hundreds of spots from specific cell lines and have used multiple methods to characterize proteins of interest. The most definitive methods for establishing the identi-

BCU IASI / CENTRAL UNIVERSITY LIBRARY

ties for proteins of interest detected by computer-assisted comparisons are protein sequence analysis and, more recently, mass spectrometry of tryptic fragments. Both methods are compatible with the quantities of protein that can be recovered from two-dimensional gels.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

30% acrylamide/0.8% bisacrylamide

30 g acrylamide
0.8 g bisacrylamide
H_2O to 100 ml

Filter solution through 0.2- to 0.45-µm filter (e.g., Micro Filtration Systems, cellulose nitrate, 0.2 µm). Store at 4°C (stable at least 3 months).

Acrylamide is a neurotoxin. Wear gloves and a dust mask when handling solid acrylamide. Wear gloves when working with acrylamide solution. Never pipet acrylamide solutions by mouth.

Agarose in reducing buffer, 1.5% (w/v)

Mix 0.15 g agarose and 10 ml reducing buffer (see recipe). Heat in boiling water bath until dissolved. Prepare immediately before use.

Agarose, 2% (w/v)

Mix 2 g agarose and 100 ml water. Stir on a hot plate until dissolved. Keeping the solution near 100°C, divide by placing 5-ml aliquots in 25-ml glass screw-cap tubes. Let the aliquots solidify. Store at 4°C (stable at least 3 months).

Ammonium persulfate, 2.5% (w/v)

0.25 g ammonium persulfate
H_2O to 10 ml
Prepare immediately before use

DNase and RNase solution

Mix 2.50 ml of 1 M Tris·Cl, pH 7.0 (*APPENDIX 2E*), 250 µl of 1 M $MgCl_2$, (*APPENDIX 2E*), and 2.2 ml water. Add to 5 mg DNase (Worthington) and dissolve DNase. Add 2.5 mg RNase (in solution; Worthington). Mix well, divide into 50- or 100-µl aliquots, and store at –80°C (stable at least 1 year).

The volume of RNase solution needed is variable and depends on the protein concentration, which is reported on the vial label (in mg/ml). The volume of RNase added should be less than 200 µl; if a larger volume is used, the amount of H_2O should be decreased proportionally.

Final concentrations are 0.5 M Tris·Cl, pH 7.0, 0.1 M $MgCl_2$, 0.1% (w/v) DNase, and 0.05% RNase.

DryStrip equilibration solutions

20 ml 1 M Tris·Cl, pH 6.8 (*APPENDIX 2E*)
72 g ultrapure urea
60 ml glycerol
2 g sodium dodecyl sulfate (SDS)
67 ml Milli-Q water
For solution 1: Add 50 mg DTT per 10 ml of equilibration buffer
For solution 2: Add 0.45 g iodoacetamide and a few grains bromphenol blue per 10 ml of equilibration buffer
Make fresh immediately before use

BOSTON / CENTRAL UNIVERSITY LIBRARY

Final concentrations are 50 mM Tris·Cl, pH 6.8; 6 M urea; 30% glycerol; and 1% SDS, in a final volume of 200 ml.

EDTA, 2% (w/v)

2 g Na_2EDTA
H_2O to 100 ml
Adjust to pH 7.0 with NaOH
Store at room temperature (stable several months)

Titrate while dissolving. EDTA is difficult to dissolve without addition of NaOH even when the disodium salt is used.

Equilibration buffer

3 g SDS
7.4 ml 2% (w/v) EDTA, pH 7.0 (see recipe)
10 ml glycerol
2 ml 1.0 M Tris·Cl, pH 8.65 (*APPENDIX 2E*)
0.3 ml bromphenol blue (saturated solution in H_2O)
H_2O to 100 ml
Store at room temperature (stable for several weeks)

Final concentrations are 3% (w/v) SDS, 0.4 mM EDTA, 10% (v/v) glycerol, and 20 mM Tris·Cl, pH 8.65.

Leupeptin, 2 mg/ml

20 mg leupeptin
10 ml water
Divide into convenient volumes
Store at –20°C (stable at least 1 year)

Lysis buffer

2.59 g urea (ultrapure)
1.6 ml H_2O
0.25 ml 2-mercaptoethanol
0.3 ml ampholytes
1.0 ml 20% (w/v) Triton X-100 solution (see recipe)
Prepare immediately before use

Use same ampholytes as for the IEF gel formulation. To dissolve urea, warm the mixture in a 30°C water bath if necessary.

Orthophosphoric acid (H_3PO_4), 0.1 M

13.7 ml 85% phosphoric acid
Water to 2 liters
Make fresh daily

Must be degassed prior to use.

PBS, 10×

152 g NaCl
24 g monobasic sodium phosphate, anhydrous
1600 ml H_2O
Adjust pH to ~6.7 with NaOH
Add H_2O to 2 liters
Store at room temperature (stable at least 1 month)

The 1× solution should be pH 7.3 to 7.5. Final concentrations are 130 mM NaCl and 10 mM sodium phosphate.

BCU IASI CENTRAL UNIVERSITY LIBRARY

PBS with proteolysis inhibitors (PBS/I buffer)

20 ml 10× PBS (see recipe)
20 ml 2% (w/v) EDTA, pH 7.0 (see recipe)
200 µl 0.15 M phenylmethylsulfonyl fluoride (PMSF) in 2-propanol
100 µl 2 mg/ml leupeptin (see recipe)
200 µl 1 mg/ml pepstatin (see recipe)
Adjust to pH 7.2 with HCl
Add H_2O to 200 ml
Prepare immediately before use

Diisopropyl fluorophosphate (DFP) is a better serine protease inhibitor than PMSF at lower temperatures (0° to 4°C); however, although both compounds are toxic, exceptional caution must be exercised with DFP owing to its volatility. If DFP is used, work in a chemical fume hood and carefully follow the supplier's precautions. DFP and PMSF have half-lives on the order of hours in aqueous neutral solutions, and the degradation rate increases rapidly as the pH is increased above neutral. Make aqueous solutions immediately before use. Use of 1 M NaOH is convenient to inactivate residual DFP or PMSF.

Final concentrations are 10 mM sodium phosphate, 130 mM NaCl, 0.2% EDTA, 0.15 mM PMSF; 1µg/ml leupeptin, and 1 µg/ml pepstatin.

Pepstatin, 1 mg/ml

10 mg pepstatin
10 ml anhydrous ethanol
Divide into convenient volumes
Store at –20°C (stable at least 1 year)

Thaw aliquots and mix well immediately before use.

Reducing buffer

0.5 g dithiothreitol (DTT)
0.1 g SDS
1.51 g Tris base
Adjust to pH 6.8 with HCl
Add H_2O to 100 ml
Prepare fresh every time

Final concentrations are 0.5% (w/v) DTT, 0.1% (w/v) SDS, and 125 mM Tris·Cl, pH 6.8.

Tris/SDS buffer

0.3 g SDS
0.6 g Tris base
Adjust to pH 8.0 with HCl
Add H_2O to 100 ml
Divide into 5-ml aliquots
Store at –80°C (stable at least 1 year)

Final concentrations are 0.3% (w/v) SDS and 50 mM Tris·Cl, pH 8.0.

Triton X-100 solution, 20% (w/v)

3 g Triton X-100
12 ml H_2O
Warm in 37°C water bath to dissolve Triton X-100
Store at 4°C (stable ~2 weeks)

Urea, 8 M

0.75 g ultrapure urea
1.0 ml H_2O
Prepare immediately before use

Avoid heating above room temperature.

BOU INST CENTRAL UNIVERSITY LIBRARY

COMMENTARY

Background Information

Two-dimensional gel electrophoresis, using isoelectricfocusing followed by SDS-PAGE, is the single most powerful analytical method currently available for separating complex protein mixtures such as whole-cell or tissue extracts. It is therefore a valuable method for following disease-related changes or for detecting changes in protein expression under diverse experimental conditions. To achieve maximum reproducibility between samples to be compared, multiple gels should be cast and run simultaneously (Anderson and Anderson, 1978a,b).

Despite the exceptionally high resolving power of the method, the total number of proteins that can be resolved in a single two-dimensional gel is only ~1000 to 2000, whereas the total number of proteins in a single mammalian cell type is likely to be at least 10 to 20 times higher. Therefore, the old guideline that a single spot on a two-dimensional gel is a single protein needs to be revised as analytical detection methods improve. Conversely, a single protein (single gene product) can produce multiple, usually adjacent spots in the isoelectrofocusing dimension owing to variable degrees of chemical or post-translational modification. Common examples of variable post-translational modifications that can usually be detected on two-dimensional gels include phosphorylation and glycosylation. Examples of chemical modifications that cause charge heterogeneity include deamidation of side-chain amines (usually asparagines), oxidation of sensitive side chains, and modification of lysines. Potential modification of lysines by urea is particularly important because urea rapidly decomposes to form cyanate, which readily reacts with amino groups, especially above pH 7. Despite potential side reactions, urea is the most useful IEF additive for maintaining solubility of proteins near their isoelectric points.

Combined with electroblotting to PVDF membranes, two-dimensional PAGE has become a valuable preparative tool for protein isolation in addition to its historical role as an analytical method. The sensitivity of many protein analysis methods has improved to the point where one or several spots from two-dimensional gels are sufficient for N-terminal or internal sequence analysis.

Commercially available equipment for running two-dimensional gels can be divided into four groups based on size: microgels (Hoefer Pharmacia Phast system), minigels (e.g., Bio-Rad or Hoefer Pharmacia), standard or full-sized gels (e.g., Bio-Rad or Hoefer Pharmacia), and large or "giant" gels (ESA Investigator 2D gel system or Hoefer Pharmacia Iso-Dalt gel system). In general, the larger the gel, the better the final resolution, but as gel size increases so do costs, difficulty of gel handling, and time requirements.

Standard-size gels provide adequate resolution for most applications and are relatively easy to handle. A 3-mm soluble ampholyte tube IEF gel or a 0.5 mm × 3 mm × 18-cm Immobiline gel has a total protein capacity of ~500 µg for complex protein mixtures such as whole-cell extracts. The maximum capacity for any single protein spot is ~0.5 to 5 µg, depending on the solubility of the protein near its isoelectric point and the separation distance from any near neighbors. A variety of alternative gel sizes, their limits, and their advantages are summarized in Table 10.4.2. The lower protein limit for any of the systems is determined strictly by the available detection methods (*UNIT 10.5*).

Proteins can be detected in two-dimensional gels by the same wide range of techniques used for one-dimensional gels. Autoradiography (*UNIT 10.11*), silver staining (*UNIT 10.5*), and electroblotting to PVDF membranes (*UNIT 10.7*) followed by colloidal gold or colloidal silver staining (*UNIT 10.8*) or immunodetection (*UNIT 10.10*) are among the most sensitive techniques available. If a larger amount of protein is available, Coomassie blue staining of the gel (*UNIT 10.5*) or amido black staining of a PVDF membrane after electrotransfer (*UNIT 10.8*) would be the detection methods of choice.

The major technical limitation in two-dimensional gel electrophoresis is gel-to-gel variation. Even when extreme care is exercised to produce highly reproducible first- and second-dimension gels, some gel-related variability among gels cast at the same time is likely to persist. Another source of variability includes differences in extraction or recovery of proteins during sample solubilization and handling. Maximizing resolution and reproducibility is especially important if computerized comparisons of two-dimensional gels of complex protein mixtures such as cell or tissue extracts are being attempted.

BCU IAS/CENTRAL UNIVERSITY LIBRARY

Table 10.4.2 Size Options for Two-Dimensional Gel Electrophoresis

Gel type	First-dimension gel		Second-dimension gel[a]		Purpose	Comments[b]
	Diameter *D* (mm)	Length *L* (cm)	Thickness *T* (mm)	Height *H* (cm)		
Microgels/minigels[c]	<1.5	<10	<*D*	<10	Analytical	1-4
	<1.5	<10	>*D*	<10	Analytical	3-6
	>1.5	<10	<*D*[d]	<10	Analytical/preparative	1,2,7,8
Full-size gels[e]	<1.5	12-18	<*D*	12-18	Analytical	1-4
	<1.5	12-18	>*D*	12-18	Analytical	3-6
	>1.5	12-18	<*D*[d]	12-18	Analytical/preparative	1,2,7,8
Giant gels[f]	<1.5	>20	>*D*	>20	Analytical	4-6,9
	>1.5	>20	<*D*[d]	>20	Analytical/preparative	1-3,7

[a]The second-dimension gel width has to be at least equal to the IEF tube gel height.

[b]Key to comments: (1) tube gel cannot be placed directly on top of second-dimension gel, and use of agarose is recommended; (2) use of stacking gel is recommended; (3) extrusion and handling are relatively difficult; (4) total protein load is limited to usually ≤50 µg for whole-cell or tissue extracts; (5) tube gel can be placed directly on top of second-dimension gel, and use of agarose is not necessary; (6) use of a stacking gel is not necessary; (7) total protein load capacity is relatively large; (8) extrusion and handling are relatively simple; (9) extrusion and handling are very difficult.

[c]Minigel systems provide rapid separations with moderate resolution. Microgels (Phastgels) are precast gels that are slightly smaller than most minigels.

[d]Use of second-dimension gels thicker than 1.5 mm is generally not recommended owing to difficulty with either efficient staining or efficient electroblotting.

[e]Full-size gels provide resolution satisfactory for most applications.

[f]Giant gels provide very good resolution. Specialized equipment is required, such as Investigator 2D (ESA), Iso-Dalt (Hoeffer Pharmacia), or homemade giant-size gel systems.

Isoelectrofocusing using soluble ampholytes

Soluble ampholytes are mixtures of low-molecular-weight organic compounds with differing side-chain pK_a values that provide buffering capacity. In an IEF gel, the ampholytes migrate to their isoelectric point, where they provide buffering capacity and hence produce stable pH gradients. In theory, any desired pH gradient could be produced by blending ampholytes with appropriate pK_a values. In practice, it is relatively easy to produce pH gradients from ~pH 3.0 or 4.0 to pH 8.0, but stable soluble gradients outside this range are usually not technically feasible. Within these pH limits, some manipulation of the gradient shape and pH range is possible by blending different amounts of specific pH range ampholytes. For example, 0.50 ml of pH 5-7 ampholytes plus 0.25 ml of pH 4-8 ampholytes can be used instead of 0.75 ml of pH 4-8 ampholytes alone to increase the separation distance of proteins in the pH 5.0 to 7.0 range.

Basic Protocol 1 is based on use of 3-mm first-dimension isoelectrofocusing gels and 1.5-mm second-dimension gels using the Bio-Rad two-dimensional gel apparatus (Protean II xi 2D). The method can be easily adapted to equipment from other suppliers or to different-sized gels by adjusting the quantities of reagents used. The protocol uses 8 M urea and Triton X-100 as solubilizing agents. Solubilization of the protein sample applied to the gel as well as maintenance of solubility during electrofocusing are the most critical factors influencing the quality of separation in the first dimension. The most common modification to Triton X-100–based procedures is addition of 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS) to the gel and solubilizing buffer mixtures. Addition of SDS to complex samples such as tissue or cell extracts can also enhance reproducible solubilization of the largest possible subset of proteins. Although SDS is charged, in the presence of Triton X-100 it is separated from proteins during focusing and migrates to the acidic end of the gel. Regardless of the method used to maintain solubility, some proteins (especially those >100 kDa) tend to precipitate at pH values approaching their isoelectric point and thus produce horizontal smears on the final second-dimension gel.

BOWMAN GRAY SCHOOL OF MEDICINE LIBRARY

Table 10.4.3 Commercially Available Precast IPG Gels and Immobiline Chemicals[a]

Name	Use	Available pH range
Immobiline DryPlate	Running one-dimensional immobilized pH gradient gels	pH 4.0-7.0, pH 4.2-4.9, pH 4.5-5.4, pH 5.0-6.0, pH 5.6-6.6
Immobiline DryStrip	Running first dimension in two-dimensional gels	
110 mm		pH 4-7L, pH 3-10L
180 mm		pH 4-7L, pH 3-10L[b], pH 3-10NL[c]
Immobiline II	Creating custom gradient immobilized pH gradient gels	pK 3.6, pK 4.6, pK 6.2, pK 7.0, pK 8.5, pK 9.3

[a]From Hoefer Pharmacia.

[b]A linear gradient with maximum resolution above pH 7.0.

[c]A nonlinear gradient with best resolution at pH 5.0-7.0.

Basic Protocol 1 requires several modifications for successful separation of very acidic (Alternate Protocol 1) or very basic (Alternate Protocol 2) proteins. In both cases, prefocusing of the gels must be avoided, and the isoelectrofocusing time has to be reduced. A short separation time does not allow the system to reach equilibrium and is used to establish the desired pH gradient. Separation of very acidic proteins requires modifications of gel and electrode solutions. Separation of very basic proteins has to be performed with the positions of electrodes and electrode solutions reversed in the electrophoresis chamber.

The total protein load per gel depends on the complexity of the sample, the solubility of proteins in the sample, and the diameter of the first-dimension gel. Approximately 4 times as much total sample can be applied to a 3-mm gel compared with a 1.5-mm gel. Another advantage of a larger-diameter isoelectrofocusing gel is that extrusion and gel handling are easier owing to improved strength of the gel. If care is exercised in loading the first-dimension gel onto the 1.5-mm second-dimension gel, the final resolution will be similar to that obtained using smaller-diameter IEF gels. The separating or resolving power of a system is dependent on the quality of ampholytes used, the slope of the pH gradient, and the lengths of both first- and second-dimension gels.

Immobilized pH gradient gels

In immobilized pH gradient (IPG) gels (Basic Protocol 2), the pH gradient is an integral part of the polyacrylamide matrix (Strahler and Hanash, 1991). Because the pH gradient is covalently associated with the polyacrylamide gel matrix, precise, reproducible, and very high-resolution separations can be achieved. A variety of precast gels and all the necessary equipment are commercially available from Hoefer Pharmacia. Reproducible two-dimensional gels can be obtained by running a sample on a narrow strip of immobilized pH gradient gel and then running it in a vertical SDS second-dimension gel. Isoelectrofocusing is performed in a horizontal electrophoresis unit in which multiple gel strips may be run simultaneously. Equipment and reagents are also available for the user to cast custom Immobiline gels in the laboratory.

Some of the major advantages of using precast IPG gels are their ease of use and high reproducibility, the time savings realized, and the fact that precision narrow-range gradients can be used to resolve small charge differences. Because the pH gradient is covalently coupled to the polyacrylamide gel matrix, the pH gradient remains stable and linear during prolonged electrophoresis, thus ensuring reproducibility. This is in contrast to conventional IEF gels, where gradient drift occurs during prolonged electrophoresis. Additionally, the precast gels can be rehydrated in water or in solutions with one or more additives such as urea, CHAPS or Triton X-100, carrier ampholytes, glycerol, and reducing agents, which may help to increase protein solubility. Precast gel strips are available with pH ranges such as pH 3.0 to 10.0 or pH 4.0 to 7.0 as well as narrower ranges (as DryPlates). In addition, a variety of Immobilines permits the user to cast IPG gels with customized pH gradients of any gradient range and shape between pH 3.0 and pH 10.0.

Table 10.4.3 lists types of commercially available gels and Immobilines. With the Immobiline system, the apparent pI of a given protein may be slightly different from that determined by other methods. Therefore, it is

BCU IASE / CENTRAL UNIVERSITY LIBRARY

recommended that a broad-range gradient be tried initially, followed by a narrower-range gradient, if needed.

Diagonal gel electrophoresis

Diagonal gel electrophoresis is a form of two-dimensional analysis useful for investigating the subunit composition of multisubunit proteins containing interchain disulfide bonds (Goverman and Lewis, 1991). Proteins are electrophoresed in the first-dimension in a tube gel (or a slab gel) under nonreducing conditions. The proteins are then reduced in situ, and the first gel (or a strip thereof) is layered onto a second gel and electrophoresed. In the second gel, the proteins migrate at right angles to the original, first-dimension migration. Most cellular proteins are not disulfide-linked and will fall on the "diagonal" in this system; that is, they migrate approximately equal distances in both directions during electrophoresis and lie approximately on the diagonal line connecting opposite corners of the gel. On reduction, component subunits of proteins connected by interchain disulfide bonds will resolve below the diagonal because the individual subunits migrate faster than the disulfide-linked complex during the second electrophoresis. Some proteins with internal disulfide bonds, but no interchain disulfides, may migrate slightly above the diagonal because internal disulfides can produce a more compact molecular shape (causing faster migration in the first dimension).

Investigator 2D gel system

The Investigator 2D gel system was introduced in 1990 by Millipore as the first commercial "large" or "giant" format two-dimensional gel system designed for analytical purposes, although analogous homemade units had been reported earlier (Garrels, 1979; Young et al., 1983). This product line, including precast first- and second-dimension gels, can now be purchased from ESA. The Investigator 2D gel system uses larger gel sizes than the gels described in this unit as well as a number of novel approaches and reagents designed to enhance resolution and gel-to-gel reproducibility. The major features of this system include the following: an increased length of the first-dimension gel (20 cm), an increased length and width of the second-dimension gel (20 × 22 cm), a thread reinforcement of the isoelectrofocusing gel, temperature control during electrophoresis of the second-dimension gel, and use of a special high-tensile-strength acrylamide to facilitate handling of the large, thin second-dimension gel. Narrow gel tubes (1.2 mm) for the first-dimension are standard, but 3-mm-inner-diameter tubes are available to accommodate larger protein loads. The 3-mm IEF gels do not have the thread reinforcement. One modification related to the above protocol includes addition of 0.3% (w/v) CHAPS in the gel solution, which is intended to improve the solubility of proteins and their migration and separation in the gel. The system is supplied with a manual that adequately describes the method.

Critical Parameters and Troubleshooting

Although no individual steps in two-dimensional gel analysis are exceptionally difficult, the large number of steps involved increase the likelihood and possible severity of errors or problems. Several steps are especially critical and may require optimization. The first is sample preparation. Proteins applied to IEF gels have to be completely solubilized. Residual precipitate or even soluble aggregates are likely to cause artifacts on the end of the tube gel or position on the IPG strip where the sample is loaded. Precipitated or aggregated proteins may also interact with soluble proteins, causing components with normally good solubility to coprecipitate or migrate anomalously.

Two general rules of thumb apply to sample solubility: (1) the more complex the sample or the more crude the extract, the more likely problems will be encountered with sample solubility, and (2) the higher the protein load applied to the gel, the more likely solubility problems will arise. Care must also be taken to avoid proteolysis during sample preparation, especially when complex, impure samples are used. If samples are frozen either before or after solubilization, they should be stored at –80°C and should not be subjected to repeated freeze-thawing. Addition of SDS to the solubilization solution increases the solubilization of some proteins; however, SDS should only be used when the IEF gels contain urea and Triton X-100, as the solubilizing agents are required for effective separation of the strongly anionic SDS molecules from the proteins during isoelectrofocusing. Heating of samples in urea-containing solutions must be avoided because urea readily decomposes to cyanate, which reacts with amino groups and causes charge heterogeneity. High concentrations of salts and buffers in the sample should be avoided. Ionic compounds increase the conductivity of the sample and can result in localized overheating, especially for Immobiline gels.

UCSD CENTRAL LIBRARY

Samples analyzed on immobilized pH gradient gels should not contain precipitates. The concentration of salts and buffer ions in the sample should be kept to a minimum (<50 mM) to avoid local overheating of the gel during electrophoresis. If the sample forms aggregates or precipitates at the point of application, apply the sample to a different location (different pH) on the gel.

Early decisions that must be made include the size of the gels required and whether a soluble ampholyte system or an Immobiline gel will be used. The major consideration affecting appropriate gel size is the degree of resolution needed. In general, the smallest gel format should be selected that will provide the needed degree of resolution, because smaller gels are easier, less expensive, and faster to run. Therefore, quick screening of samples or analysis of relatively simple samples can easily be accomplished with microgels or minigels. In contrast, if detailed qualitative or quantitative comparisons of cell or tissue extracts are planned, standard-size or large gels are indicated. Similarly, 3-mm or larger first-dimension tube gels followed by 1.5-mm second-dimension gels in the standard or large format are indicated if the two-dimensional gels will be used for preparative isolation of a protein for applications such as raising antibodies or conducting structural analysis. Immobilized pH gradient gels should very seriously be considered as an alternative to soluble ampholyte gels for most separations owing to their stable and reproducible pH profiles. The IPG gels are particularly appropriate when a narrow pH range is required.

Immobilized pH gradient gels are typically run at 2500 to 3500 V and typically require a focusing time of 16 to 18 hr. Optimal focusing conditions may be experimentally determined by applying the sample to different positions on the gel and estimating the time for the migration patterns to coincide. Some proteins may require longer run times to reach their pI. Because there is no gradient drift, the potential problems with longer run times are limited to sample denaturation or drying out of the gel. These problems usually can be minimized by including a reducing agent in the rehydration solution and/or coating the top surface of the gel with paraffin oil.

The quality of the first-dimensional separation is strongly dependent on the purity of the reagents used, especially the urea and ampholytes. One fairly commonly encountered frustration, when soluble ampholyte gels are used, is that different batches of ampholytes from the same supplier will sometimes produce markedly different two-dimensional gel patterns. Therefore, it is advisable to purchase an adequate supply of a single lot of ampholytes to meet anticipated needs for an entire study where such an approach is feasible. However, whereas ampholytes usually have a reasonably long shelf life at 4°C (usually up to a year), shelf life as well as total ampholyte requirements often cannot be predicted with much certainty.

When any doubt arises about the purity or quality of ampholytes or any other reagent, the reagent should be replaced immediately. Constant monitoring of the system performance, especially when changing lots of ampholytes, urea, or acrylamide, can help minimize potential reagent-associated problems. In most cases, the best standard for a given two-dimensional gel system is an experimental sample or control that is available in sufficient quantity so that many replicate aliquots can be frozen and stored for an extended time at –80°C; alternatively, a sample that can be reproducibly prepared over a long time frame would make an acceptable standard. Such an experimental standard or reference is more likely to detect subtle, but experimentally important, changes in the two-dimensional gel system than commercially available IEF or SDS gel standard mixes.

Another critical factor is equilibration of the first-dimension gel in the second-dimension equilibration buffer. During this step, urea diffuses out of the IEF gel while SDS and reducing reagent diffuse into the gel. If the gel is inadequately saturated with SDS, vertical streaking will result. However, if the gel is incubated in the equilibration buffer for an extended time, a substantial amount of the protein can rapidly diffuse out of the large-pore IEF gel. Losses arising from diffusion can be critical for any experiment because different proteins will diffuse at different rates, but rigorous control of the incubation step is especially important if quantitative comparisons among gels are planned. The simplest method of controlling the incubation time is to freeze the extruded IEF gel after a carefully controlled 5-min incubation in the equilibration buffer; any additional equilibration incubation time required can then be incorporated and carefully controlled when the sample is thawed for loading onto the second-dimension gel.

Another crucial step is loading of the equilibrated IEF gel onto the top of the second-dimension gel. Any irregularity or obstruction between the two gels, including particles of dirt or air bubbles, will affect the flow of current

BCU IAS / CENTRAL UNIVERSITY LIBRARY

and disrupt the resolution of proteins in the final gel. Similarly, poor contact or any movement of the IEF gel during electrophoresis of the proteins out of the IEF gel into the second-dimension gel will lead to artifacts. Therefore, it is advisable to embed the IEF gel in a buffered agarose matrix to ensure good electrical contact between the gels and to prevent gel movement after electrophoresis is initiated.

Finally, the choice of second-dimension gel composition and separation conditions can influence the quality of results. A proper percentage of acrylamide should be selected to optimize resolution within the desired molecular mass range. If gradient gels are needed, use of a multiple gel casting stand is the best way to ensure reproducibility among samples within a single experiment. Further details on optimization of two-dimensional gel systems are presented by Hochstrasser et al. (1988).

When no technical, sample-related, or reagent-related problems are encountered, the final stained two-dimensional gels should contain numerous rounded or slightly elliptical spots. Typically, more than 1000 spots can be detected on a standard 16 × 14–cm gel when using a sensitive staining protocol such as silver staining or autoradiography and a whole-cell extract as a sample. Some horizontal streaks for most high-molecular-mass proteins (proteins exceeding ~100 kDa) are common owing to the decreased solubility of larger proteins near their isoelectric points, even in the presence of urea and nonionic detergent. However, excessive horizontal smearing of proteins smaller than 100 kDa indicates poor isoelectrofocusing, which could be related to one or more of the following factors: sample improperly solubilized or contaminated with interfering substances such as large nucleic acid molecules, poor purity of reagents (check the urea first), poor-quality ampholytes, or insufficient isoelectrofocusing (total volt-hours too low). It is important to note that in general the solubility of any protein is the lowest near its isoelectric point, but there are vast differences among proteins in terms of both the minimum concentration where precipitation becomes a problem and the degree to which precipitation can be prevented by adding different solubilization agents. The best conditions for maintaining solubility during isoelectricfocusing for a given sample type must be determined empirically, although the most universal conditions are those described in the protocols in this unit. In contrast, IEF systems that do not use any detergents or denaturants are limited to that fairly small percentage of proteins which maintain good solubility near their isoelectric point.

If high-molecular-weight proteins are expected but are not present in the final two-dimensional gel, check the sample preparation protocol as well as the sample storage conditions. The most likely problem is proteolysis during sample preparation. Multiple freeze-thawing cycles could contribute to this problem. Vertical smears on the two-dimensional gel suggest (1) insufficient equilibration of the IEF gel (not enough SDS bound to the proteins), (2) poor contact between the IEF and second-dimension gels, or (3) problems related to the stacking gel (too short or wrong buffer). Use of a stacking gel is especially important when large-diameter IEF gels are loaded onto smaller second-dimension gels.

Omission of Triton X-100 or other nonionic or zwitterionic detergent from the final sample loaded on the gel can yield poor results, especially for samples containing SDS, because the amount of detergent in the IEF gels alone may be insufficient to remove bound SDS from proteins. The presence of Triton X-100 in the sample is especially important when SDS sample buffer is used to solubilize protein samples (i.e., after immunoprecipitation). The amount of Triton X-100 in the lysis buffer is normally sufficient for effective dissociation of SDS from proteins. If poor results are encountered with SDS-containing samples, try decreasing the final SDS concentration and/or increasing the final Triton X-100 concentration in the sample.

If no proteins are detected on the gel, check whether (1) the total protein load is appropriate for detection method used, (2) the orientation of electrical connections is wrong or electrical connection during isoelectrofocusing is poor (all gels from that run will be blank), (3) an air bubble obstructs current in a single IEF tube, or (4) the electrical connection is incorrect or is poor during the second-dimension gel separation. Careful monitoring of current and voltage at the beginning, during, and at the end of electrophoretic separations is strongly recommended. Recording the initial and final current and voltage will also facilitate troubleshooting. Additional guidelines for troubleshooting and evaluating artifacts in two-dimensional gel electrophoresis are described by Dunbar (1987).

Anticipated Results

A two-dimensional electrophoretic separation of proteins should produce a pattern of round or elliptical spots separated from one another.

BOSTON CENTRAL UNIVERSITY LIBRARY

The pI range of the separated proteins as well as the observed molecular weight range depend on the first-dimension isoelectrofocusing protocol and the percentage of acrylamide used for the second-dimension gel. A complex protein mixture such as a whole-cell extract should produce more than 1000 silver-stained spots distributed over most of the gel area. Fewer spots will be detected with less sensitive detection techniques such as Coomassie blue staining. On the other hand, separation of radiolabeled proteins and use of multiple exposures permit detection of many low-abundance proteins.

Time Considerations

Time requirements are very dependent on gel size and whether an external cooling unit is used to permit faster separations. Isoelectricfocusing using the standard-size gel format described in Basic Protocol 1 with 3-mm tubes is most conveniently done in an overnight run of ~16 to 18 hr. This separation time can be decreased to ~5 to 6 hr using higher voltages and an external cooling device. Isoelectrofocusing of 18-cm-long IPG gels requires ~16 to 18 hr. Extruding a set of sixteen IEF tube gels and freezing them in equilibration buffer takes 1 to 2 hr, including setup time. Preparing and running SDS gels is described in *UNIT 10.1*. It takes ~30 min to thaw, equilibrate, and load two second-dimension gels.

Overall, if standard-size gels are used without external cooling, it will take ~3 working days before the results of two-dimensional electrophoresis are obtained. A single person can conveniently run about 16 two-dimensional gels in one week, depending on the amount of electrophoresis equipment available. The rate-limiting step in most laboratories is running the second-dimension gels because 16 soluble ampholyte IEF gels or 12 IPG gels can be focused in one run, but loading, running, and detecting results from 12 to 16 second-dimension gels requires substantial operator time and electrophoresis equipment.

Protein Detection in Gels Using Fixation

Detection of proteins in polyacrylamide gels is essential for purification and analysis of proteins. This unit presents basic protocols for detection of proteins by Coomassie blue staining and silver staining. All protocols involve fixing the protein within the gel. Alternate protocols for Basic Protocol 1 detail rapid Coomassie blue staining (Alternate Protocol 1), which is slightly less sensitive, and acid-based Coomassie blue staining (Alternate Protocol 2), which avoids the need for destaining. Basic Protocol 2 for silver staining is accompanied by three alternate protocols: nonammoniacal silver staining (Alternate Protocol 3), which uses more stable solutions; rapid silver staining (Alternate Protocol 4), which involves fixation with formaldehyde instead of glutaraldehyde; and the enhanced-background, two-stage method (Alternate Protocol 5), which employs fixation without cross-linking to enhance sensitivity and also includes an optional reduction step to reduce background staining. A Support Protocol for gel photography is provided as well.

The protocols in this unit and *UNIT 10.6* require proteins that have been previously separated by one- or two-dimensional electrophoresis (*UNITS 10.1-10.4*). Coomassie blue staining is relatively quick and inexpensive, whereas silver staining is considerably more expensive but between 10 and 100 times more sensitive. When subsequent removal of the protein from the gel is desired, detection methods without fixation should be used (*UNIT 10.6*).

COOMASSIE BLUE R-250 STAINING

BASIC PROTOCOL 1

Coomassie brilliant blue R-250 binds nonspecifically to almost all proteins, which allows detection of protein bands in polyacrylamide gels. In this procedure, proteins separated on a polyacrylamide gel are simultaneously fixed and stained in the Coomassie blue staining solution, which turns the entire gel blue. Destaining eliminates the background while the protein bands retain the blue color. Gels can be photographed or dried to maintain a permanent record. Alternatively the "wet" gel can be sealed in a plastic bag with a small amount of destaining solution and stored for many months at 4°C.

Materials

Coomassie blue R-250 staining solution (see recipe)
Polyacrylamide gel containing protein of interest (*UNITS 10.1-10.4*)
Destaining solution: 15% methanol/10% acetic acid (v/v; store up to 1 month at room temperature)
7% (v/v) acetic acid (optional)
Protein-based destaining material (optional): white 100% wool yarn, cellulose sponge, *or* Whatman 3MM filter paper
Gel dryer (optional)

NOTE: Only high-purity water such as Milli-Q-purified water or equivalent should be used throughout the protocol, unless otherwise specified.

1. Add ~10 gel volumes Coomassie blue R-250 staining solution to a plastic or glass container with lid.
2. Remove polyacrylamide gel from the electrophoresis unit and place in staining solution, then place container on a platform shaker and agitate gel slowly to prevent it from adhering to the container.

   CAUTION: *Rapid agitation can result in gel breakage.*

BOSTON GENERAL UNIVERSITY LIBRARY

The appropriate length of time to stain a gel depends on the gel thickness as well as the percentage of acrylamide. In general, gels ≤1 mm thick require only 30 min to 1 hr of staining, whereas gels >1 mm thick require a minimum of 1 to 3 hr of staining. Also, the higher the percentage of acrylamide, the longer it will take to stain the gel. Gels can be left in staining solution overnight without adverse effects.

3. Remove staining solution and rinse the gel briefly with deionized water to remove excess stain.

   Do not reuse staining solution.

4. Add 5 to 10 gel volumes destaining solution and place the container with gel on shaker.

   For more efficient destaining and to reduce waste, a protein-based destaining material such as a piece of wool yarn (6 to 12 in. long), a cellulose sponge (1 in. × 1 in.), or Whatman 3MM filter paper (1 in. × 1 in.) can be added to a minimal amount of destaining solution to bind the dye as it is released from the gel. Alternatively, the destaining solution can be changed several times until the gel shows a clear background with blue protein bands.

   CAUTION: *Overdestaining can occur if the gel is left in destaining solution for a prolonged period (>24 hr) or if the dye-binding material is left with the gel in the destaining solution for more than 2 to 3 hr.*

5. For storage, place gel in a thermally sealed or resealable plastic bag with 1 to 2 ml destaining solution or 7% acetic acid.

   Gels can be stored sealed in plastic bags for several weeks at room temperature and months at 4°C.

6. For a permanent record, photograph the gel (see Support Protocol) or dry the gel as described here. Place a wet piece of Whatman 3MM filter paper on a gel dryer and position the gel (rinsed with water) on top of the filter paper. Cover gel with a piece of plastic wrap and then add a second piece of wet filter paper. Dry 1 to 2 hr at ~80°C or according to gel dryer instructions. As an alternative gel drying method, use a porous membrane to sandwich the gel in a supporting frame, such as BioDesign Gel Wrap. In this case, dry the gel on the countertop at room temperature overnight.

ALTERNATE PROTOCOL 1

RAPID COOMASSIE BLUE G-250 STAINING

This protocol utilizes Coomassie brilliant blue G-250 in place of the Coomassie brilliant blue R-250 used in Basic Protocol 1. Also called xylene brilliant cyanin G, Coomassie brilliant blue G-250 (greenish hue) stains with approximately the same sensitivity as Coomassie brilliant blue R-250 (reddish hue). The G-250 stain produces a somewhat brighter blue coloration than the deep blue of the R-250 stain. The G-250 dye is less soluble than R-250 and is used in a colloidal state rather than as a solution. Due to its lower solubility, G-250 preferentially binds to the protein bands and not to the polyacrylamide gel itself; therefore, little or no destaining is necessary. The procedure requires fixation of gels prior to staining. Protein staining then develops rapidly and can be observed easily through the staining solution. Although the procedure provides faster detection of proteins in gels than Basic Protocol 1, it is often slightly less sensitive, especially with thick gels.

***Additional Materials** (also see Basic Protocol 1)*

Isopropanol fixing solution: 25% isopropanol/10% acetic acid (v/v; store several months at room temperature)
Rapid Coomassie blue G-250 staining solution: 10% (v/v) acetic acid/0.006% (w/v) Coomassie brilliant blue G-250 (Bio-Rad; store several months at room temperature)
10% (v/v) acetic acid

BCU IASTM CENTRAL UNIVERSITY LIBRARY

1. To a plastic container with lid add ~10 gel volumes isopropanol fixing solution. Remove gel from the electrophoresis unit and place in fixing solution. Agitate container on a platform shaker for 10 to 15 min for 1-mm-thick gel or 30 to 60 min for 1.5-mm-thick gel.
2. Discard fixing solution and add 5 to 10 gel volumes rapid Coomassie blue G-250 staining solution. Agitate 30 min to 1 hr for 1-mm-thick gel or 2 to 3 hr for 1.5-mm-thick gel.

   Staining of protein bands becomes apparent within 5 to 15 min.
3. Remove staining solution after appropriate time. Add 5 to 10 gel volumes of 10% acetic acid and agitate slowly. Destain (1 to 2 hr) until a clear background with blue protein bands appears.
4. For storage, place gel in a resealable plastic bag at 4°C with a small amount of 10% acetic acid.
5. To photograph gel, see Support Protocol. To dry gel, see Basic Protocol 1 (step 6).

ACID-BASED COOMASSIE BLUE G-250 STAINING

ALTERNATE PROTOCOL 2

The acid-based Coomassie brilliant blue G-250 staining procedure fixes and stains the gels simultaneously and, unlike the first basic and alternate protocols, does not require a destaining solution. Color intensifies when the gels are placed in water after the staining period, and as little as 0.1 µg protein per band can be detected. Acid-based Coomassie blue G-250 staining has a sensitivity similar to that of the basic Coomassie blue R-250 staining. More heavily loaded protein bands can be detected within 30 min, but ~5 hr is needed to visualize light bands.

Additional Materials (also see Basic Protocol 1)

Acid-based Coomassie blue G-250 staining solution (see recipe)

1. Remove polyacrylamide gel from the electrophoresis unit. If gel contains SDS, incubate in 5 to 10 gel volumes deionized water for a minimum of 5 to 15 min depending on gel thickness to allow SDS to diffuse out.

   SDS will precipitate in the staining solution and produce an opaque background.
2. Place gel into a container with ~100 ml acid-based Coomassie blue G-250 staining solution. Place gel on a platform shaker and agitate gently for 5 hr to overnight.

   Heavily loaded proteins will be visible within 30 min. However, greatest sensitivity is achieved by staining for at least 5 hr.
3. Pour off staining solution and replace with deionized water.

   Even after the gel has been stained overnight, protein bands will not be completely resolved until the gel is placed into deionized water. Bands will appear bright blue against a clear background within 2 to 5 min.
4. For storage, place gel in 1 to 2 ml water in a resealable plastic bag at 4°C.
5. To photograph gel, see Support Protocol. To dry gel, see Basic Protocol 1 (step 6).

BCU/AS/CENTRAL UNIVERSITY LIBRARY

BASIC PROTOCOL 2

SILVER STAINING

Silver staining is about 10 to 100 times more sensitive than Coomassie blue staining; however, results with silver staining vary from protein to protein. After being treated with silver nitrate, the gel is developed until a desired staining intensity is reached. The gel is then fixed with the A component of the Kodak Rapid Fixer reagent. Because the absolute staining intensity is controlled by the length of reaction in the developer and staining intensity is variable for different proteins, estimation of protein amounts using silver staining is generally not advisable unless known quantities of the protein of interest are included on the same gel to calibrate staining intensity.

Materials

Fixing solution A: 50% methanol/10% acetic acid (v/v; store 1 month at room temperature)
Fixing solution B: 5% methanol/7% acetic acid (v/v; store 1 month at room temperature)
10% (w/v) glutaraldehyde
Ammoniacal silver nitrate solution (see recipe)
Citrate developing solution (see recipe)
Kodak Rapid Fixer A

NOTE: Wear gloves that have been thoroughly rinsed with deionized water when handling all materials. Take special care to avoid touching all but the corners of the gel to prevent staining artifacts.

CAUTION: Ammoniacal silver nitrate solution becomes explosive on drying. Discard immediately after use by precipitating the silver chloride with 1 M HCl and washing the mixture down the drain with copious amounts of water, or dispose of solution as required by local regulations.

Fix and stain proteins

1. Add 5 to 10 gel volumes fixing solution A to a plastic or glass container equipped with a lid. After electrophoresis place gel in the container and agitate for 30 min on a platform shaker.
2. Decant fixing solution A, and then add 5 to 10 gel volumes fixing solution B. Fix gel for 60 min with agitation.
3. Decant fixing solution B, and add 5 to 10 gel volumes of 10% glutaraldehyde. Agitate for 30 min in a fume hood.

   CAUTION: *Glutaraldehyde is an irritant. Wear gloves and work only in a fume hood.*
4. Decant glutaraldehyde and wash gel with 5 to 10 gel volumes water for five times, 15 min each time, with agitation. Then add 10 gel volumes water and agitate overnight to remove all traces of glutaraldehyde.
5. Decant water and rinse gel 1 more time with 5 to 10 gel volumes water to remove any residual glutaraldehyde.
6. Decant the last rinse, and add 3 to 5 gel volumes silver nitrate solution. Agitate for 20 min.

Develop stain and process gel

7. Place gel in a clean container and add 5 to 10 gel volumes water. Agitate about 30 sec. Repeat the washing step five times.

BCU IASI CENTRAL UNIVERSITY LIBRARY

8. Add 3 gel volumes diluted citrate developing solution (diluted 1:20 in water). When brown precipitate appears (~30 sec), decant solution, add 5 gel volumes fresh diluted citrate developing solution, and agitate until desired band intensity is attained.
9. After decanting developing solution, add 5 gel volumes diluted Kodak Rapid Fixer A (126 ml in a final volume of 500 ml with water) and agitate for 5 min.

   Kodak Rapid Fixer contains two solutions, Rapid Fixer A and Rapid Fixer B. Only Rapid Fixer A is needed.
10. Decant Rapid Fixer A, add 5 gel volumes water, and agitate for 15 min. Repeat five times.
11. Store gel in a resealable plastic bag at 4°C. Alternatively, photograph gel (see Support Protocol) or dry gel in a gel dryer (see Basic Protocol 1, step 6).

    Silver-stained gels should be photographed as soon as possible because, with time, changes in protein staining and background will be observed.

NONAMMONIACAL SILVER STAINING

ALTERNATE PROTOCOL 3

The nonammoniacal silver staining procedure is similar to Basic Protocol 2 except that more stable solutions are used for staining. Using this procedure, some proteins may be detected that are not recognized by other silver staining methods.

Additional Materials (also see Basic Protocol 2)

5 µg/ml dithiothreitol (DTT; make fresh daily)
0.1% (w/v) silver nitrate
Carbonate developing solution (see recipe)
2.3 M citric acid
0.03% (w/v) sodium carbonate

Fix and stain proteins

1. Remove gel from electrophoresis apparatus and place in a plastic or glass container equipped with a lid. Add 5 to 10 gel volumes fixing solution A. Agitate for 30 min on a platform shaker.
2. Decant fixing solution A, and add 5 to 10 gel volumes fixing solution B. Agitate for 30 min.
3. Remove fixing solution B, add 50 ml of 10% glutaraldehyde, and agitate for 10 min in a fume hood.

   CAUTION: *Glutaraldehyde is an irritant. Wear gloves and work only in a fume hood.*
4. Decant glutaraldehyde solution. Add 5 to 10 gel volumes water and agitate for 15 min. Repeat eight times.

   Alternatively, wash gel overnight in 30 to 40 gel volumes water with slow agitation. The next day add fresh water and agitate for 30 min to ensure that all traces of glutaraldehyde are removed so a clear background is attained.
5. Decant water and add 5 gel volumes of 5 µg/ml DTT. Agitate 30 min.
6. Pour off DTT and, without rinsing, add 5 gel volumes of 0.1% silver nitrate. Agitate 30 min.

BOULDER CENTRAL UNIVERSITY LIBRARY

Develop stain and process gel

7. Decant silver nitrate solution. Rinse gel once for 15 sec with water by filling the container with water and then pouring it out. Then rinse gel quickly two times with a few milliliters carbonate developing solution. Finally, add 100 ml carbonate developing solution and agitate until bands appear as desired.

8. When proper staining has been attained, add 5 ml of 2.3 M citric acid directly to the carbonate developing solution to stop the staining reaction. Agitate for 10 min, replace the solution with water, and agitate for 30 min. Repeat four more times.

   Always use a 1:20 (v/v) ratio of 2.3 M citric acid to carbonate developing solution to neutralize the solution, thus stopping the reaction. If the pH is too high, color development will continue; if the pH is too low, the color will bleach away.

9. To store gel, soak the gel in 5 to 10 gel volumes of 0.03% sodium carbonate for ~1 hr with agitation to prevent bleaching, then place in a resealable plastic bag. Store gel at 4°C.

10. To photograph gel, see Support Protocol. To dry gel, see Basic Protocol 1 (step 6).

ALTERNATE PROTOCOL 4

RAPID SILVER STAINING

Unlike the previous two silver staining procedures (Basic Protocol 2, Alternate Protocol 3) which use glutaraldehyde as a fixative, rapid silver staining employs formaldehyde to fix the gel. The procedure has a sensitivity similar to that of the previous protocols. Also, the developing solution contains thiosulfate to inhibit background staining by dissolving unspecific surface staining. This method is rapid but may not be quite so sensitive as other methods, especially for small proteins.

Additional Materials (also see Basic Protocol 2)

50% methanol/12% acetic acid (v/v)
95% ethanol (optional)
Formaldehyde fixing solution (see recipe)
0.02% (w/v) sodium thiosulfate
0.1% (w/v) silver nitrate
Thiosulfate developing solution (see recipe)
50% methanol

Fix and stain proteins

1. To prevent protein diffusion and improve background, fix gel after electrophoresis, if desired, for a minimum of 1 hr to overnight in 50% methanol/12% acetic acid. Wash gel with 95% ethanol three times, 20 min each time, before proceeding with step 2.

2. Add 3 gel volumes formaldehyde fixing solution. Place container on a platform shaker, then agitate 15 min for a 1-mm-thick gel or 30 min for a 1.5-mm-thick gel.

3. Decant fixing solution, then wash gel by adding 5 to 10 gel volumes water and agitating for 5 min. Repeat two times.

4. Remove water and add 3 gel volumes of 0.02% sodium thiosulfate. Agitate for 1 min.

5. Decant sodium thiosulfate and add 5 to 10 gel volumes water. Agitate for 1 min. Repeat two times.

6. Decant water and add 3 gel volumes of 0.1% silver nitrate. Agitate for 10 min.

BCU IASI CENTRAL UNIVERSITY LIBRARY

Develop stain and process gel

7. Remove silver nitrate, add 5 to 10 gel volumes water, and agitate for 1 min. Repeat two times.
8. Decant water. Add a few milliliters of thiosulfate developing solution until a brown precipitate forms (30 sec), decant, and add 3 gel volumes fresh thiosulfate developing solution.
9. Just before bands reach desired intensity, wash the gel quickly with water to remove excess thiosulfate (to avoid background staining). Stop the reaction by adding 50% methanol/12% acetic acid and agitate for 10 min.
10. Wash the gel with 5 to 10 gel volumes of 50% methanol with agitation for ~30 min to remove acetic acid. Repeat one time.

    The methanol washes are important to prevent darkening of protein bands over a prolonged period.
11. Store gel in a resealable plastic bag at 4°C.
12. For a permanent record, photograph gel (see Support Protocol) or dry gel (see Basic Protocol 1, step 6).

ENHANCED-BACKGROUND (TWO-STAGE) RAPID SILVER STAINING

ALTERNATE PROTOCOL 5

The enhanced-background rapid silver staining method is a two-stage staining procedure that enhances the sensitivity of most proteins and decreases background staining. In this method, however, proteins are not chemically cross-linked by either glutaraldehyde or formaldehyde; hence some proteins, especially those of low molecular weight, may be selectively lost during staining. The first part of the procedure is a rapid silver staining method that is easier and quicker than both basic silver staining and nonammoniacal silver staining. The second part of the procedure, which is optional, improves sensitivity and lessens background staining of the gel.

Additional Materials (also see Basic Protocol 2)

Rapid fixative 1: 40% methanol/10% acetic acid (v/v; store 1 month at room temperature)
Rapid fixative 2: 10% methanol/5% acetic acid (v/v; store 1 month at room temperature)
1× oxidizer (see recipe)
0.17% (w/v) silver nitrate
Thiosulfate developing solution (see recipe)
5% (w/v) acetic acid
Farmers reducer (see recipe)

Rapid Fixation Silver Staining

Fix proteins

1. After electrophoresis, soak gel in 5 gel volumes rapid fixative 1 in a glass or plastic container for 60 min, agitating container on a platform shaker.
2. Pour off used rapid fixative 1 and add 5 gel volumes rapid fixative 2. Agitate for 30 min.
3. Pour off used rapid fixative 2 and add another 5 gel volumes fresh rapid fixative 2. Agitate for 30 min.

BCUMSI CENTRAL UNIVERSITY LIBRARY

Stain and develop gel

4. Pour off used rapid fixative 2 and add 100 ml of 1× oxidizer. Agitate for 10 min.
5. Pour off oxidizer, add 5 gel volumes water, and agitate for 15 min. Repeat four times.
6. Add 100 ml of 0.17% silver nitrate and agitate for 45 min.
7. Wash gel with running water for 2 min.
8. Add 1 gel volume thiosulfate developing solution. After a brown precipitate appears (~30 sec), decant solution and add 5 gel volumes fresh thiosulfate developing solution.
9. After protein bands have reached the desired intensity, stop the reaction by pouring off developing solution and replacing with 5% acetic acid.
10. Pour off acetic acid, add 5 gel volumes water, and agitate 15 min. Repeat three times.
11. To improve background and sensitivity, continue to step 12. Otherwise, store the gel at 4°C in a resealable plastic bag with 5% acetic acid. Alternatively, photograph (see Support Protocol) or dry the gel according to step 6 in Basic Protocol 1.

Improving Sensitivity (Optional)

12. Remove water, add 5 gel volumes Farmers reducer, and agitate for 10 min.

    After this step the gel should be transparent and yellow, and void of any silver-stained bands.

13. Remove reducer and wash gel by adding 5 gel volumes water and agitating for 15 min. Repeat wash five times.

    The gel must be colorless before continuing; therefore, it is preferable to do the last wash overnight.

14. Repeat steps 6 to 10. Store the gel in a sealed plastic bag at 4°C or photograph (see Support Protocol) or dry the gel (see Basic Protocol 1, step 6) for a permanent record.

SUPPORT PROTOCOL

GEL PHOTOGRAPHY

There are several photographic methods that can be used to obtain a permanent record of gels. The choice of method depends on the quality of print desired and access to photographic equipment. The gels must be destained properly for best results; otherwise resolution between background and protein bands will be minimal.

Cameras and film. Fixed-hood (Polaroid DS34) and copy-stand (Polaroid MP-4) cameras, which use instant film, enable fast and easy production of fairly high-quality records. The Polaroid DS34 camera is compact and portable, making it easy to use on the benchtop. The MP-4 camera system is a more complex instrument but is more versatile than the DS34. Both cameras require a light source; for best results a light box that emits even lighting should be used. Use of a deep yellow filter (Kodak Wratten filter no. 8) for Coomassie blue–stained gels and a blue-green filter (Kodak Wratten filter no. 58) for silver-stained gels is necessary for sharp photographic resolution of stained protein bands versus background.

Polaroid type 667 (3¼ × 4¼–in.) black-and-white film is generally used for the DS34 camera, and type 667 or type 57 (4 × 5–in.) black-and-white film is used for the MP-4. For 667 or 57 film an aperture of f16 and a shutter speed of 1/60 to 1/30 sec are recommended; exposure speed is dependent on the light box intensity. If a negative image is desired, Polaroid type 55 (4 × 5–in.) or type 665 (3¼ × 4¼–in.) film can be used with

BCU IAS CENTRAL UNIVERSITY LIBRARY

a shutter speed of ¼ to ½ sec and an aperture of f16. If images on photographs appear too light, the shutter speed or aperture should be increased, and vice versa if the images appear too dark. All settings indicated are approximate, and for best-quality photographs conditions must be determined on a trial basis.

For greatest versatility, 35-mm gel photography can be used with Kodak T-Max 100 or T-Max 400 film. Both films produce negatives with high image quality, but the T-Max 400 film has a higher speed. Photography on 35-mm film also requires a deep yellow filter for Coomassie blue–stained gels and a blue-green filter for silver-stained gels as recommended for the fixed-hood and copy-stand Polaroid cameras.

Contact prints. Kodak X-Omat duplicating film can be used for contact prints as an alternative photography method, especially for silver-stained gels where filters may produce differences in color. However, contact photography does not produce the high-quality images seen with the photographic methods listed above. For contact photography, a piece of glass or plastic is placed between the "wet" gel and the X-ray film in the dark. After the film is briefly exposed using a light source, it is developed in an automated X-ray film processor or manually developed according to the manufacturer's instructions as follows. Develop film with Kodak GBX solution between 20° (5 min) and 26°C (2 min) with no agitation. Then wash with running water for 30 sec at room temperature with continuous agitation. Fix for 2 to 4 min in GBX solution or Kodak Rapid Fixer with intermittent agitation (5 sec every 30 sec), wash with running water for 10 min at room temperature, and let dry.

Gel documentation. Permanent records of stained gels can also be made using a wide range of commercial gel documentation systems. The systems generally involve either a video camera or a densitometric laser scanner that acquires an image which is stored as a digital file in a computer. Computer software allows further processing of the image. In addition to providing digital storage of the image, such systems can produce hard copies of reasonable quality on high-resolution printers.

REAGENTS AND SOLUTIONS

NOTE: Only high-purity water such as Milli-Q-purified water or equivalent should be used to prepare all solutions, unless otherwise specified.

Acid-based Coomassie blue G-250 staining solution

Prepare 0.2% (w/v) Coomassie brilliant blue G-250 (Bio-Rad) in water. Add an equal volume of 2 N H_2SO_4. Mix well and let stand for 3 hr minimum. Filter through Whatman no. 1 filter paper. Measure recovered volume and add 1/9 vol of 10 N KOH. Finally, add 100% (w/v) trichloroacetic acid (TCA) to a final concentration of 12% (w/v). The final concentration of Coomassie blue is ~0.08% (w/v). Store up to several months but maintain solution below pH 1.0.

Ammoniacal silver nitrate solution

Mix 2.5 ml concentrated NH_4OH and 32 ml of 0.36% (w/v) NaOH with stirring, then add H_2O to 150 ml. Continue stirring and slowly add 6 ml of 19.4% (1.2 g/6 ml) silver nitrate for a final concentration of 0.75% (w/v) silver nitrate. A brown precipitate will initially form on adding silver nitrate and will disappear with mixing. Make fresh each time. Silver nitrate stock solution (19.4%) can be stored up to several months at 4°C.

CAUTION: *Ammoniacal silver nitrate solution is explosive on drying. Discard immediately after use by precipitating silver chloride with 1 M HCl, then washing the*

CHIMIE

mixture down the drain with copious amounts of water (if permitted by local regulations) or disposing of it in another approved manner.

Carbonate developing solution

0.5 ml 37% (v/v) formaldehyde
30 g sodium carbonate (3%, w/v)
H_2O to 1 liter
Make fresh each time

Citrate developing solution

0.5 g sodium citrate
0.5 ml 37% (v/v) formaldehyde
H_2O to 100 ml
Make fresh every time

Coomassie blue R-250 staining solution

Concentrated stock: Mix 24 g Coomassie brilliant blue R-250 (Bio-Rad or Pierce) and 600 ml methanol. Add 120 ml acetic acid. Stir for 2 hr minimum, and preferably overnight. Store up to several months at room temperature.

Staining solution: Mix 1 liter methanol and 60 ml Coomassie blue R-250 concentrated stock. Add 800 ml H_2O, then 200 ml concentrated acetic acid. If precipitation occurs, filter the solution through Whatman no. 1 filter paper prior to use. Store up to several months at room temperature.

The staining solution has approximate final concentrations of 50% (v/v) methanol, 0.1% (w/v) Coomassie brilliant blue R-250, and 10% (v/v) acetic acid.

Farmers reducer

5 g potassium ferricyanide
8 g sodium thiosulfate
H_2O to 500 ml
Make fresh every time

Formaldehyde fixing solution

400 ml methanol
0.5 ml 37% (v/v) formaldehyde
H_2O to 1 liter
Store ≤1 month at room temperature

Oxidizer, 10× and 1×

10× stock:
5 g potassium dichromate
1 ml 70% (w/v) nitric acid
H_2O to 500 ml
Store up to several months at 4°C
1× working solution:
Dilute 10× oxidizer 1/10 with H_2O
Make fresh each time

Thiosulfate developing solution

15 g sodium carbonate
0.5 ml 37% (w/v) formaldehyde
0.2 ml 1% (w/v) sodium thiosulfate
H_2O to 500 ml
Make fresh each time

RCU IASI CENTRAL UNIVERSITY LIBRARY

Background Information

Coomassie blue and silver staining are the two most common approaches used for protein detection in gels with fixation. Silver staining relies on binding of silver to amino acid side chains, primarily sulfhydryl and carboxyl groups, and Coomassie blue binds nonspecifically to proteins. Silver staining is about 10 to 100 times more sensitive than Coomassie blue staining but it is more complex and time-consuming.

The Basic and Alternate Protocols described for Coomassie blue staining differ most significantly in time required. The rapid Coomassie blue G-250 staining procedure (Alternate Protocol 1) uses isopropanol for fixing instead of methanol, and the colloidal stain produces a low background, which allows for faster protein staining (bands appear within 15 min); however, it is not as sensitive as Basic Protocol 1 involving Coomassie blue R-250 (Weber et al., 1972). The acid-based Coomassie blue staining procedure (Blakesley and Boezi, 1977) also uses Coomassie blue G-250, but it does not involve a separate fixation step (Alternate Protocol 2). Acid-based staining achieves a sensitivity similar to that of Coomassie R-250, although for maximum sensitivity gels must be stained 5 hr to overnight.

Basic Protocol 2 for silver staining (Oakley et al., 1980) is a more sensitive protein detection method compared to the nonammoniacal and rapid two-stage alternate silver staining protocols; however, the procedure uses unstable ingredients and tends to require more expensive reagents. Nonammoniacal silver staining (Alternate Protocol 3) is based on a method described by Morrissey (1981). The two-stage silver staining procedure (Alternate Protocol 5) is a modification of the method described by Gorg (1985) and consists of two parts: the first stage, involving rapid silver staining, is followed by an optional series of steps to reduce background. The rapid silver staining procedure (Alternate Protocol 4; Blum et al., 1987) is a quick and easy way to detect proteins within 50 min and, like the alternate two-stage silver staining method, uses thiosulfate to reduce background impurities.

Critical Parameters and Troubleshooting

All solutions used in preparing the polyacrylamide gels as well as the staining solutions must contain high-purity reagents. In addition, gel solutions should be filtered to avoid artifacts in the gel. This is especially important in silver staining, which is based on a photochemical process where impurities can increase background and cause artifactual staining. Powder-free gloves should be used at all times, and care should be taken to touch only the very corners of the gels. One common contaminating protein is skin keratin, which shows up as multiple bands with molecular weights between 55,000 and 60,000. If such bands appear in blank lanes where no protein was loaded, most likely the stacking gel, solubilizing buffer, and/or electrode buffer are contaminated. The problem can be eliminated by avoiding contact of skin and hair with gel and buffer solutions.

Anticipated Results

Silver staining is about 10 to 100 times more sensitive than Coomassie blue staining. The basic silver staining protocol (Basic Protocol 2) enables detection of 1 to 5 ng protein per band, whereas basic Coomassie staining (Basic Protocol 1) has a sensitivity of 0.05 to 0.5 μg protein per band.

Time Considerations

In general, Coomassie blue staining tends to be easier and faster than silver staining. Basic Coomassie staining of standard-sized gels (11 × 16 cm) that are 1.5 mm thick require at least 2 to 3 hr of staining followed by destaining for at least several hours to overnight. Minigels require less time, ~30 min for staining and about the same time for destaining. The rapid Coomassie blue staining procedures (Alternate Protocol 1) allow visualization of protein bands within 5 to 15 min. Silver staining, on the other hand, is very time-consuming because the gels must be treated with many different solutions. Also, gels require successive washes with water to remove glutaraldehyde for good background in the silver staining and nonammoniacal silver staining methods (Basic Protocol 2 and Alternate Protocol 3), and to remove Farmers reducer in the second part of the two-stage silver staining procedure (Alternate Protocol 5). Rapid silver staining (Alternate Protocol 4), however, is the easiest and the most time-efficient of all the silver staining methods as it takes only ~50 min.

Protein Detection in Gels Without Fixation

UNIT 10.5 describes protein detection in gels using methods that fix the protein within the gel. Such methods are not always suitable, particularly when protein recovery from the gel is the ultimate goal. Fixatives remove SDS from gels, causing the protein to become entwined in the gel matrix; subsequent extraction from the gel is usually not practical without partial cleavage of the protein or dissolution of the gel matrix. In this unit, methods for the detection of proteins without fixation are described. In general, the sensitivity of the methods is lower than that of protein detection with fixation. Sensitivity is dependent on the volume of the protein band within the gel; hence, sensitivity is the highest for sharp, narrow bands. Techniques described in this unit include basic protocols for protein detection in gels by SDS precipitation, preparation of contact blots, and use of the fluorescent labels IAEDANS and fluorescamine to detect proteins in gels. Several additional methods, including the use of tryptophan fluorescence, guide strips, and minimal protein staining, are discussed in the Commentary.

PROTEIN DETECTION IN GELS BY SDS PRECIPITATION

BASIC PROTOCOL 1

Although proteins can be detected in SDS-containing gels by simply chilling at 0° to 4°C for 3 to 5 hr to precipitate free SDS, resolution is low and special precautions must be taken in preparing and running the gels. The method presented here involves the use of high-ionic-strength solutions to precipitate the SDS and produces the same effect more reliably. Using this method, the SDS in the gel precipitates and forms an opaque background, whereas the SDS bound to the proteins does not precipitate, creating a clear protein band.

Materials

SDS-polyacrylamide gel containing protein of interest (*UNITS 10.1-10.4*)
4 M sodium acetate, pH unadjusted (*APPENDIX 2E*; store at 4°C; stable up to 6 months)
Black, nonreflective surface
Fluorescent desk lamp

NOTE: All steps are performed at room temperature.

1. Immediately after electrophoresis, place the polyacrylamide gel containing the protein of interest into a covered container with 10 to 12 gel volumes of 4 M sodium acetate.
2. Place on a platform shaker at low speed for 40 to 50 min for 1-mm-thick gels or longer for thicker gels.
3. View the gel over a black, nonreflective surface using a fluorescent desk lamp to illuminate the gel from the side. If the gel bands are not yet visible, allow gels to continue to soak.

   Monitor gels about every 15 min, or more often if incubation must continue longer than 1 hr. Be careful not to allow the incubation in high-ionic-strength solution to proceed unattended as the resolution will begin to decrease after a few hours.

4. For recovery of proteins by electroelution, soak gel slices in water to reduce the ionic strength.

   In general, soaking gel slices in 50 ml water for 1 hr, changing the water every 15 min, should be sufficient.

BOSTON CENTRAL UNIVERSITY LIBRARY

BASIC PROTOCOL 2

PREPARATION OF CONTACT BLOTS

Unlike electroblot procedures (*UNIT 10.7*) where it is desired to transfer all of the protein in the gel onto the membrane surface, contact blots are used to create merely a surface replica of the gel by transferring a small amount of protein to the transfer membrane while leaving most of the protein in the gel. The method involves making a gel/membrane sandwich that is soaked in a Tris/glycine transfer buffer for a short time to effect transfer of proteins from the gel to the membrane. The membrane is then stained to visualize proteins. Because the membrane will contain little protein, a high-retention polyvinylidene difluoride (PVDF) membrane should be used, and it must be treated with a sensitive stain such as AuroDye (Amersham) or colloidal gold (*UNIT 10.8*). Protein bands can then be identified in the gel by direct comparison with the transfer membrane.

Materials

Polyacrylamide gel containing protein of interest (*UNITS 10.1-10.4*)
100% methanol
1× transfer buffer (see recipe)

PVDF transfer membrane: 0.2 µm polyvinylidene difluoride (PVDF) membrane (Bio-Rad)
Whatman no. 1 filter paper

Additional reagents and equipment for staining membranes (*UNIT 10.8*)

NOTE: Use powder-free gloves when handling all materials for this procedure, and handle membranes with forceps at the edges to avoid potential artifactual staining.

Prepare transfer membrane and gel

1. Cut PVDF transfer membrane slightly larger than the polyacrylamide gel containing the protein of interest. Cut three slightly larger pieces of Whatman no. 1 filter paper.

2. Wet PVDF membrane in 100% methanol in a clean glass dish for 5 sec. Decant methanol and pour in 1× transfer buffer. Incubate membrane in transfer buffer for at least 5 min.

   The PVDF membrane will wet almost immediately with the 100% methanol. Because the membrane is strongly hydrophobic it will not wet efficiently in either water or transfer buffer alone.

3. Remove polyacrylamide gel from the electrophoresis unit and mark the first lane by cutting off a small piece of the gel on the lower corner of that side. Rinse gel briefly in transfer buffer and place face down into a plastic container with lid.

   The cut edge should now be on the lower right-hand edge of the gel if the gel was loaded from the left-hand side.

Make gel/membrane sandwich

4. Pour ~2 ml transfer buffer on top of the gel.

5. Starting at a place on the gel that has the most buffer on it, lower the prepared PVDF membrane onto the gel. Check carefully for bubbles. Trim the edges of the membrane to the exact size of the gel, including the cut marking the first lane described in step 3.

   Do not cover the gel with too much buffer or the transferred protein bands will appear diffuse on the membrane. Use only enough buffer so that the membrane can be placed on top of the gel without creating bubbles. If a bubble is detected, lift that portion of the membrane to release the bubble and lower the membrane slowly back onto the gel.

ECU IAS / CENTRAL UNIVERSITY LIBRARY

6. Wet the three precut pieces of filter paper with transfer buffer and layer one at a time on top of the membrane. Smooth gently by rolling a test tube or pipet over the surface after adding each layer to eliminate bubbles.

Transfer and stain protein

7. Top with a glass plate to ensure tight contact between the gel and membrane. Cover the plastic container with lid and allow transfer to continue by diffusion for 15 to 30 min.

   The glass plate should be slightly larger than gel/membrane sandwich.

8. After opening the container and removing the glass plate, remove the filter paper from the membrane. To ensure proper realignment after staining the membrane, mark three corners of the gel/membrane sandwich with a syringe needle dipped in permanent ink by piercing through both membrane and gel.

   The membrane and gel should be adequately marked for proper realignment before disassembling the gel/membrane sandwich.

9. Remove the membrane and stain it with a sensitive stain. Keep the gel covered in plastic wrap at 4°C while the membrane is being stained.

10. Once the membrane is stained, identify the position of protein bands in the unstained gel by realigning the gel over the stained blot. Mark bands of interest with a needle dipped in permanent ink as in step 8 or excise the band with a sharp scalpel.

IAEDANS MODIFICATION OF PROTEINS

BASIC PROTOCOL 3

N-Iodoacetyl-*N'*-(5-sulfo-1-naphthyl)ethylenediamine (1,5-I-AEDANS or IAEDANS) is a modified iodoacetic acid (IAA) reagent formed by linkage of IAA to an amino-naphtholsulfonic acid fluorophor. This reagent specifically modifies cysteine residues. IAEDANS-modified cysteines have an excitation maximum of ~340 nm and an emission maximum of 418 nm. In this procedure, modification of protein with the fluorescent label is performed prior to electrophoresis. Several dialysis steps may be needed to provide labeled proteins suitable for electrophoresis. A major advantage of this method is that proteins can be modified in crude mixtures and labeled proteins can be followed through all subsequent steps, including elution from the gel as well as visualization in the gel.

Materials

Protein sample (<5 mg protein in 0.3- to 3-ml volume)
0.75 M Tris·Cl (pH 8.6)/15 mM EDTA (make with 4°C water, measure pH at that temperature, and use within 1 week; store at 4°C)
Urea (Bio-Rad)
Dithiothreitol (DTT or Cleland's reagent; Calbiochem)
Argon or nitrogen gas
N-Iodoacetyl-*N'*-(5-sulfo-1-naphthyl)ethylenediamine (IAEDANS; Sigma; keep yellow crystals desiccated in the dark at –20°C)
2-mercapthoethanol
Additional reagents and equipment for dialysis (*APPENDIX 3B*) and electrophoresis (*UNITS 10.1-10.3*)

CAUTION: Use UV-rated eye protection when working with UV lamps.

BCU ASC CAITRA UNIVERSITY LIBRARY

1. Dialyze 0.3 to 3 ml protein sample (<5 mg total protein) twice against 1 liter Tris/EDTA buffer at 4°C, for a minimum of 3 hr each time.

   The Tris scavenges the cyanate (CN^-) produced by decomposing urea (see below). The indicated volumes are convenient ranges, but the method can be adapted for smaller or larger volumes if needed.

2. Remove protein from the dialysis tubing and measure the volume. Place sample in a tube and add dry urea to a final concentration of 9 M (0.833 g/ml original volume). Bring the solution to room temperature to dissolve urea.

   When the urea is added the sample volume will increase to ~1.5 ml for each 1 ml original volume. It is important to take this into account in calculating amounts of reagents.

3. Immediately add DTT to a final concentration of 20 mM (4.62 mg/1.5 ml reaction solution, based on volume after urea addition).

   DTT will reduce any oxidized components including artificial disulfides that may have formed during protein purification procedures or storage. 2-mercaptoethanol should not be substituted for DTT because it is a weaker reducing reagent.

4. Flush the tube with argon or nitrogen and seal to provide an inert atmosphere. Incubate the tube 1 hr at 37°C.

5. Add 30.1 mg IAEDANS/1.5 ml reaction mixture. Mix to dissolve the reagent, flush with argon or nitrogen, and reseal the tube. Wrap the entire tube carefully in aluminum foil.

   Because IAEDANS is light-sensitive, minimize the time and amount of exposure to light. The indicated quantity of IAEDANS is sufficient to neutralize the DTT (2 moles IAEDANS per mole DTT) plus a moderate excess over thiol groups in the protein. Because IAEDANS modifies thiol groups, this excess is necessary for complete labeling of cysteine residues in the protein.

6. Incubate the sample 1 hr at room temperature. Stop the reaction by adding 2-mercaptoethanol to 100 mM final concentration.

   The sample will appear greenish-yellow in color.

7. Dialyze the protein for ≥4 hr against the desired buffer. Repeat with fresh dialysis buffer until the protein sample is colorless. Conduct the first dialysis in the dark.

   IAEDANS dialyzes away slowly, so each dialysis should be performed for a minimum of 4 hr. Longer times are better. The dialysis can be followed by using a hand-held UV lamp. The protein should be colorless and strongly fluorescent, whereas unreacted reagent is yellow and weakly fluorescent.

   Samples do not have to be completely dialyzed prior to electrophoresis. One dialysis following the labeling is sufficient to reduce the level of unreacted IAEDANS such that it will not interfere with electrophoretic separation; the weakly fluorescent underivatized reagent will migrate near the dye front.

8. Perform gel electrophoresis, following movement of IAEDANS-modified protein during and after the electrophoresis by exposing gels to a hand-held UV lamp. If desired, excise fluorescent bands from the gel with a sharp scalpel and monitor the efficiency of subsequent removal from the gel by exposure to UV light.

BCU IASI CENTRAL UNIVERSITY LIBRARY

FLUORESCAMINE LABELING OF PROTEINS

BASIC PROTOCOL 4

Fluorescamine, or 4-phenylspiro[furan-2(3*H*),1′-phthalan]-3,3′-dione, reacts with α-amino groups of proteins and with the ε-amino groups of lysine residues. The sensitivity of fluorescamine labeling is therefore dependent on the number of lysine residues in a particular protein, but in general as little as 0.5 µg of protein should be easily detected. The excitation maximum for fluorescamine is 390 nm and the emission maximum is 475 nm. This method involves labeling of proteins before they are electrophoresed, like the IAEDANS procedure, but is quicker because only a single round of dialysis is needed, following labeling.

Materials

Protein sample (0.5 to 1 mg/ml)
15 mM sodium phosphate buffer, pH 8.5 (*APPENDIX 2E*; prepare with 4°C water just before use)
SDS (Bio-Rad)
Sucrose
Dithiothreitol (DTT; optional)
1 mg/ml fluorescamine (Sigma) in acetone
5 mg/ml bromphenol blue (optional)
Boiling water bath
Additional reagents and equipment for dialysis (*APPENDIX 3B*) and electrophoresis (*UNIT 10.1*)

CAUTION: Use UV-rated eye protection when using UV lamps.

1. Dialyze 100 µl protein sample against 1 liter of 15 mM sodium phosphate buffer, pH 8.5, at 4°C for a minimum of 3 hr.
2. Remove protein from the dialysis tubing and add dry SDS and sucrose to a final concentration of 5% (w/v) each.

   Alternatively, lyophilize the sample and dissolve the protein (0.5 to 1 mg) in 100 µl of 15 mM sodium phosphate, pH 8.5, containing 5% (w/v) SDS and 5% (w/v) sucrose. Use of Tris should be avoided because it will react with the fluorescamine reagent.

3. Heat the sample 5 min in a boiling water bath. Cool to room temperature.

   If reduction with DTT is necessary to reduce disulfides, add the reducing reagent (20 mM DTT final concentration) prior to heating.

4. Add 5 µl of 1 mg/ml fluorescamine in acetone to the protein mixture and mix well.

   Labeling will occur rapidly, and the degree of modification can be controlled to some extent by the time of incubation prior to electrophoresis. For example, 1 min is sufficient for moderate labeling and 30 min for extensive labeling.

5. Add 5 µl of 5 mg/ml bromphenol blue as a tracking dye, if desired, and apply a 10-µl sample to a polyacrylamide gel well.
6. Conduct electrophoresis. Visualize labeled proteins during or after separation with a hand-held UV lamp.

BCU ASTON CENTRAL UNIVERSITY LIBRARY

REAGENTS AND SOLUTIONS

Use high-purity water such as Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Transfer buffer

20× stock solution:
200 mM Tris base
2.0 M glycine
Do not adjust pH
Stable up to 1 year at room temperature
1× working solution:
50 ml 20× stock
100 ml methanol
H_2O to 1 liter
Do not adjust pH
Make 1× working solution fresh daily

COMMENTARY

Background Information

Polyacrylamide gel electrophoresis is widely used for the separation of protein mixtures (*UNITS 10.1-10.4*), and a variety of methods to detect the separated proteins have been published. Methods involving fixation of the protein within the gel are presented in *UNIT 10.5*. Fixation is used to inhibit diffusion of the proteins within and out of the gel matrix. Unfortunately, the fixation process eliminates biological activity of the protein. If the protein is needed in its native form and/or recovery of the intact protein from the gel is needed, methods for detection in polyacrylamide gels that do not involve fixation are necessary. In general, the latter methods are required when the protein must be eluted from a polyacrylamide gel. Historically, a standard procedure for locating a desired protein has involved making 1-mm slices of an entire gel, eluting protein from each slice, and assaying for the desired protein. That procedure is time-consuming, and it is likely that the gel will not be cut in the best place. This makes it preferable to visualize specifically the protein in the gel, without fixation. Several methods currently available for this purpose are discussed in this unit.

The choice of label for detecting proteins in polyacrylamide gels without fixation is largely dependent on the ultimate use to which the protein will be put. If it is desirable to modify the protein as little as possible, SDS precipitation and contact blot preparation offer the least manipulation of the proteins (Basic Protocols 1 and 2). The most reliable method for precipitating free SDS uses high-ionic-strength solutions (Higgins and Dahmus, 1979), although chilling gels at 0° to 4°C can be used under certain running conditions (Wallace et al., 1974). Making contact blots involves preparing a gel/membrane sandwich similar to that described for electroblotting (*UNIT 10.7*); however, in a contact blot transfer is achieved by diffusion. The transfer buffer listed in Basic Protocol 2 is approximately half-strength Towbin buffer (Towbin et al., 1979), but other low-ionic-strength transfer buffers may be suitable as well.

Fluorescent labels chemically alter the protein and may affect migration in gels prepared both with and without SDS, but they offer the advantage that the protein can be monitored at all subsequent steps including removal from the gel, which can be problematic. The fluorescent label IAEDANS is especially attractive and can assist in localizing proteins containing cysteine residues. The IAEDANS modification method described in Basic Protocol 3 is based on that of Speicher et al. (1983). Another fluorescent label, fluorescamine, modifies N-terminal amino groups and ε-amino groups on lysine residues; it is preferred over the alternative fluorescent label dansyl chloride because neither its free form nor its hydrolysis products are fluorescent. Labeling conditions are usually selected that minimally modify any individual sites. The simple method of fluorescamine labeling presented in Basic Protocol 4 is based on a procedure described by Eng and Parkes (1974). The fluorescent labels can also be advantageous when the whole protein or peptide products after specific protein cleavage are subjected to HPLC because peaks containing

BCU IASTE TEXTBOOK UNIVERSITY LIBRARY

the desired product can be identified by fluorescence.

In addition to the protocols given in this unit, several alternative simple, nonperturbing methods may be used.

Intrinsic tryptophan fluorescence. In this procedure, the gel is frozen in a suitable container which is floated in liquid nitrogen. Proteins are detected using a hand-held UV lamp. Sensitivity depends on the final temperature achieved, the intensity of the lamp, and the number of tryptophan residues in the protein. In most cases, sensitivity is similar to that obtained with Coomassie blue staining.

Guide strip staining. Multiple identical lanes are run on a polyacrylamide gel. The end lanes of the gel (and the center lane, for improved accuracy) are cut out and stained by one of the methods listed in *UNIT 10.5*. Meanwhile, the unstained portion of the gel is kept in plastic wrap at 4°C. Once the stained portions of the gel have been destained and the size of the gel is again identical (ideally) to that of the unstained portion, the stained gel slices can be lined up with the unstained gel. From this alignment, the region of the desired protein band can be estimated and the corresponding portion of the gel excised.

Minimal protein staining. With this rapid detection method, the gel is treated briefly (1 to 5 min) with Coomassie blue R-250 (*UNIT 10.5*) so that the stain and fixative do not have time to penetrate into the gel matrix, and only the protein molecules near the surface are actually fixed and stained. This method, however, has two drawbacks. The brief staining procedure will emphasize gel surface artifacts, which could lead to incorrect localization of the protein band, and the portion of sample that is fixed in the gel is likely to vary appreciably.

Critical Parameters

In all procedures, it is essential to use high-purity reagents. In addition, if the protein of interest is to be eluted from the gel, it is important to consider all the factors that may affect protein activity after isolation. Although fluorescent probes provide the most sensitive and easiest detection, the modifications must be assessed through the use of appropriate controls to evaluate potential shifts in migration resulting from the chemical modification. When reaction conditions are optimized for complete modification, IAEDANS labeling can be used for two-dimensional electrophoresis using isoelectric focusing (*UNIT 10.4*) with little difficulty (Speicher et al., 1983).

The use of fluorescent probes offers a sensitive alternative for detecting proteins in unstained gels. It is crucial, however, to follow the protocols carefully to obtain efficient and specific labeling of proteins. The modification with IAEDANS is dependent on the pH (pH 8.4 to 8.6 is optimal), state of denaturation (8 to 10 M urea), level of reduction (50- to 200-fold excess of DTT over cysteines in the protein under argon at 37°C for 1 to 2 hr), and the concentration of IAEDANS (allow 2 moles IAEDANS for every mole of DTT plus at least a 10- to 20-fold molar excess of IAEDANS over SH groups). A larger excess of IAEDANS as well as changes in reaction time or pH can lead to modification of other amino acids. Incomplete reduction can lead to incomplete modification. It is therefore important that DTT be used instead of the weaker reducing agent 2-mercaptoethanol. Because modification is performed prior to electrophoresis, incomplete modification of cysteines will result in heterogeneity in isoelectric focusing separations as each modified residue adds a negative charge to the molecule. Molecular weight shifts can also occur, especially when a large number of cysteines are modified in a given protein. A useful alternative approach is to delete the reduction step and/or forgo the use of urea to modify only cysteines not involved in disulfide bonds or solvent-exposed cysteines, respectively. If the reduction step is deleted, the amount of IAEDANS should be reduced to 4.3 mg/1.5 ml of reaction solution (Basic Protocol 3).

The fluorescamine-protein interaction changes the net charge of proteins so that mobilities are changed in polyacrylamide gels run in the absence of SDS. As the charge of the protein is less important in SDS-polyacrylamide gels, moderately labeled proteins should run with similar mobilities to the unlabeled proteins.

Troubleshooting

There are several problems associated with detecting proteins in unstained gels. Perhaps the most common problem arises from the quantity of protein to be detected. With the exception of fluorescent labeling methods to detect proteins, these methods are not very sensitive, and some practice may be required before proteins are detected reliably. One problem that may occur with contact blots is blurring of the transferred bands. If this occurs, it is most likely due to the presence of too much buffer in the transfer sandwich or to insufficient

POLLINS CENTRAL UNIVERSITY LIBRARY

contact between the gel and membrane. Only enough buffer to keep the gel and membrane moist is needed. Improved contact can be achieved by placing a 100-ml beaker filled with water on top of the glass plate. The cover to the gel box must be omitted in this case. Also, if the gel is not rinsed with transfer buffer prior to exposure to the transfer membrane, protein binding to the membrane may be inhibited. On the other hand, if the gel is left in the transfer buffer too long, too much SDS will be removed from the gel and the transfer will not be efficient; therefore, only a brief rinse of the gel is recommended (~10 sec). If insufficient protein is transferred to the membrane by contact blotting, a brief electrotransfer (*UNIT 10.7*) can be used. Transfer time and transfer voltage should be kept as low as consistent with adequate detection sensitivity to ensure that a minimal amount of protein is transferred from the gel.

With the fluorescent labels, if the modification is incomplete or appears to be nonspecific, the reaction conditions should be carefully reviewed. Check calculations for the amount of fluorescent label added as well as reaction pH, reduction conditions, and length of labeling as all these parameters are important for successful labeling of the protein.

Anticipated Results

SDS precipitation and fluorescent labels yield similar sensitivities and should detect as little as 0.5 μg protein. This is only a general estimate, however, as the level of fluorescent labeling is dependent on the number of modified residues in the protein sample. The sensitivity of a contact blot depends on both the amount of protein transferred and the membrane staining technique (see *UNIT 10.8*). The most sensitive staining techniques can detect as little as 2 ng protein.

Time Considerations

The detection of proteins in unstained gels can take as little as 5 min or as long as 1 day, depending on the method. The quickest method available is monitoring of tryptophan fluorescent bands in the gel. SDS precipitation with high ionic strength (Basic Protocol 1) occurs within 10 min for protein bands containing ≥5 μg protein. Contact blots (Basic Protocol 2) are relatively quick to set up and require a short period for protein transfer to occur (30 min). However, the transfer membranes must be stained with a sensitive stain such as AuroDye (Amersham) which takes a minimum of 1 to 4 hr.

With fluorescent labeling, dialysis of the proteins both before and after labeling can consume the majority of time. Dialysis of unlabeled protein into the modification buffer can be done the night before labeling. With fluorescamine (Basic Protocol 4), labeling of the dialyzed protein can be completed within 30 min, and the sample is ready to load on a gel immediately. IAEDANS labeling (Basic Protocol 3) requires more time to complete; although the labeling procedure itself takes only 2 to 3 hr, the reaction mixture should be dialyzed at least 4 hr before the protein is run on a polyacrylamide gel to minimize interference of reaction by-products with the gel separation.

Electroblotting from Polyacrylamide Gels

Electroblotting of proteins from polyacrylamide gels onto retentive membranes is usually performed to facilitate procedures leading to protein identification and characterization. It has been used for immunoblotting (or Western blotting), N-terminal protein sequencing, in situ protease or chemical cleavage of proteins for further structural analysis (*UNIT 11.2 & UNIT 11.5*), protein band detection using sensitive stains such as AuroDye colloidal gold (*UNIT 10.8*), and protein elution. The electroblotting methods in this unit require that the proteins have already been separated on a polyacrylamide gel (*UNITS 10.1-10.4*). However, if the blotted protein bands will be used for N-terminal protein sequencing or sequencing of cleavage/digestion products, refer to the specific requirements detailed in Alternate Protocol 1, which may affect electrophoresis conditions. Including protein markers or prestained standards in gels is useful because they will transfer to the membrane and can be used to indicate the size of proteins after immunostaining.

This unit contains procedures for electrophoretically transferring proteins onto a variety of membranes including polyvinylidene difluoride (PVDF; Basic Protocol) and nitrocellulose (Alternate Protocol 2) and derivatized membranes. The choice of membrane type for electrotransfer is dependent on the ultimate application for the blot membrane. High-retention PVDF binds proteins tightly and is well suited for applications such as sequencing where high protein amount is critical (Alternate Protocol 1), whereas low-retention membranes may be advantageous for subsequent protein extraction or immunoblot analysis. Most protocols are designed for use with tank transfer setups; Alternate Protocol 3 presents procedures for electroblotting in semidry systems.

In some cases, stained blots are used only to identify protein band patterns while leaving the gel unmodified for subsequent steps (*UNIT 10.8*). If such minimal protein transfer is desired, contact blotting is a suitable alternative (*UNIT 10.6*). This unit also describes procedures for eluting proteins from membranes using detergents (Basic Protocol 2) or acidic extraction with organic solvents (Alternate Protocol 4).

Unless otherwise indicated, the following protocols are primarily designed for electrotransferring proteins from SDS gels (*UNITS 10.1-10.4*). As proteins in other types of gels have much lower charge densities and, sometimes, opposing net charges for different proteins, substantial modifications to the protocols must be made for these specialized applications (*UNIT 10.2*).

ELECTROBLOTTING ONTO PVDF MEMBRANES

BASIC PROTOCOL 1

The following procedure is based on electrotransfer from polyacrylamide gels containing 0.2% sodium dodecyl sulfate (SDS) in the gel solution and electrophoresis and sample buffers. It uses a Bio-Rad solid plate tank transfer apparatus with 7 cm spacing between the electrode plates, which can accommodate gels up to 14 × 18 cm in size and requires ~2.5 liters transfer buffer. The choice of PVDF membrane depends on the planned subsequent use: high-retention Trans-Blot membranes (Bio-Rad) are suitable for protein sequencing, whereas low-retention Immobilon-P membranes (Millipore) are recommended for low-background immunodetection or staining and for recovering proteins from membranes.

Materials

1× transfer buffer (see recipe)
Polyacrylamide gel containing proteins of interest (*UNITS 10.1-10.4*)
100% methanol

Powder-free gloves
Electroblotting apparatus: "solid" plate electrode tank transfer system (e.g., Trans-Blot Cell, Bio-Rad)
Glass dishes and trays
Gel support sheet (e.g., porous polyethylene sheet, Curtin Matheson)
PVDF transfer membrane: 0.2 µm PVDF membrane (Bio-Rad) or Immobilon-P (Millipore)
Whatman no. 1 filter paper
Power supply (500 V, 300 mA)

Additional reagents and equipment for staining gels (*UNIT 10.5*)

NOTE: Use powder-free gloves when handling all materials for this procedure and handle membranes with forceps at the edges to avoid potential artifactual staining.

Equilibrate the gel and membrane in transfer buffer

1. Prior to blotting, prepare the blotting apparatus by thoroughly rinsing with high-purity water.

   The optional porous polyethylene sheet is hydrophobic, and it is difficult to get water or buffer into the pores. Be sure to hydrate or "wet" it properly by spraying water under pressure through the sheet or by submerging the entire polyethylene sheet in methanol and then submerging in high-purity water.

2. Fill the transfer tank with 1× transfer buffer. Submerge the gel cassette holder, fiber pads, and polyethylene sheet (after initial hydration as described in step 1) in transfer buffer. Place them inside the tank or submerge in transfer buffer using a separate tray.

   The transfer buffer can be left in a covered transfer tank for up to 2 hr prior to use. Longer times should be avoided because the methanol in the buffer will evaporate, significantly changing the buffer composition.

3. Prepare the polyacrylamide gel containing proteins of interest by disassembling the gel apparatus, removing the stacking gel with a razor blade, and cutting a small piece from the lower left-hand corner of the gel (near lane 1 for gels loaded left to right; see Fig. 10.7.1) to aid in identifying the lanes in subsequent steps.

4. Briefly equilibrate the gel in a glass dish containing ~250 ml of 1× transfer buffer for an appropriate time based on gel thickness (0.5-mm-thick gels for 1 min; 0.75- to 1-mm gels for 5 min; 1.5-mm gels for 15 min).

   Longer equilibrations in transfer buffer prior to electrotransfer may extract too much SDS from the gel and hence reduce transfer efficiency. This equilibration step will remove excess SDS and prevent the gel from swelling during transfer. The negatively charged SDS allows proteins to move toward the transfer membrane in an electric field. On the other hand, too much SDS decreases binding of protein to PVDF membranes. Therefore, the amount of SDS is critical for transfer yield (see Critical Parameters and Troubleshooting).

5. Cut the PVDF transfer membrane about 0.5 to 1 cm larger than the gel. Cut a piece of Whatman no. 1 filter paper ~0.5 cm larger than the PVDF membrane.

6. Wet the PVDF membrane in a clean glass dish containing 100% methanol for 5 sec. Transfer membrane to a tray containing transfer buffer.

BGU IASI / CENTRAL UNIVERSITY LIBRARY

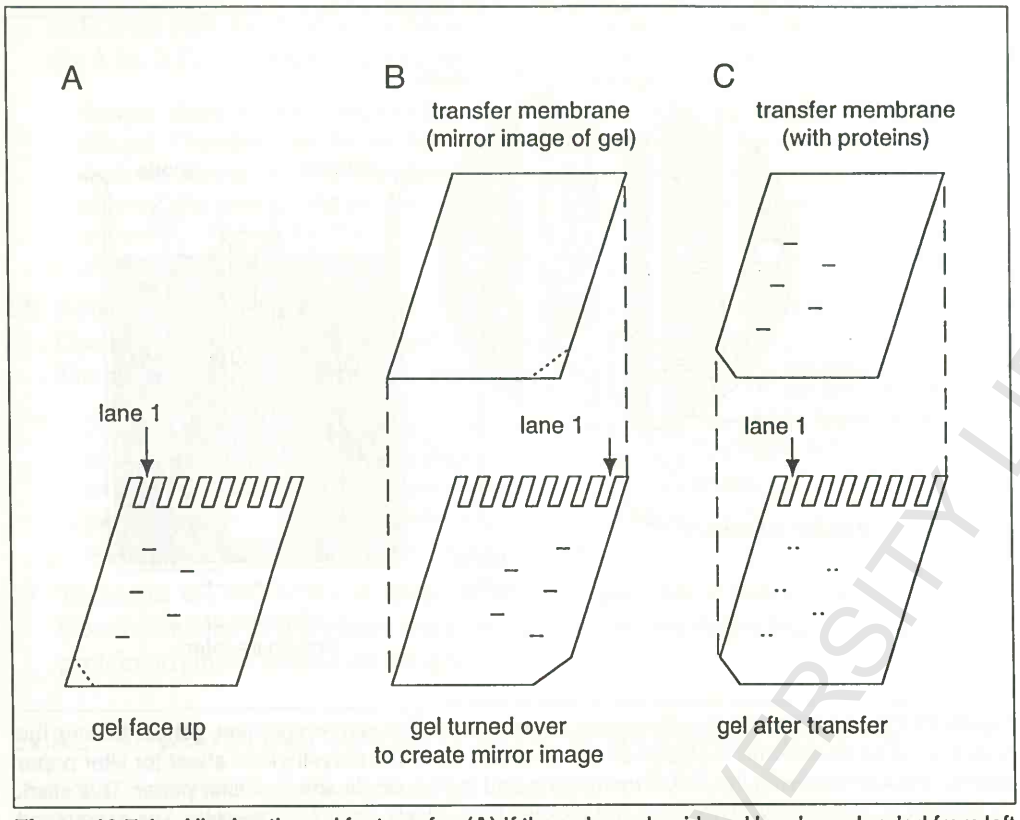

Figure 10.7.1 Aligning the gel for transfer. **(A)** If the polyacrylamide gel has been loaded from left to right, cut a small piece from the corner of the lower left-hand edge of the gel near the first lane. **(B)**When preparing the transfer sandwich, turn the gel over so that the cut edge is on the lower right-hand corner of the gel. This will ensure that the transferred proteins will appear in the same order as in the original gel. **(C)**After transfer, trim the membrane above the cut corner of the gel to mark orientation. Dots indicate where the proteins were before transfer.

The PVDF membrane will wet almost immediately with the 100% methanol. The hydrophobic membrane will not wet in either water or transfer buffer alone. After initial wetting in methanol, do not let the membrane dry; if drying occurs, rewet the membrane in 100% methanol.

Prepare the gel/membrane transfer sandwich

7. Place the opened gel holder cassette on a clean, flat surface. Place one transfer buffer–wetted fiber pad (see step 2) on the top surface, followed by the gel support sheet.

   A sheet of porous polyethylene is preferred as a support because it is rigid and facilitates handling, but filter paper can be used as a simple alternative. If the polyethylene sheet is used, place it with the smooth side up (toward the gel).

8. Place the gel face down on the support, so that the cut edge is now on the right-hand side (see Fig. 10.7.1B). Pour 5 to 10 ml transfer buffer on top of the gel.

9. Remove wet PVDF membrane from the tray containing transfer buffer (step 6). Eliminate air bubbles on both surfaces of membrane by sliding the membrane across the edge of the glass tray. Resubmerge membrane in transfer buffer for a few seconds and then position membrane above gel, letting its center contact the gel, and slowly lower the membrane from the center outward to force any bubbles to the edge of the gel. Rinse gloved hands with high-purity water and smooth the membrane gently to

BOSTON CENTRAL UNIVERSITY LIBRARY

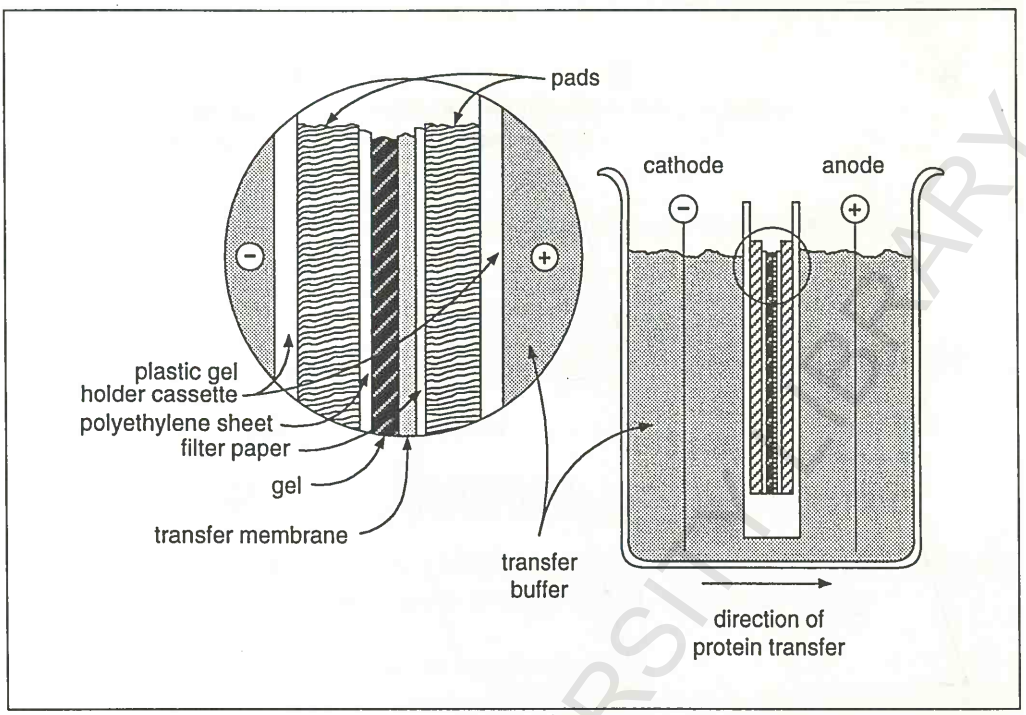

Figure 10.7.2 Electroblotting with a tank transfer unit. The polyacrylamide gel containing the protein(s) to be transferred is placed on the smooth side of the polyethylene sheet (or filter paper sheets) and covered with the PVDF membrane and then a single sheet of filter paper. This stack is sandwiched between two fiber pads and secured in the plastic gel holder cassette. The assembled cassette is then placed in a tank containing transfer buffer. For transfer of negatively charged protein, the membrane is positioned on the anode side of the gel. Charged proteins are transferred electrophoretically from the gel onto the membrane.

ensure uniform contact with the gel. Inspect the membrane for any trapped air bubbles.

This step is extremely important. Air bubbles will prevent the transfer of proteins.

10. Briefly wet the filter paper with transfer buffer and cover the PVDF membrane. Smooth gently to remove any air bubbles. Place the other fiber pad on top of the membrane and close the holder.

Do not allow any area of the PVDF membrane to dry during assembly, or transfer will not occur in these areas. The transfer sandwich should fit together snugly to provide good contact between the membrane and gel. The complete gel sandwich should look like that in Figure 10.7.2.

Conduct protein electrotransfer

11. Slide the assembled transfer cassette into the tank with the gel on the cathode side and the membrane on the anode side.

Proteins in an SDS-polyacrylamide gel have a net negative charge and will migrate toward the anode. For transfer from another type of gel, the orientation of the cassette may need to be reversed.

12. Fill the transfer tank with 1× transfer buffer so that the buffer completely covers the electrode panels but does not touch the electrical connectors.

13. Connect the power supply and perform the transfer at constant current compatible with complete transfer from the gel. For a Bio-Rad Trans-Blot tank transfer apparatus

BCU IASI CENTRAL UNIVERSITY LIBRARY

with solid plate electrodes, use 200 to 250 mA constant current. Transfer 0.5-mm gels for 1 hr, 0.75- to 1-mm gels for 2 hr, and 1.5-mm gels for 3 hr.

Longer times do not appear to increase transfer yield but may lead to overheating of the gel. Transfers can be carried out at constant voltage as well, but the current may increase during the run. Use caution to prevent overheating and/or unacceptably high current. Because of the amount of heat generated at higher transfer rates, it may be necessary to run the transfer in a cold room or with a cooling core to prevent overheating.

14. At the end of the transfer period, turn off the power and disconnect the power supply. Open the transfer sandwich and remove the membrane and gel (Fig. 10.7.1C). Thoroughly rinse the membrane with high-purity water, three times, 5 min each.

The membrane can be stained as described in UNIT 10.8 or used for other detection methods. Stained or unstained membranes can be air dried (for ~30 min) and stored in resealable plastic bags at room temperature for several weeks or at −20°C for a permanent record. Dried membranes can be rehydrated in 50% or 100% methanol and used for subsequent detection procedures.

15. To assess the efficiency of transfer, stain the proteins remaining on the gel with Coomassie blue or with more sensitive silver solutions, depending on the amount of protein originally loaded on the gel.

ELECTROBLOTTING OF PROTEINS FOR SEQUENCE ANALYSIS

ALTERNATE PROTOCOL 1

One-dimensional or two-dimensional gel electrophoresis combined with electroblotting to PVDF membranes provides a method to obtain proteins of high purity that can be used directly for N-terminal protein sequence analysis. The major concern is avoiding possible chemical modification of proteins such as N-terminal blocking. Simple precautions such as casting gels in advance and modifying the composition of reagents to protect proteins minimize the possibility of side reactions during electrophoresis and electroblotting and are described in this protocol.

NOTE: Use high-quality water such as Milli-Q-purified water or equivalent and high-purity electrophoresis reagents (i.e., Bio-Rad) throughout for best results.

Additional Materials (also see Basic Protocol 1)

Thioglycolate (thioglycolic acid, sodium salt; Sigma)
PVDF transfer membrane: 0.2-µm PVDF membrane (Bio-Rad), ProBlott (Perkin-Elmer), or Immobilon-P^{SQ} (Millipore)

Additional reagents and equipment for one- or two-dimensional gel electrophoresis (*UNITS 10.1 & 10.4*) and for staining membranes (*UNIT 10.8*) and gels (*UNIT 10.6*)

1. Cast polyacrylamide gel including stacking gel at least 24 hr but not more than 48 hr prior to use. Store the gel at room temperature until needed, being sure to protect it from dehydration (e.g., store submerged in high-purity water).

For preparing gels choose an acrylamide concentration such that the protein will migrate as a sharp, tight band with an R_f between 0.2 and 0.8. Casting a gel in advance allows complete polymerization, reduces the amount of oxidants and free radicals, and minimizes the possibility of blocking the N terminus or other amino groups of the protein.

2. Add thioglycolate to the electrophoresis buffer in the cathode buffer chamber to a final concentration of 0.1 mM (11.4 mg per liter buffer).

Thioglycolate scavenges remaining free radicals and oxidants in the gel.

BOURNEMOUTH UNIVERSITY LIBRARY

3. Solubilize samples in either 2× or 5× Laemmli solubilizing buffer containing sucrose or glycerol but not urea. Heat to 37°C for 15 min.

   If possible, avoid boiling the sample, as the high temperature increases the risk of chemical modification of the protein. Boiling may be necessary for complete solubilization of some samples, however (e.g., whole viruses).

4. Conduct gel electrophoresis. Proceed with electroblotting (see Basic Protocol 1, steps 1 to 14).

5. After transfer is complete, rinse the membrane six times for 5 min each with a large volume of water (at least 200 ml each time).

   The membrane must be thoroughly rinsed with water immediately after transfer is complete. It is critical that the membrane is not allowed to dry prior to thorough rinsing because even partial drying can prevent effective removal of Tris and glycine.

6. Stain the membrane with amido black or Ponceau S to detect proteins. Stain the gel after transfer as appropriate to judge transfer efficiency.

ALTERNATE PROTOCOL 2

ELECTROBLOTTING ONTO NITROCELLULOSE MEMBRANES

The electroblotting procedure for nitrocellulose membranes differs little from that for PVDF membranes. Nitrocellulose is compatible for use with a moderate amount of SDS (up to 0.1%) in the transfer buffer. The delicate membranes must, however, be handled carefully and protected from high concentrations of organic solvents.

Additional Materials (also see Basic Protocol 1)

0.45-µm nitrocellulose transfer membrane (Schleicher & Schuell)

Additional reagents and equipment for membrane (*UNIT 10.8*) and gel staining (*UNIT 10.6*)

1. Prepare the transfer apparatus and gel as described for PVDF membranes (see Basic Protocol 1, steps 1 to 4).

2. Cut the nitrocellulose transfer membrane to a size slightly larger than the gel and cut a piece of filter paper slightly larger than the membrane.

3. Wet the membrane by slowly introducing the membrane from one corner into a glass dish of 1× transfer buffer. Equilibrate the membrane for 15 min.

   IMPORTANT NOTE: *Never soak the membrane in 100% methanol. During electrotransfer and staining, avoid exposure to high concentrations of organic solvents, which will dissolve the membrane. Up to 20% methanol can be used in the transfer buffer without affecting the membrane.*

4. Proceed with electrotransfer as above for PVDF membranes (see Basic Protocol 1, steps 7 to 13).

5. When transfer is complete, rinse membrane three times for 5 min each with high-purity water; detect proteins on the membrane using an aqueous stain such as Ponceau S if desired.

6. Assess efficiency of transfer by staining the gel after transfer as appropriate.

BCU IASI/CENTRAL UNIVERSITY LIBRARY

PROTEIN ELECTROBLOTTING IN SEMIDRY SYSTEMS

ALTERNATE PROTOCOL 3

An alternative to the tank transfer system is the semidry transfer system. In this procedure, the gel is stacked horizontally on top of the membrane in the transfer apparatus. Because only a small volume of transfer buffer is used, SDS from the gel is less effectively diluted, which may result in incomplete binding and lower yields, especially with PVDF membranes. For this reason, semidry transfer units are not recommended when reproducible high recoveries of electroblotted proteins are desired (e.g., for subsequent sequence analysis). Some procedures recommend stacking multiple transfer sandwiches to achieve several transfers simultaneously. To prevent unbound protein from migrating through the next gel and onto the membrane in the next transfer stack, sheets of porous cellophane sheets or dialysis membrane are placed between adjacent transfer stacks (see Fig. 10.7.3). Semidry electrotransfer requires shorter transfer times than tank transfer.

Additional Materials (also see Basic Protocol 1)

Semidry transfer apparatus
Mylar mask (optional)

Prepare the transfer sandwiches

1. Cut transfer membrane just slightly larger than the gel containing proteins to be transferred, then equilibrate in the appropriate transfer buffer (see Basic Protocol 1, step 6).
2. Cut six sheets of filter paper the same size as the transfer membrane and wet thoroughly in transfer buffer.

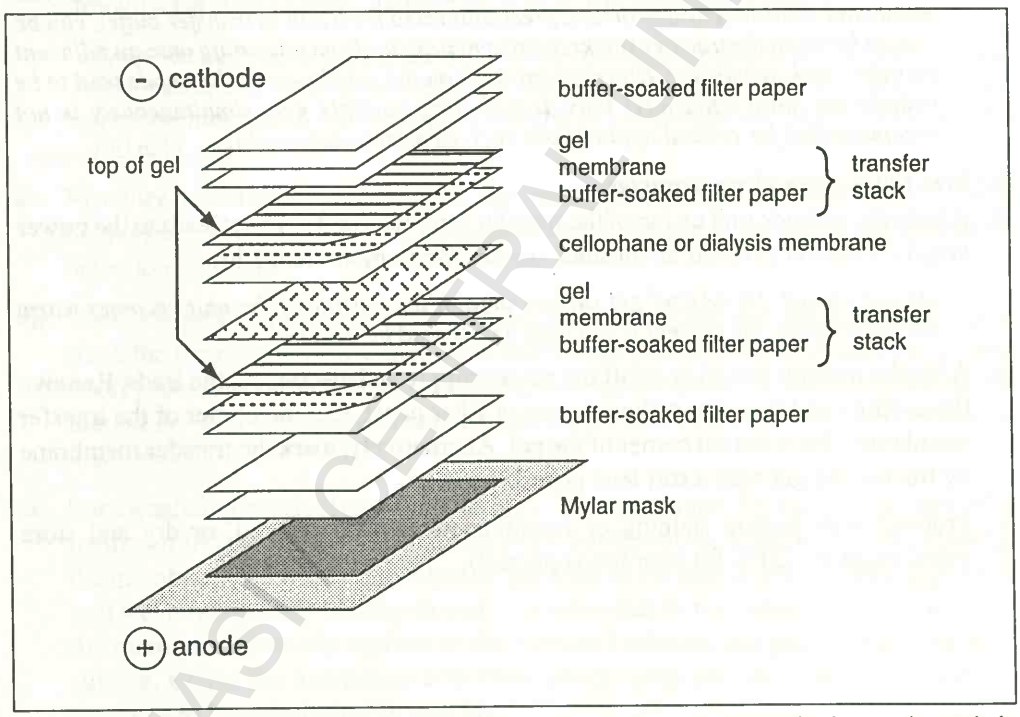

Figure 10.7.3 Electroblotting with a semidry transfer unit. In most cases, the lower electrode is the anode, as shown. Position the Mylar mask (optional) directly over the anode. Layer on three sheets of filter paper that have been wetted in transfer buffer. For negatively charged proteins, place the preequilibrated transfer membrane on top of the filter paper followed by the gel and three additional sheets of wetted filter paper. If multiple gels are to be transferred, separate the transfer sandwiches by inserting a sheet of porous cellophane or dialysis membrane between each stack. Place the cathode on top of the assembled transfer stack(s). Transfer the proteins by applying a maximum current of 0.8 mA/cm^2 gel area.

UCL BIOMEDICAL CENTRAL UNIVERSITY LIBRARY

3. Remove gel containing proteins of interest from the electrophoresis unit. Using a razor blade, cut the lower corner of the gel at the first lane. Equilibrate the gel in transfer buffer (see Basic Protocol 1, step 4).

4. Layer a Mylar mask (optional) followed by three sheets of filter paper on the anode of the transfer unit. Smooth each piece of filter paper to avoid trapping air bubbles between the layers.

   It is important to remove all air bubbles from the transfer stack as they will block the flow of current through that area of the gel, creating blank spots on the transfer membrane.

5. Layer the prepared transfer membrane on top of the filter paper. Gently roll a test tube or Pasteur pipet over the membrane to push out any air bubbles.

6. Place the gel on top of the transfer membrane so that the cut edge is on the left-hand side. With a pair of scissors, cut the lower corner of the membrane even with the gel (to aid in realigning gel and blot after final staining). Again, remove any air bubbles (see Basic Protocol 1, step 9).

   When assembling this transfer sandwich, the gel is placed on top of the membrane, in contrast to the opposite order for tank type sandwich assembly as in Basic Protocol 1. Therefore, it is unnecessary to turn the gel over to obtain the proper orientation (compare Figs. 10.7.1 and 10.7.3).

7. Layer the remaining three sheets of filter paper individually on top of the gel, rolling out any air bubbles after each addition.

   It is possible to transfer multiple gels simultaneously using semidry blotting. As shown in Figure 10.7.3, a sheet of porous cellophane (Hoefer Pharmacia) or dialysis membrane (Bio-Rad or Sartorius), preequilibrated for 5 min in transfer buffer, can be placed between the transfer stacks to prevent proteins from migrating onto an adjacent transfer stack membrane. However, proteins on the gel closest to the anode tend to be transferred more efficiently; thus, transferring multiple gels simultaneously is not recommended for critical applications such as protein sequencing.

Perform the protein electrotransfer

8. Attach the cathode unit on top of the transfer sandwich and connect leads to the power supply. Transfer proteins at constant current for no more than 1 hr.

   Do not exceed 0.8 mA/cm^2 gel surface area. If the outside of the unit becomes warm during transfer, the current is too high and should be lowered.

9. After the transfer period, turn off the power supply and disconnect the leads. Remove the cathode and uppermost three layers of filter paper. Cut the corner of the transfer membrane above the cut corner of the gel. Alternatively, mark the transfer membrane by tracing the gel with a soft lead pencil.

10. Proceed with protein staining or immunodetection, as desired, or dry and store membranes at –20°C for later use (optional).

BCU IASI / CENTRAL UNIVERSITY LIBRARY

PROTEIN ELUTION FROM PVDF MEMBRANES USING DETERGENTS

BASIC PROTOCOL 2

Binding affinities of most proteins to PVDF membranes are relatively strong. The most efficient protocol for protein recovery from PVDF membranes requires the use of detergents, which limits the possible use of extracted samples because detergents are often incompatible with subsequent procedures. This protocol is a simple procedure to elute proteins from the membrane into a Triton/SDS solution. A protocol that employs acidic extraction with organic solvents is also described (Alternate Protocol 4).

Materials

Polyacrylamide gel containing proteins of interest
Ponceau S stain (*UNIT 10.8*; optional)
50% methanol (optional)
Triton/SDS elution buffer (see recipe)

PVDF transfer membrane (Immobilon-P, Millipore)
Transfer apparatus: solid plate electrode tank transfer system (e.g., Trans-Blot, Bio-Rad)

Additional reagents and equipment for staining membranes (*UNIT 10.8*)

1. Prepare gel and membrane for transfer as for PVDF membranes (see Basic Protocol 1, steps 1 to 6).
2. Assemble the gel/membrane transfer sandwich and place in transfer tank (see Basic Protocol 1, steps 7 to 10).
3. Conduct electrotransfer (see Basic Protocol 1, steps 11 to 14), using lower field strengths for step 13 (e.g., transfer for 6 hr at 100 mA for 1.5-mm gels).

   Temperatures >20°C during the transfer can increase the interaction between protein and matrix and make extraction more difficult. If problems arise in eluting proteins from the membrane, try running the transfer in a cold room overnight at low currents (50 mA).

4a. Visualize transferred proteins with any membrane-compatible stain (*UNIT 10.8*). If bound stain will interfere with subsequent steps, use one of the following alternative detection methods.

4b. Visualize proteins with Ponceau S stain (*UNIT 10.8*). After staining with Ponceau S, wash the membrane with water, place under clear plastic wrap, and mark bands with a soft pencil by outlining the protein band through the plastic. Completely destain the membrane with water (a permanent indentation made by the pencil will be left on the membrane).

4c. For visualizing bands after partial drying of the membrane, fill a glass dish with 50% methanol and place the dry membrane on the surface of the solution. Do not submerge the membrane. Identify protein bands (portions of the membrane containing proteins will wet more quickly and dry slower than areas that do not contain protein). Remove the membrane from the surface of the methanol solution and place on a clean glass surface. Cover the membrane with clear plastic wrap and use a pencil to mark the protein bands as described in step 4b.

5. Excise the band(s) of interest by carefully cutting the membrane with a clean razor blade or scalpel.

   Do not allow the membrane to dry during this process. Keep the membrane wet (e.g., submerged in water) at all times (unless using the partial drying procedure).

B.C.U. „M. EMINESCU" IAŞI
CHIMIE

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

6. Place the excised membrane band in a 1.5-ml microcentrifuge tube containing 0.2 to 0.5 ml of Triton/SDS elution buffer for every square centimeter of membrane. Microcentrifuge the sample 10 min at maximum speed, at room temperature, to release the protein from the membrane.

7. Remove supernatant, place it in a new microcentrifuge tube, and microcentrifuge again to remove any particulate material.

Multiple extractions with the elution mixture significantly aid quantitative recovery. In most cases, three extractions remove 90% to 100% of the protein from the membrane.

ALTERNATE PROTOCOL 4

PROTEIN ELUTION FROM PVDF MEMBRANES USING ACIDIC EXTRACTION WITH ORGANIC SOLVENTS

Blotted proteins are usually of high purity and thus good candidates for additional characterization. If the protein cannot be further characterized on the blot and contamination of samples with large amounts of detergent (Support Protocol 1) is unacceptable, acidic elution with organic solvents may be an alternative. The use of organic solvents limits this protocol to PVDF membranes, which have high chemical resistance. This protocol may produce highly variable recoveries for different proteins and is best suited for relatively low-molecular-weight proteins and peptides (<50 kDa).

Additional Materials (also see Basic Protocol 2)

Extraction solution (see recipe)
50% methanol
1:2 (v/v) acetonitrile/formic acid

NOTE: All solutions should be made with high-purity water and can be stored at room temperature for at least 1 month.

1. Rinse the desired number of 1.5-ml microcentrifuge tubes (two tubes per sample) three times with extraction solution, and air dry under an aluminum foil dust cover.

Minimize possible contamination with dust at all times.

2. Visualize and mark the protein bands by partial drying of the membrane using 50% methanol (see Support Protocol 1, step 4c). Use a scalpel or razor blade to cut out the protein bands.

3. Place pieces of membrane containing the protein of interest in a clean microcentrifuge tube.

Combining several bands from multiple gels is usually necessary. Use a pair of tweezers cleaned with 100% methanol to transfer the membrane pieces to the microcentrifuge tube. Avoid contaminating the membrane pieces and microcentrifuge tube with airborne dust or residues from fingers.

4. Add 200 µl extraction solution to each microcentrifuge tube.

An alternative mixture of 1:2 acetonitrile/formic acid seems to be as efficient as the extraction solution described above for some proteins.

5. Agitate tubes for 48 hr at 4°C.

6. Repeat the extraction using 1:2 acetonitrile/formic acid. Combine the extracts.

Multiple extractions (up to three) with the same or different solvent mixtures are often beneficial. The extracts should be combined and kept on ice at all times.

7. Lyophilize protein extracts to provide highly purified samples suitable for most subsequent experiments.

RGU IASL CENTRAL UNIVERSITY LIBRARY

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

***Extraction solution** (40% acetonitrile/1% trifluoroacetic acid)*

Add 1.0 ml trifluoroacetic acid to 59 ml high-purity water, then add 40 ml acetonitrile. Store at room temperature. Solution is stable for at least 1 month in a tightly sealed container.

Transfer buffer, 20×

200 mM Tris base
2.0 M glycine
Do not adjust pH of final solution (stable at room temperature for at least 1 month)

(Prepare 1× transfer buffer by mixing 200 ml 20× stock, 400 ml methanol, and water to 4 liters.) Prepare 1× transfer buffer on the same day of use. Keep at room temperature.

Triton/SDS elution buffer

50 mM Tris·Cl, pH 9.0 (*APPENDIX 2E*)
2% (w/v) SDS (*APPENDIX 2E*)
1% (v/v) Triton X-100

Prepare solution on the same day of use. Keep at room temperature.

COMMENTARY

Background Information

The transfer of proteins from polyacrylamide gels onto blot membranes offers many benefits. Transferred proteins can be eluted from the membrane, probed with antibodies (immunoblotting), used for N-terminal protein sequencing as well as other structural analyses including amino acid analysis, protease cleavage (*UNIT 11.2*), and chemical cleavages (*UNIT 11.5*), or stained by a variety of highly sensitive techniques. In addition, several manipulations can be performed on the same blot by loading samples in multiple lanes on the gel before electroblotting.

Prestained protein standards are useful guides for cutting the membrane prior to different analysis procedures, such as using one part for immunoblotting and the other for protein staining. Prestained radiolabeled standards are useful for aligning the blot membrane with autoradiograms. Prestained standards will migrate differently on the gel compared with the unmodified standard proteins, usually showing higher molecular weight.

During electrotransfer, proteins migrate out of gels in an electric field according to the charge on the protein. Most electrotransfers employ a tank transfer apparatus (Fig. 10.7.2) in which the gel/membrane transfer sandwich is mounted in a cassette and placed in a tank of Tris/glycine/methanol transfer buffer. The semidry transfer system (Fig. 10.7.3) is an alternative. The major advantages of the semidry system are its use of substantially less buffer and the shortening of transfer time due to the close positioning of the electrodes, which produces a high field strength with minimal heating. A variety of transfer membranes, which can effectively bind proteins based on different types of protein-membrane interactions, are commercially available. These include PVDF, nitrocellulose, and nylon membranes as well as a number of derivatized membranes.

PVDF membranes bind proteins primarily through hydrophobic interactions and are commonly used for their chemical resistance as well as physical stability. High-affinity PVDF membranes such as Trans-Blot (Bio-Rad), Pro-Blott (Perkin-Elmer), and Immobilon-P^{SQ} (Millipore) are preferred for blots intended for use in N-terminal protein sequencing, whereas low-retention membranes such as Immobilon-P (Millipore) may produce lower background in both immunoblotting and common staining procedures. In addition, low-retention membranes are preferred when proteins will be extracted from the membrane.

Nitrocellulose binds proteins primarily by hydrophilic and/or electrostatic interactions and for this reason is less sensitive than PVDF

BYU SOUTHERN UNIVERSITY LIBRARY

membranes to the concentration of SDS in both the gel and transfer buffer. Its tolerance to SDS allows relatively good recovery of poorly migrating proteins because higher concentrations of SDS can be left in the gel or added to the transfer buffer without adversely affecting protein binding to the membrane. In addition, nitrocellulose is often used for immunoblots, although PVDF membranes have replaced nitrocellulose for this application in many laboratories. The major limitations of nitrocellulose are its poor binding of low-molecular-weight proteins and peptides, mechanical weakness, and lack of resistance to organic solvents.

PVDF can be derivatized to modify the nature of protein-membrane interactions and to potentially increase the strength of protein binding. Derivatization most commonly involves adding a charge to the membrane so that proteins will be held on the membrane by electrostatic charges as well the usual hydrophobic or hydrophilic interactions. The procedure for electrotransfer onto derivatized membranes is essentially identical to that for PVDF or nitrocellulose membranes described in this unit. Although derivatized membranes are better for binding RNA and DNA, most derivatized membranes have not offered clear advantages for blotting proteins.

One commercially available derivatized PVDF membrane that has potentially useful binding properties for proteins is Immobilon-CD (Millipore), which has been derivatized to produce a cationic surface so that it behaves like an ion-exchange support (Patterson et al., 1992). In addition, the membrane is treated to prevent nonspecific protein adsorption. The well-defined nature of the protein/Immobilon-CD interaction allows good recoveries of electroblotted proteins under relatively mild conditions. Proteins may be recovered from CD membranes nearly quantitatively using denaturing detergent solutions such as 4 M guanidine hydrochloride/0.1% Triton X-100. Proteins can be fragmented using a variety of enzymes and proteases either directly on the Immobilon-CD membrane or after elution. If the proteins are to be digested after elution, the enzymes should be tested for compatibility with the elution buffer.

Proteins can also be eluted from Immobilon-P membranes, and two procedures for doing so are described in this unit: protein elution using detergents (Support Protocol 1; Szewczyk and Summers, 1988) and acidic elution with organic solvents (Support Protocol 2; D.W.S., unpub. observ.). Although gel electrophoresis combined with subsequent electroblotting is often the most powerful procedure for microscale protein isolation, identification, and characterization, one limitation of this system is that subsequent elution of proteins from PVDF membranes in good yields is often difficult.

Critical Parameters and Troubleshooting

The protocols listed in this unit should be sufficient for the transfer of most proteins. The efficiency of protein transfer is easily assessed by staining both the transfer membrane and the gel after transfer. When difficulty is encountered in the transfer recovery of a specific protein, several factors can be considered to improve transfer efficiency.

A first consideration is the type of gel used to separate proteins for transfer. Higher percentages of acrylamide make the transfer of proteins out of the gel more difficult. Gel thickness also affects transfer: the thicker the gel, the farther the protein has to migrate to reach the membrane. In general, effective transfer of proteins out of gels up to 1.5 mm thick can be achieved; thicker gels, although having increased protein capacity, offer little advantage owing to reduced removal of proteins from the thicker gel matrix.

In this unit, the transfer buffer described is essentially half-strength Towbin buffer (Towbin et al., 1979). This buffer contains a mixture of Tris and glycine and is the buffer of choice if the electroblotted proteins will be used for sequence analysis. Tris, glycine, and most other low-molecular-weight buffer components do not normally bind to PVDF membranes and can be completely removed by thorough rinsing with high-purity water. However, incomplete rinsing or partial drying of the membrane prior to rinsing can result in high residual levels of these compounds, which could be detrimental for sequence analysis.

The amino groups in the buffer act as scavengers for contaminants that could potentially modify proteins. Several simple precautions noted in Alternate Protocol 1 can be taken to minimize side reactions of proteins during electrophoresis and electroblotting (Speicher, 1989). If possible chemical modifications are not critical, several other buffers may be used. CAPS buffer (cyclohexylaminopropanesulfonic acid; LeGendre and Matsudaira, 1988) has a high pH (pH 11) and low ionic strength and, therefore, because of its low conductivity,

permits the use of high electric fields. For the transfer of very basic proteins that bind SDS poorly, high pH may prove advantageous in keeping the total net protein charge negative; however, the high pH of the CAPS buffer can also lead to deamination of sensitive side chains. Other types of electrotransfer buffers such as Tris/borate (Vandekerckhove et al., 1985) do not differ significantly in overall performance from the Tris/glycine buffer and may be used if N-terminal protein blockage is not a major concern.

Selection of membrane type is dependent on the ultimate use of the transferred protein, although high-retention PVDF membranes are most often chosen because they bind proteins more tightly than nitrocellulose membranes and have greater chemical and mechanical stability. For immunoblots, either nitrocellulose or Immobilon-P (Millipore) are preferred by some investigators because they produce a lighter background than high-retention PVDF membranes.

It is not uncommon in electroblot procedures to observe less than optimal transfer of proteins. If the membrane is entirely blank and little or no protein is left in the gel after transfer, it is likely that the electrodes were connected in a reversed order or that the membrane was placed on the wrong side of the gel. Blank spots on membranes are caused by air bubbles, which block the flow of current.

Another problem often encountered with poor transfer of proteins relates to the amount of SDS in the gel, which coats the proteins and improves mobility during electrotransfer. Nitrocellulose membranes are not sensitive to the amount of SDS in the gel and can even tolerate addition of SDS to the transfer buffer to encourage transfer of recalcitrant proteins. PVDF membranes are more sensitive to excess SDS, which can inhibit protein binding to the hydrophobic membrane; nevertheless, in a limited number of cases, addition of SDS to the transfer buffer may be beneficial. Low-retention PVDF membranes are particularly sensitive to excess SDS concentrations, whereas high-retention PVDF membranes are less so. Methanol is a common component of many transfer buffers because it facilitates dissociation of bound SDS from proteins. Therefore, if proteins transfer from the gel efficiently but do not bind well to PVDF membranes, the methanol concentration can be increased to 20% and/or the gel can be preequilibrated in transfer buffer for 15 to 30 min prior to transfer to reduce the SDS concentration (Mozdzanowski et al., 1992). Conversely, if proteins remain in the gel after transfer, the methanol concentration can be reduced or eliminated, and if necessary a low concentration of SDS (0.005%) can be added to the transfer buffer to facilitate electrotransfer from the gel.

If proteins have transferred efficiently but the stained membrane has blurred bands or a swirled pattern, it is likely that there was insufficient contact between the gel and membrane during transfer. The transfer sandwich should be held together firmly both to avoid having the gel shift position during transfer and to ensure close contact between the gel and membrane. Another common problem with transfers is the presence of bright white spots within protein bands on the membrane. These are due to air bubbles trapped between the gel and membrane or, in the case of PVDF membranes, possibly due to local drying of the membrane during transfer unit assembly. As indicated in the protocols, it is very important to check for air bubbles before electrotransfer. Air bubbles can be rolled out from the two surfaces by using a test tube, or the membrane can be carefully lifted to release the bubble and replaced without shifting the position of either gel or membrane.

Anticipated Results

Proteins in the middle two-thirds of the gel usually transfer to high-retention PVDF membranes with an average yield of 50% to 80%. The protein pattern on PVDF membranes stained with amido black or Coomassie blue should closely resemble the pattern on duplicate lanes of the gel stained with Coomassie blue. The staining intensity on the blot should be slightly higher than on the gel because the proteins are concentrated on the surface of the blot rather than distributed throughout the thickness of the gel. Proteins below the dye front usually will not be recovered on the membrane. Proteins in the top 20% of the gel are often incompletely transferred out of the gel.

Time Considerations

Assembling the transfer unit takes ~30 min. Electroblotting can be completed in 2 to 4 hr in most cases using a tank transfer unit and in ~1 hr using a semidry blotting unit.

Detection of Proteins on Blot Membranes

Staining of blot transfer membranes permits visualization of proteins and allows the extent of transfer to be monitored. In the protocols described in this unit, proteins are stained after electroblotting from one-dimensional or two-dimensional polyacrylamide gels to blot membranes such as polyvinylidene difluoride (PVDF), nitrocellulose, or nylon membranes (*UNIT 10.7*). PVDF is the preferred, more universal membrane and is emphasized here; however, most stains work similarly on nitrocellulose, and many can be used on alternative blotting membranes.

The first six Basic Protocols describe the use of six general protein stains—amido black, Coomassie blue, Ponceau S, colloidal gold, colloidal silver, and India ink. In addition, the fluorescent stains fluorescamine and IAEDANS, which covalently react with bound proteins, are described in Basic Protocol 7 and the Alternate Protocol. Table 10.8.1 lists approximate detection limits for each nonfluorescent stain as well as membrane compatibilities. The dimensional stability of blotted membranes facilitates direct, precise comparisons of staining patterns using different detection methods. For example, protein staining can be directly compared with immunoreactivity by staining one portion of a blot with a general protein stain while subjecting another portion containing duplicate samples to immunoblotting. When it is desirable to cut replicate lanes from the blot prior to any staining, prestained standards provide very useful visual reference points.

NOTE: High-purity water (from a Milli-Q purification system or equivalent) should be used throughout the protocols, and all plastic and glass boxes must be thoroughly cleaned before use to avoid staining artifacts. Membranes should be handled only by the edges with forceps. All steps should be performed at room temperature (unless otherwise described) and with gentle agitation. Use of an orbital shaker is recommended for steps that take longer than 1 min. If a PVDF membrane is allowed to dry after transfer, wet for 5 sec in 100% methanol and rinse with water before staining. Volumes of stain, destain, and wash solutions should be sufficient to cover the membrane and allow it to float freely. Unless noted otherwise, solutions may be stored for several months at room temperature.

Table 10.8.1 Staining Sensitivities and Membrane Compatibilities for Nonfluorescent Stains[a]

Stain	Minimum amount detected[b]	Membrane type[c]		
		PVDF	Nitrocellulose	Nylon
Amido black	50 ng	+	+	+
Coomassie blue	50 ng	+	–	+
Ponceau S	200 ng	+	+	+
Colloidal gold	2 ng	+	+	–
Colloidal silver	5 ng	+	+	–
India ink	5 ng	+	+	–

[a]Sensitivity of fluorescent stains is very dependent on protein amino acid composition.

[b]Minimum amount detected based on amount of protein loaded onto gel. The actual amount on the blot will be slightly lower because of losses during electrotransfer. Values are based on use of a full-sized gel (11 cm × 16 cm × 1.5 mm). Sensitivity will be ~2 to 5 times higher when minigels (8 cm × 10 cm × 1.0 mm) are used because the protein bands are concentrated on a smaller area of membrane.

[c]+ indicates stains well; – indicates membrane not compatible.

BOWLING GREEN STATE UNIVERSITY LIBRARY

BASIC PROTOCOL 1

AMIDO BLACK STAINING

Amido black is used to stain proteins on blot transfer membranes. Transferred proteins (>50 ng/band) appear as dark blue bands on a light blue background. Amido black has a sensitivity similar to that of Coomassie blue, but it stains faster. It is the preferred stain for protein sequencing and in situ cleavage of proteins for determining internal sequences because the mild staining and destaining conditions minimize the likelihood that any protein will be extracted during the procedures.

Materials

Protein sample electroblotted to PVDF, nitrocellulose, or nylon membrane (*UNIT 10.7*)
Amido black 10B stain: 0.1% (w/v) amido black (naphthol blue black 10B, Sigma) in 10% (v/v) acetic acid
5% (v/v) acetic acid
Plastic boxes

1. Place blot transfer membrane in a plastic box and wash with water three times for 5 min each.
2. Stain membrane with amido black 10B stain for 1 min.

   Longer staining times only increase background and hence decrease sensitivity.
3. Destain the membrane with 5% acetic acid twice for 1 min each.
4. Rinse the membrane with water twice for 10 min each, then air dry.

BASIC PROTOCOL 2

COOMASSIE BLUE R-250 STAINING

Coomassie blue R-250 can be used with most types of blot membranes except nitrocellulose (high concentrations of organic solvents can dissolve nitrocellulose membranes). Coomassie blue has a similar sensitivity to amido black. Coomassie blue–stained proteins (>50 ng/band) appear as dark blue bands against a light blue background. The sequence of washing with water, staining, and destaining is similar to that for amido black staining (Basic Protocol 1), but the staining step is lengthened to 5 min.

Materials

Blot transfer membrane (*UNIT 10.7*)
Coomassie blue stain: 0.025% (w/v) Coomassie brilliant blue R-250 (Bio-Rad) in 40% methanol/7% acetic acid (v/v)
50% methanol/7% acetic acid (v/v)
Plastic box

1. Place blot transfer membrane in a clear plastic box. Wash with water three times for 5 min each.
2. Stain membrane with Coomassie blue stain for 5 min.

   If proteins on PVDF membranes are to be subjected to N-terminal sequencing, acetic acid should be omitted from the staining and destaining solutions to minimize protein extraction.
3. Destain membrane with 50% methanol/7% acetic acid for 5 to 10 min.
4. Rinse with water several times, then air dry.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

PONCEAU S STAINING

BASIC PROTOCOL 3

Ponceau S is the least sensitive general protein stain described here. Transferred proteins (>200 ng/band) appear as red bands on a pink background. Major advantages of Ponceau S staining are that it is simple, rapid, and reversible. If desired, essentially all of the stain can be removed by extended destaining as described in steps 4 to 6. This can be particularly advantageous if the blot is to be reused after initial protein staining for a second detection method such as immunoblotting.

Materials

Blot transfer membrane (*UNIT 10.7*)
Ponceau S stain: 0.5% (w/v) Ponceau S (Sigma) in 1% (v/v) acetic acid
200 µM NaOH/20% (v/v) acetonitrile
Plastic box

1. Place blot transfer membrane in a plastic box and wash with water three times for 5 min each.
2. Stain membrane with Ponceau S stain for 30 sec to 1 min.
3. Destain membrane with several changes of water for 30 sec to 1 min each, then air dry. If the stain is to be extracted from protein bands (steps 4 to 6) prior to employing a second detection method, omit drying.

   Do not overdestain because the protein bands will be difficult to detect. Stop destaining when the background has a very slight pink tinge.

4. Make a permanent record of the staining pattern by photocopying or photographing the blot. Alternatively, mark the positions of the bands of interest directly on the blot by overlaying the wet blot with plastic wrap or a plastic bag and using a pencil or pen to outline the bands. Press with moderate pressure to make a permanent indentation on the membrane.
5. Extract Ponceau S stain from the protein bands with 200 µM NaOH/20% acetonitrile for 1 min.
6. Wash membrane with water three times for 5 min each, then air day.

COLLOIDAL GOLD STAINING

BASIC PROTOCOL 4

Colloidal gold is a highly sensitive stain. AuroDye (Amersham) is a ready-to-use commercial source of colloidal gold stain in a low-pH buffer. AuroDye should be used without dilution. Transferred proteins (>2 ng/band) will appear as red bands on a pink background. A higher signal may be obtained with alkali treatment of the membrane prior to staining by washing the membrane with 1% KOH followed by several rinses with phosphate-buffered saline (PBS). Glass rather than plastic boxes must be used to hold the membranes and solutions. Glass is easier to clean than plastic and is less likely to give artifacts. Ideally, a set of glass trays should be dedicated to the procedure.

Materials

Blot transfer membrane (*UNIT 10.7*)
Tween 20 solution: 0.3% (v/v) Tween 20 in PBS (*APPENDIX 2E*; prepare solution fresh weekly and store at 4°C)
AuroDye colloidal gold reagent (Amersham; store at 4°C)
Glass box

BOTANY / SOUTH TRAL UNIVERSITY LIBRARY

1. Place blot transfer membrane in a glass box. Wash with water three times for 5 min each.
2. Incubate membrane with Tween 20 solution for 30 min at 37°C with gentle agitation.
3. Wash membrane with Tween 20 solution three times for 5 min each at room temperature.
4. Rinse membrane several times with water.
5. Stain membrane with AuroDye for 2 to 6 hr (until desired color formation).

   Use only enough stain to cover the membrane completely.
6. Rinse membrane thoroughly with water, then air dry.

BASIC PROTOCOL 5

COLLOIDAL SILVER STAINING

Colloidal silver is a more economical stain than colloidal gold. The staining procedure is rapid, although the ferrous sulfate solution must be prepared immediately before use. Transferred proteins (>5 ng/band) appear as black bands on a light brown background for nitrocellulose and on a dark background for PVDF.

Materials

Blot transfer membrane (*UNIT 10.7*)
40% (w/v) sodium citrate (store at 4°C for several months)
20% (w/v) ferrous sulfate ($FeSO_4 \cdot 7H_2O$), prepared fresh
20% (w/v) silver nitrate (store at 4°C for several months)
Glass box

1. Place blot transfer membrane in a glass box and wash with water three times for 5 min each.
2. Add 5 ml of 40% sodium citrate and 4 ml of 20% ferrous sulfate to 90 ml water. Stir vigorously and slowly add 1 ml of 20% silver nitrate over ~1 to 2 min to form a suspension.
3. Immediately use the suspension to stain the membrane for ~5 min.

   The staining suspension should be used within 30 min.
4. Rinse membrane with water, then air dry.

BASIC PROTOCOL 6

INDIA INK STAINING

India ink is used to stain electroblotted proteins on blot transfer membranes. Transferred proteins (>5 ng/band) appear as black bands on a gray background. Sensitivity may be enhanced by brief alkali treatment of the membrane with 1% KOH followed by several rinses with PBS.

Materials

Blot transfer membrane (*UNIT 10.7*)
Tween 20 solution: 0.3% (v/v) Tween 20 in PBS (*APPENDIX 2E*; prepare solution fresh weekly and store at 4°C)
India ink solution: 0.1% (v/v) India ink (Pelikan 17 black) in Tween 20 solution (store 1 month at room temperature)
Plastic box

1. Place blot transfer membrane in a plastic box. Wash with water three times for 5 min each.

PCU IASI CENTRAL UNIVERSITY LIBRARY

2. Wash membrane with Tween 20 solution four times for 10 min each.
3. Stain membrane with India ink solution for 2 hr or overnight.
4. Rinse with water until an acceptable background is obtained, then air dry.

FLUORESCAMINE LABELING

BASIC PROTOCOL 7

Fluorescamine, or 4-phenylspiro[furan-2(3*H*),1′-phthalan]-3,3′-dione, is used to introduce a fluorescent label on electroblotted proteins via reaction with free amines. Transferred proteins are visualized on blot transfer membranes with UV light. This stain can be very sensitive and can be used in conjunction with a second detection method such as immunoblotting (also see Basic Protocol 3). However, the protein is irreversibly modified because fluorescamine reacts with available amino groups (i.e., lysines and the protein N terminus if it was not previously blocked).

Materials

Blot transfer membrane (*UNIT 10.7*)
Sodium bicarbonate solution: 100 mM sodium bicarbonate in 0.3% (v/v) Tween 20, pH 9.0 (prepare fresh weekly and store at 4°C)
Fluorescamine stain: 0.25 mg/ml fluorescamine (Sigma) in sodium bicarbonate solution (prepare fresh daily)
Plastic box

1. Place blot transfer membrane in a plastic box. Wash with water three times for 5 min each.
2. Wash membrane with sodium bicarbonate solution twice for 10 min each.
3. Label protein bands with fluorescamine stain for 15 min. Use enough staining solution to cover the membrane completely.
4. Wash membrane with bicarbonate solution three times for 5 min each.
5. Rinse membrane several times with water.
6. Visualize transferred proteins with UV light.

IAEDANS LABELING

ALTERNATE PROTOCOL

N-iodoacetyl-*N*′-(5-sulfo-1-naphthyl)ethylenediamine (IAEDANS or 1,5-I-AEDANS) is used for fluorescent labeling of electroblotted proteins on blot transfer membranes. Because IAEDANS reacts with free cysteines, disulfides in the sample must first be reduced with dithiothreitol (DTT). Transferred protein bands are visualized under UV light.

Additional Materials (also see Basic Protocol 7)

DTT solution: 200 mM dithiothreitol (DTT) in 100 mM Tris·Cl, pH 8.6 (*APPENDIX 2E*; prepare immediately before use)
100 mM Tris·Cl, pH 8.6 (*APPENDIX 2E*)
N-iodoacetyl-*N*′-(5-sulfo-1-naphthyl)ethylenediamine (IAEDANS; Sigma; store desiccated in the dark at –20°C)
Glass box

1. Place blot transfer membrane in a glass box. Wash with water three times for 5 min each.
2. Incubate membrane with DTT solution for 30 min to reduce disulfides in the sample.
3. Wash membrane with 100 mM Tris·Cl (pH 8.6) three times for 5 min each.

BOSTON CENTRAL UNIVERSITY LIBRARY

This washing step probably could be deleted if proteins have been electroblotted from a reducing gel (i.e., containing DTT and/or 2-mercaptoethanol). However, it is advisable to include this simple step routinely as some oxidation may occur during electrotransfer or on the blotted membrane itself during drying or storage.

4. Dissolve 86 mg IAEDANS (2 mM final concentration) in 100 ml of 100 mM Tris·Cl (pH 8.6).

   This step should be carried out in the dark (solution should be made fresh daily).

5. Add IAEDANS solution to the membrane and allow the reaction to proceed in the dark for 30 min with shaking.
6. Wash membrane with 100 mM Tris·Cl (pH 8.6) twice for 5 min each. Thoroughly rinse membrane with water to remove excess reagent.
7. Visualize the transferred proteins under UV light.

COMMENTARY

Background Information

The recent rapid expansion in the use of electrophoretic transfer of separated proteins to different types of membranes has necessitated the adaptation of existing protein staining techniques to transfer membranes. On-blot staining techniques serve multiple purposes, including detection of proteins for structural analysis and use in parallel with antibody reactivity to correlate precisely immunoreactivity with protein staining patterns. For the latter purpose an advantage of on-blot staining is that duplicate sections of membrane can be cut out and one section used for immunoblotting (*UNIT 10.10*) while a second section with duplicate lanes is stained with a general protein stain. The two pieces can then be precisely realigned. In contrast, a direct comparison of an immunoblot with a stained polyacrylamide gel is much less precise because of shrinking and swelling of the gel.

The most common membranes used for electroblotting are polyvinylidene difluoride (PVDF) and nitrocellulose. PVDF membranes have become increasingly popular because they are easy to handle and store, whereas nitrocellulose membranes are brittle and tend to break easily when dry. A number of PVDF membranes are now commercially available that have subtle but important differences in protein binding properties resulting from different proprietary manufacturing processes. For example, Bio-Rad Trans-Blot or Millipore Immobilon-P^{SQ} PVDF membranes generally show higher protein binding capacities and higher binding affinities compared to Immobilon-P (Mozdzanowski and Speicher, 1992). Use of high-retention PVDF membranes usually results in higher and more consistent electroblotting recoveries of most proteins than the use of either low-retention PVDF membranes or nitrocellulose. However, high-retention PVDF membranes tend to exhibit higher staining backgrounds, and it is more difficult to extract proteins or peptides from such membranes.

The protocols for staining with amido black, Coomassie blue, Ponceau S, and AuroDye follow the suppliers' recommendations. It should be noted that when staining PVDF membranes with Coomassie blue before N-terminal sequencing, omitting acetic acid from both the stain and destain solution is recommended to minimize potential extraction of protein from the membrane (Speicher, 1989).

The protocol for India ink staining of electroblotted proteins is essentially that of Hancock and Tsang (1983). Different brands of India ink may be used, but staining sensitivity may vary as a result.

The colloidal gold stain is the most sensitive membrane stain described here. As an alternative to commercially available colloidal gold stains, Moeremans et al. (1985) describe methods for preparing gold and iron solutions.

Fluorescent labels are advantageous because they can be used not only for sequential detection methods on the same blot with minimal potential interference, but also for detection prior to protein extraction from the membrane. For example, after visualization of proteins with a fluorescent label, the blot can be photographed and specific bands marked with a pencil, either directly on the membrane or through a plastic bag. The latter method leaves a permanent indentation on the membrane. The blot can then be probed with antisera (i.e., immunoblotted; *UNIT 10.10*).

PCU IASI-BEIJING UNIVERSITY LIBRARY

The protocol for fluorescamine labeling is based on the procedure described by Vera and Rivas (1988). Fluorescamine itself is not strongly fluorescent; however, when combined with the primary amines of proteins (i.e., N termini and lysine residues) it yields a highly fluorescent product. IAEDANS is an iodoacetic acid analog containing a naphthalene ring and is fluorescent under UV light. When the sample protein is reduced either prior to gel electrophoresis or with DTT after blotting, all cysteines are potentially available for reaction with IAEDANS. When the protein is not reduced, some cysteines may be involved in disulfide bonds and therefore not available for reaction. Additionally, some cysteines may be sterically inaccessible because of adsorption to the membrane and therefore will not react.

An additional visualization technique for PVDF membranes is transillumination, described by Reig and Klein (1988). In that technique, the membrane is dried at room temperature, then wet with 20% methanol and viewed on a white light box. Protein bands appear as clear areas. Sensitivity is usually comparable to that of Coomassie blue staining.

Critical Parameters and Troubleshooting

High-quality water (from a Milli-Q purification system or equivalent) should be used throughout these protocols. All plastic and glass boxes must be thoroughly cleaned by rinsing with water before use to avoid staining artifacts. Blot membranes should be handled by the edges only with gloves or, preferably, with forceps. This precaution is most critical for the more sensitive stains (i.e., colloidal gold, colloidal silver, and India ink). When using PVDF membranes, it is especially critical that the membrane does not dry between steps. If drying occurs, wet the PVDF membrane for 5 sec with 100% methanol, then rinse several times with water.

A brief alkali treatment can enhance staining with India ink or colloidal gold. In a procedure described by Sutherland and Skerritt (1986), the membrane is washed with 1% (w/v) KOH for 5 min followed by several rinses with PBS. The alkali treatment can easily be incorporated at the beginning of the procedures if desired.

Anticipated Results

Approximate detection limits and membrane compatibilities are listed in Table 10.8.1. It should be noted that detection limits may vary with gel size and the percentage of polyacrylamide in the gel used in preparation of the blot transfer membrane. The sensitivity of fluorescent stains is related to the number of reactive amino groups (fluorescamine) or cysteine residues (IAEDANS) present in the protein of interest.

Time Considerations

The total time required for staining with amido black, Coomassie blue, and Ponceau S is 30 min to 1 hr; colloidal gold requires 4 to 6 hr; colloidal silver requires 1 hr; whereas staining with India ink requires 2 hr to overnight. Fluorescent labeling requires ~1 hr. The optional alkali enhancement (see Critical Parameters and Troubleshooting) requires an additional 30 min at the beginning of the India ink and colloidal gold staining procedures.

Capillary Electrophoresis of Proteins and Peptides

Capillary electrophoresis (CE) is a high-resolution technique for the separation of a wide variety of molecules of biological interest such as metabolites, drugs, amino acids, nucleic acids, and carbohydrates. This unit focuses on the use of CE to separate proteins and peptides. As with polyacrylamide gel electrophoresis (PAGE; *UNIT 10.1*), CE separations of proteins and peptides are based on charge-to-mass ratios. While PAGE separations are restricted to polyacrylamide matrices and a relatively small number of buffer systems; CE separations can be achieved in a variety of different matrices using a wide range of electrophoresis buffers. Consequently, there is a much greater flexibility in the design of optimal separation protocols.

CE employs a fused-silica capillary column, which may or may not be derivatized, either in free solution or in the presence of a fluid matrix. In contrast to PAGE, the resulting protein or peptide bands cannot be fixed or stained. The CE separation is, in essence, a dynamic one and is more analogous to high-performance liquid chromatography (HPLC) than PAGE. However, CE separation is based on electrophoretic parameters, so it can be viewed as orthogonal to HPLC, which is based primarily on solvent partitioning principles. The combination of these two techniques is very powerful for analyzing and characterizing proteins and peptides. The initial expectation that CE would play a major role in protein separations has not been realized. However, it is particularly useful for determining the purity of a sample and for rapid, efficient, and quantitative evaluation of protein purification techniques.

For best separation results, it is necessary to optimize the procedure. If some properties of the protein are known—e.g., its isoelectric point (pI)—the selection of a suitable running buffer is relatively straightforward. In fact, CE itself can be used to determine the isoelectric point of a protein, either in purified form or in a mixture, by focusing the sample in a pH gradient that is generated within the capillary during electrophoresis (Basic Protocol 1). After refocusing, the sample is mobilized either by changing the anode buffer, or by applying a hydrodynamic force to the column to move the separated components past the detector. However, there is little information available that will predict the potential of a protein to interact with the capillary wall. Underivatized silica capillaries have a strong tendency to adsorb proteins, thereby immobilizing them and making protein separations impractical. If such interactions occur, then an additive or a coated capillary column is required. A certain amount of trial and error is involved, and it may be necessary to perform several CE runs to optimize the separation conditions for a given protein. One approach to optimization is described in Basic Protocol 2.

CE is most useful for separations of peptides (Basic Protocol 3) because it offers great flexibility in separation parameters. It can be used to monitor proteolytic digestions and optimize digestion conditions for the production of a representative peptide fingerprint of a protein. This profile can subsequently be used to provide structural information about the protein, especially when used in conjunction with reversed-phase HPLC (RP-HPLC). It can be used to screen peptide fractions that are obtained from a preparative RP-HPLC separation of a protease digestion. Fractions that contain single or major components are suitable candidates for protein sequence analysis. Similarly, CE can be used to assess the purity of synthetic peptides. In the presence of an internal standard, it can provide quantitative information about the various components that are present in a peptide mixture. CE can also be used as a micropreparative technique—with either multiple separations that are pooled (Basic Protocol 4) or a single, larger-scale separation (Alternate Protocol 1)—for the isolation of peptides from a protease digestion (in much the

BOSTON CHURCH LIBRARY

same way that RP-HPLC is currently used). In most of these examples the same capillary column can be used for all the separations. Only changes in buffer composition, ionic strength, and the presence or absence of additives are required for each specific application.

INSTRUMENTATION

CE separation in its simplest form can be achieved by passing a high voltage between two buffer reservoirs that are joined by a liquid-filled fused silica capillary (Fig. 10.9.1). This results in the generation of electroosmotic flow (EOF; see Separation Theory), which allows the molecules of interest to be carried from one end of the capillary to the other. The capillaries are generally 30 to 50 cm long with 50 to 75 μm i.d. The net total volume of these capillaries is in the low microliter range. For comparison, the volume of a slab gel lane is ~1000 μl. The capillaries are thin walled; this allows rapid and efficient exchange of the Joule heating resulting from the high voltages (20 to 25 kV) that are necessary for electrophoretic separations. This heat dissipation minimizes the negative convective effects that could result in band broadening during electrophoresis. The fused-silica capillary is coated on the outside with a polyimide layer that confers excellent tensile strength to the otherwise fragile capillary. The polyimide sheathing is carefully burned from a small portion of the capillary to expose a section of the silica. This clear section of the capillary is inserted into the light path of a UV detector and becomes the flow cell. As the protein and peptide molecules are swept through the capillary by EOF, they pass through the detector light path and are registered on the UV monitor. In effect the capillary becomes a very-low-volume flow cell.

IMPORTANT NOTE: The removal of the polyimide coating makes the capillaries susceptible to breakage. Capillaries that are not provided in cartridges by the manufacturer should be handled with care to avoid breakage.

The combination of high field strength and large surface-to-volume ratios results in rapid and very efficient separations of both proteins and peptides. Sample loading volumes are routinely in the nanoliter range, with starting sample concentrations of ~0.1 μg/μl for UV

[b]Abbreviations: C, CE system control software; DA, data acquisition; FAC, forced-air convection.

detection. On-capillary preconcentration protocols are available when starting concentrations are below these levels. Clearly, with respect to sensitivity, speed, and versatility, CE can offer some significant advantages over gel electrophoresis for the separation of proteins and peptides.

As shown in Figure 10.9.1, CE can require minimal instrumentation. However, in reality, due to the high voltages that are utilized, safety issues require that the capillary column be incorporated into a dedicated CE instrument. These instruments can provide efficient capillary cooling and online detection of analytes. Table 10.9.1 lists a number of commercially available instruments and some of their characteristics. For the purpose of this discussion it is assumed that a generic CE system possessing the following capabilities is used: an active capillary cooling system, a UV detector capable of monitoring at 200 nm, a thermostatted autosampler, and a chromatographic data package. Given this basic unit a variety of separations can be performed, depending upon the nature of the proteins or peptides that are being separated.

SEPARATION THEORY

CE is part of the family of electrophoretic techniques that separate species based upon their size and ionic properties. An ion (i) placed into an electric field will move in the direction parallel to the field with a velocity (v_i) as follows:

$$v_i = \mu_i E$$

Here μ_i is the electrophoretic mobility of species i and E is the electric field, as defined by the following equation, where V is the voltage and L is the total length from electrode to electrode:

$$E = \frac{V}{L}$$

BCU ASTON CENTRAL UNIVERSITY LIBRARY

The electrophoretic mobility of an ion (μ_i) is:

$$\mu_i = \frac{q}{6 \pi \eta a_i}$$

where q is the charge on the ion, η is the viscosity of the solution, and a_i is the radius of the ion.

As seen from these three equations, the movement of the molecule in the column is dependent on the applied voltage, the length of the column, the charge on the molecule, and the size of the molecule.

In CE, buffer flow is generated inside the column when the electric field is applied. This flow is from the cathode electrode to the anode electrode in a fused-silica capillary column (from left to right in Fig. 10.9.1); this movement of the buffer is called the electroosmotic flow (EOF). In addition, normal electrophoretic separation occurs whereby a positively charged molecule moves in the same direction as the EOF, a negatively charged molecule moves in a direction opposite to the flow, and a neutral molecule is carried along by the flow. Thus, the total velocity of the molecule (μ_t) is given by the following equation, where μ_{eo} is the EOF in the column.

$$\mu_t = (\mu_{eo} + \mu_i) E$$

The magnitude of the EOF will vary as a function of the pH of the carrier buffer. In uncoated fused-silica columns, a low pH generates a slow EOF, whereas a high pH generates a fast flow. The flow can be suppressed or completely reversed depending on the coating on the column or organic modifier added to the carrier buffer (Landers et al., 1992; Tsuiji and Little, 1992). Thus, EOF is another parameter that can be optimized to aid in difficult separations. Neutral molecules, because they are all carried along by the flow, can be difficult to separate. Addition of a micelle to the carrier buffer results in the partitioning of molecules between the micelle and carrier buffer and can effectively resolve neutral molecules (Khaledi, 1994).

STRATEGIC PLANNING

Proteins can be separated on coated or uncoated capillary columns, and the choice of separation protocol depends on the specific properties of the target protein. The most important property is the pI, which can be determined by either conventional gel electrophoresis or CE. The use of a buffer ~2 pH units above the pI is optimal for CE separations. Table 10.9.2 lists a number of buffers and their pH ranges. The presence of high salt concentrations in the sample can interfere with the separation process, so dialysis or dilution may be required. Protein concentrations of microgram per microliter are optimal for CE separations; however, on-capillary concentration protocols exist that allow the separation of proteins with concentrations 1 to 2 orders of magnitude lower.

Peptides can be effectively separated in open-tube fused-silica capillary columns. The EOF generated within the capillary causes separation of both charged and neutral peptides. The respective migration times are dependent upon both the pH of the electrophoretic separation and the charge-to-mass ratios of the peptides. For example, at low pH, peptides with net positive charge migrate towards the anode faster than neutral or negatively charged peptides. Even negatively charged peptides are swept towards the anode by EOF. In practice this migration order is further modified by the mass of the peptides, with small positively charged peptides having faster migration rates.

The choice of buffer for CE is of primary importance. The use of buffer systems that separate at high pH significantly alters the migration positions of peptides relative to those

PGU IAS / CENTRAL UNIVERSITY LIBRARY

Table 10.9.2 Useful Electrolytes for CE of Peptides

Electrolyte	Useful pH range	Minimum useful wavelength (nm)
Phosphate	1.14-3.14	195
Citrate	3.06-5.40	260
Acetate	3.76-5.76	220
MES	5.15-7.15	230
Phosphate	6.20-8.20	195
Tris	7.30-9.30	220
Borate	8.14-10.14	180

of low-pH separations. The selection of a specific buffer is dictated both by its buffering capacity at a selected pH and by its minimum usable UV absorbance wavelength. Characteristics of some useful buffer systems are shown in Table 10.9.2. Small differences in the pH or composition of the buffer can have a significant impact on the absolute mobilities of the peptides, so it is advisable to adjust the pH of buffers accurately and reproducibly. Alternatively, a suitable internal standard can be incorporated into the separation in order to obtain relative mobilities. For the separation of peptides from a tryptic digest of a protein, where almost every peptide carries at least two positive charges, a phosphate buffer of pH 2.0 to 3.0 is commonly used. Likewise, for V8 protease digestions (which cleaves C-terminal to glutamic acid residues), the preferred separation conditions use a borate buffer with a pH range of 8.0 to 9.0.

SEPARATION OF PROTEINS BY ISOELECTRIC FOCUSING

BASIC PROTOCOL 1

Isoelectric focusing (IEF) separations can be performed readily by CE; this can be a useful first step in selecting subsequent buffer systems for protein separations. Proteins and peptides are amphoteric in nature, so their charge is dictated by the surrounding carrier buffer. When a protein or peptide is placed in an electric field, it moves to a region where the surrounding pH equals its isoelectric point (pI); at this point the molecule stops moving. A pH gradient is generated in a coated capillary column by filling the column with a sample solution that contains ampholytes. A high-pH solution (sodium hydroxide) is placed in the cathode reservoir and a low-pH solution (phosphoric acid) is placed in the anode reservoir. An electric field is then applied across the column and the ampholytes and the sample move to a location in the column corresponding to their respective pIs. If the molecule drifts out of the isoelectric region, a charge is induced by the surrounding pH solution and the molecule moves back to the region of zero charge. Narrow regions are formed with pI resolutions on the order of 0.01 pH units. To determine the pI location of a particular protein in the column, markers of known pIs are added to the sample mixture, and extrapolation between markers yields the pI of the protein of interest.

After separation of the sample in the absence of EOF, mobilization of the proteins past the detector is necessary. A simple replacement of the anode reservoir with the buffer in the cathode reservoir establishes EOF and causes the sample zone to migrate pass the detector. The separation discussed here assumes there is no EOF in the column during focusing. However, separations may also be done in the presence of EOF (Mazzeo and Krull, 1992).

BOURNEMOUTH UNIVERSITY LIBRARY

Materials

Ampholyte mixture, pH 3 to 10 (Bio-Rad)
Sample containing 0.5 to 1.0 mg/ml protein
IEF markers (optional)
20 mM sodium hydroxide (NaOH; store at 4°C)
10 mM phosphoric acid (store at 4°C)

50-µm-i.d. coated silica capillary column
CE instrument (see Table 10.9.1)

1. Add ampholyte mixture to 0.5 ml protein sample to give a final concentration of 2.5% (v/v) ampholytes.

   If desired, add IEF markers to a final concentration of 0.1 mg/ml to calibrate the column.

2. Add the solution to the sample reservoir. Fill the capillary by pressurizing the reservoir (0.5 psi).

3. Place 10 mM phosphoric acid in the anode reservoir (negative end). Place 20 mM NaOH in the cathode reservoir (positive end).

4. Focus the sample 4 to 6 min at 8 to 10 kV constant voltage. Monitor the current until it reaches steady state.

   The instrument should be operated in accordance with the manufacturer's instructions.

5. Mobilize the sample by placing 20 mM NaOH in the anode reservoir and setting the voltage to 10 kV. Monitor the mobilization of the proteins past the detector 15 to 20 min.

   Another method for mobilizing the proteins past the detector is to apply a hydrodynamic force to one end of the column and push the zones past the detector. Commercially available CE instruments have this capacity as an option. To minimize distortion of the pI regions, a constant electric field (10 kV) must be applied at the same time. The pressure applied is small (0.5 psi) and is maintained for the entire time of mobilization.

6. Wash the column after each run with 10 mM phosphoric acid for 1 min at 0.5 psi. Store the column at room temperature in running buffer (short-term) or water (long-term).

BASIC PROTOCOL 2

SEPARATION OF PROTEINS

To use CE for protein analyses, the more that is known about the particular protein, the higher the success rate for developing a separation method. Knowing the pI of a protein permits selection of the appropriate run buffer to maximize differences in the charge-to-size ratio. IEF separation performed using CE (Basic Protocol 1) can be a useful first step in selecting subsequent buffer systems for protein separations on an underivatized capillary column. If no protein is detected, it has probably adsorbed to the silica surface of the column. Repeating the separation in the presence of an ionic detergent such as SDS will coat the protein with negative charge and prevent adsorption. However, this means that proteins will separate on the basis of size alone. Alternatively, if the pI of the protein is unknown, the separation can often be achieved by using a coated capillary column in the presence of high-pH, high-ionic-strength buffer.

RCU IASVIC CENTRAL UNIVERSITY LIBRARY

Materials

Sample containing 10 mg/ml protein
50 mM and 500 mM sodium borate, pH 8.0 to 9.5 (for separation of proteins with unknown pI)
5 mM and 50 mM buffer at pH >pI (for separation of proteins with known pI; see Table 10.9.2)
50-µm-i.d. coated (unknown pI) *or* uncoated (known pI) fused-silica capillary column
CE instrument (see Table 10.9.1)

For separations of proteins with unknown pI

1a. Dilute protein sample 1:10 (v/v) with 50 mM sodium borate buffer to give a final concentration of 1.0 mg/ml.

Alternatively, dialyze sample (at a concentration of 1 mg/ml) in 50 mM sodium borate buffer.

2a. Fill a coated column with 500 mM sodium borate buffer.

3a. Inject the sample hydrodynamically, e.g., 3 sec at 1 psi.

Consult the manufacturer's instruction manual for the proper procedure.

4a. Separate using the following conditions:

Detector wavelength: 200 nm
Temperature: 25°C
Run voltage: 10 kV
Run time: 30 min.

For separations of proteins with known pI

1b. Dilute protein sample 1:10 (v/v) with a 5 mM buffer that has a pH above the pI of the protein to induce a charge on the protein (final protein concentration = 1.0 mg/ml).

Alternatively, dialyze sample (at a concentration of 1 mg/ml) in 5 mM buffer.

2b. Fill an uncoated capillary column with the same buffer at 50 mM.

3b. Inject the sample hydrodynamically, e.g., 3 sec at 1 psi.

Consult the manufacturer's instruction manual for the proper procedure.

4b. Separate using the following conditions:

Detector wavelength: 200 nm
Temperature: 25°C
Run voltage: 25 kV
Run time: 30 min.

If the protein of interest is not detected, add 10 mM SDS to the run buffer to induce a charge on the molecule. If the peaks are too broad, add 0.1% (w/v) methylcellulose to coat the column and reduce adsorption of the molecule onto the wall of the column. The addition of SDS and/or methylcellulose will increase the run time of the separation.

BCU IALH CENTRAL UNIVERSITY LIBRARY

ANALYTICAL PEPTIDE SEPARATIONS

CE is particularly useful for separating specific peptides from complex mixtures such as the products of proteolytic digestion. In this procedure, the peptide mixture to be analyzed is placed in a sample vial at the cathode end of the capillary column. The anode reservoir contains running buffer. The sample is loaded into the capillary either electrokinetically or by pressure or vacuum, then the sample vial is replaced by running buffer and electrophoresis begins. The following protocol describes the use of a P/ACE 5000 CE instrument (Beckman) using low-pressure sample injection. However, other instruments (see Table 10.9.1) are capable of similar separations when operated according to the manufacturer's instructions.

Materials

Peptide mixture: e.g., tryptic digest of β-lactoglobulin (Applied Biosystems)
0.05 M and 0.25 M sodium phosphate buffer, pH 2.30 (store at 4°C)
0.1 M sodium hydroxide (NaOH)

75-μm-i.d. fused-silica capillary column (Beckman)
CE instrument (e.g., P/ACE 5000, Beckman, or equivalent; see Table 10.9.1)

1. Precondition the capillary by flushing with the following solutions:

   10 column volumes of 100 mM NaOH at low pressure (0.5 psi)
   10 column volumes water
   4 column volumes of 0.25 M sodium phosphate buffer, pH 2.3.

   Store the column in 0.25 M sodium phosphate buffer, pH 2.3, at 25°C.

   When changing to a different separation buffer, equilibrate the column 4 hr with the new buffer (Strickland and Strickland, 1990).

   If a new capillary is being used, it is essential that this preconditioning step be performed prior to attempting separations.

2. Prepare the peptide mixture by dissolving 10 nmol (~300 μg) in 10 ml of 0.05 M sodium phosphate buffer, pH 2.30. Freeze unused mixture in 100-μl aliquots.

3. Apply 10 to 20 nl sample using low-pressure injection for 10 sec at 0.5 psi.

   Consult the manufacturer's manual for the proper procedure.

4. Separate the peptide mixture using the following conditions:

   Electrolyte: 0.05 M sodium phosphate buffer, pH 2.3
   Detector wavelength: 200 nm
   Temperature: 25°C
   Voltage: 25 kV.

   Consult the manufacturer's manual for proper operating conditions.

5. Rinse the column with the following solutions:

   0.5 min with water
   1.0 min with 0.1 N NaOH
   1.5 min with water
   1 min with 0.25 M sodium phosphate buffer, pH 2.30.

   Store the column in running buffer or water at room temperature.

   An example of a separation protocol for a Beckman P/ACE 5000 instrument with a 37-min run time is described in Table 10.9.3.

MICROPREPARATIVE CAPILLARY ELECTROPHORESIS: MULTIPLE SEPARATIONS

BASIC PROTOCOL 4

Although CE has been most commonly used for analytical separations, considerable interest has developed in using its high resolving power in micropreparative applications. Two basic approaches have evolved, one utilizing multiple separations and collections from an analytical capillary (Bergman and Jornvall, 1992) and the other utilizing a single separation and collection on a much larger-diameter (150-µm-i.d.) capillary (see Alternate Protocol). For the multiple collection approach to be effective, the elution times of the peptides must be reproducible. The following method uses the P/ACE 5000 capillary electrophoresis instrument to separate a mixture of peptides.

Materials

Peptides: ACTH 4-100, angiotensin I, and angiotensin II (Sigma)
0.05 mM and 0.25 mM sodium phosphate buffer, pH 2.30 (store at 4°C)
0.1 M sodium hydroxide (NaOH)

75-µm-i.d. fused-silica capillary column (Beckman)
CE instrument (e.g., P/ACE 5000, Beckman, or equivalent; see Table 10.9.1)
Conical microvials (Beckman)

1. Precondition the capillary column by flushing with the following solutions at low pressure (0.5 psi):

   10 column volumes of 0.1 M NaOH
   10 column volumes of water
   4 column volumes of 0.25 M sodium phosphate buffer, pH 2.3.

   Store in 0.25 M sodium phosphate, pH 2.30.

   When changing to a different separation buffer, equilibrate the column 4 hr with the new buffer (Strickland and Strickland, 1990).

2. Prepare a peptide mixture by dissolving 0.2 mg each of ACTH 4-10, angiotensin I, and angiotensin II in 1 ml of 0.05 M sodium phosphate buffer, pH 2.3 (final concentration = 0.6 mg/ml peptide). Store 100-µl aliquots at –20°C.

BCU IAŞI / COLECŢIA CENTRALĂ UNIVERSITY LIBRARY

3. Load 10 to 20 nl peptide mixture by low-pressure injection for 10 sec at 0.5 psi.

Consult the manufacturer's manual for the proper procedure.

4. Separate the mixture using the following conditions:

Electrolyte: 0.05 M sodium phosphate, pH 2.30
Detector wavelength: 200 nm
Temperature: 25°C
Run voltage: 25 kV
Fraction size: 1 min.

Consult the manufacturer's manual for proper operating conditions.

5. Replace the standard outlet reservoir (anode) with a series of conical microvials, each containing 10 µl of 0.05 M sodium phosphate buffer, pH 2.30. Collect 3-min fractions into each of the vials for the length of the separation.

6. Repeat the injection and separation (steps 3 to 5) four times and combine the contents from the corresponding fraction numbers.

It will take 2 to 3 hr to complete the fractionation.

7. Screen fractions for peptide content using the analytical separation previously described (see Basic Protocol 3).

ALTERNATE PROTOCOL

MICROPREPARATIVE CAPILLARY ELECTROPHORESIS: SINGLE SEPARATION

In this micropreparative protocol, a larger quantity of the peptide mixture is loaded onto a 150-µm-i.d. capillary column and the fractions are collected from a single separation (Kenny et al., 1993). For the single-collection approach the CE instrument must be able to effectively control the capillary temperature at the elevated power levels that are required for electrophoresis. Forced air cooling is generally inadequate for this purpose.

***Additional Materials** (also see Basic Protocol 4)*

4:1 (v/v) 0.5 M sodium phosphate buffer (pH 2.50)/ethylene glycol
150-µm-i.d. fused-silica capillary column (Polymicro)

1. Prepare peptide mixture and precondition the column (see Basic Protocol 4, steps 1 and 2).

2. Load 0.1 µl peptide mixture by low-pressure injection for 10 sec at 0.5 psi.

Consult the manufacturer's manual for the proper procedure.

3. Separate the peptide mixture using the following conditions:

Electrolyte: 0.05 M sodium phosphate buffer, pH 2.30
Detector wavelength: 200 nm
Temperature: 25°C
Run voltage: 7.5 kV
Fraction size: 3-min per collection vial.

Consult the manufacturer's manual for proper operating conditions.

4. Replace the standard outlet reservoir (anode) by a series of conical microvials each containing 10 µl of 4:1 (v/v) 0.5 M sodium phosphate buffer/ethylene glycol. Collect 3-min fractions into each vial for the length of the separation.

It will take ~2 hr to fractionate the sample.

FCU IASI / CENTRAL UNIVERSITY LIBRARY

5. Screen fractions for peptide content using the analytical separation protocol (see Basic Protocol 3).

COMMENTARY

Background Information

Protein separation is one of the more difficult types of separation to perform by capillary electrophoresis (CE; Novotny et al., 1990). Each protein has it own set of optimal separation conditions, and one optimized protocol will not necessarily transfer well to the separation of a different protein. The more that is known about the properties of the molecule, the easier it will be to optimize the separation conditions. The most important property is probably the pI, because it will dictate the selection of pH and ionic strength conditions for the initial separation attempt. However, a variety of other properties must also be taken into account when optimizing a separation protocol: shape (globular or fibrous), aggregation tendencies, solubility in dilute solutions, salt requirements, thermal stability, and hydrophobic nature. Several parameters can be varied within CE separations in order to utilize this knowledge—e.g., temperature, buffer/salt selection, ionic and nonionic detergents, and matrix additives (polyacrylamide, methylcellulose). Several protocols have been developed that can serve as useful starting points for most protein separations. Table 10.9.4 lists references for some groups of proteins. Furthermore, many of the manufacturers listed in Table 10.9.1 have developed additional protocols for protein separations.

Ultimately, the selection of an appropriate separation protocol for a protein depends on the specific properties of that protein. However, there are separation approaches that utilize specific properties of proteins. IEF-CE separates on the basis of charge alone; CE in the presence of ionic detergents such as SDS separates on the basis of size alone; and CE using underivatized capillaries at low pH or derivatized capillaries at high salt and high pH separates on the basis of both size and charge. Successful CE separations also depend on the behavior of other contaminants that are present in the mixture. It may also be possible to take advantage of the knowledge gained from previous purification steps, e.g., ion-exchange or size-exclusion chromatography, to select CE separation conditions.

Analytical-scale separation of peptides by CE has found application in a variety of areas. Proteolytic digestions can be monitored by placing the digestion mixture in a sample vial on the sample table that is equilibrated to 37°C. The instrument can then be programmed to analyze an aliquot at desired intervals, such as every 4 hr. Digestion is complete when a stable CE profile is obtained. Also, fractions collected from an HPLC separation of a protease digest can readily be screened orthogonally by CE to determine the homogeneity of any given peak. Fractions with a single major component can then be subjected to protein sequence analysis.

The sensitivity of UV detection at 200 nm is such that digest levels of ≥100 pmol can be effectively screened by this method. Below these load levels the fractions have to be reduced in volume or preconcentrated on the capillary to achieve a sufficiently high concentration for visualization (Dolnik et al., 1990; Burgi and Chien, 1992).

Selection of an appropriate micropreparative protocol will depend on the type of instrumentation that is available. The single-separation, large-diameter capacity protocol will only work with a CE instrument that has adequate cooling capabilities. The multiple-separation, analytical capillary protocol will work on any CE instrument that has reproducible and stable electrophoretic mobilities.

Critical Parameters

For protein analysis, the charge on the protein is the most important parameter for sepa-

Table 10.9.4 References for Separations of Different Protein Types

BCU SHORT TERM LOAN LIBRARY

ration. However, the charge-to-shape ratio also plays a role in effective separation of proteins. The charge on the protein is controlled by the buffer and the additives used for the run. The shape is determined by the denaturing conditions of the solutions. The surface charge on a protein may ultimately dictate the extent of wall interactions in addition to electrophoretic mobility, whereas shape has its greatest effect upon mobility alone.

The recovery of peptides from underivatized silica capillary columns appears to be very good—even at subpicomole levels. However, proteins are frequently irreversibly bound to these same capillaries. Clearly, at some point a "peptide" must become a "protein" in the context of CE. There is little published data available to clarify this issue, although good recoveries of peptides 30-40 amino acids in length have been obtained from underivatized capillary columns. If the recoveries of higher molecular weight peptides are poor, then the separation should be repeated using a coated capillary column. During peptide synthesis, single-amino-acid-deletion products are frequently produced. The properties of these deletion products are very similar to those of the expected species, so the deletion products may not be readily resolved by reversed-phase HPLC. In this case, CE has proven to be a very useful orthogonal technique because of its high resolution power and separation based on charge-to-mass ratios. However, it must be emphasized that the effective separation and detection of proteins and peptides requires relatively high solute starting concentrations.

When using uncoated columns, a sodium hydroxide rinse is required to maintain the capillary surface. However, this rinse is never used with coated capillaries because it will remove the coating. Commercially available coated columns are satisfactory but linear polymers (e.g., methylcellulose) have been used with more success (Palmieri and Nolan, 1994). If a protocol can be worked out for the molecule of interest, rapid CE analysis with little loss of starting material can augment the tools used now for protein analysis (e.g., HPLC).

Troubleshooting

Mechanical and electrical problems that might be encountered during instrument use are addressed in the troubleshooting sections of the manufacturers' manuals. One of the common difficulties is the loss of electrical contact during a run. This loss of current can be caused if a small bubble forms in the column during injection or if the power generated by the run is so great that the solution boils or outgasses. Purging the column after a failed run removes any bubbles in the column. The sample vial must contain enough sample to cover the end of the column during injection to prevent injection of air into the column. The sample vial can dry out during a long run, so sample temperature control or the use of the proper cap on the vial is required to slow evaporation. Reducing the buffer concentration or the run voltage can eliminate bubble formation during a run. Degassing the run buffer is also useful if the outgassing problems continue.

The instrument sometimes arcs during a run; this is caused by salt deposits or moisture on the high-voltage electrode stations. Particular attention should be given to keeping the electrode stations salt free. Moisture buildup can be minimized by reducing the separation voltage by 5 kV. Frequent visual inspection is also advised.

The column can plug up because of salt deposition if the column dries out. Washing the column with water dissolves the plug; storing the column in water if it is not going to be used for a long period of time prevents plugging. Proteins can precipitate during a run and plug the column. Using lower protein concentrations prevents this type of plugging.

Anticipated Results

Electrophoretic profiles for both protein and peptide separations should be highly reproducible. However, absolute migration times may vary from run to run, especially if the separation temperature is not adequately controlled. For this reason, the use of an appropriate internal standard is highly recommended (see the manufacturer's instructions).

At load levels <50 pmol of digest, the recovery of peptides from a narrow-bore (1-mm) HPLC separation is poor. A convenient upper separation range for micropreparative CE is ~50 pmol of digest. The use of CE as a preparative separation technique therefore complements conventional HPLC capabilities. Recoveries from micropreparative CE separations are essentially quantitative down to the low picomole level, although postseparation handling losses can be significant. To use the multiple separation approach, the CE instrument must be capable of maintaining very stable migration times. Not all instruments have this capability, so it is advisable that the method be used for simple mixtures of peptides. The single-separation approach is recommended for more com-

plex mixtures. Because the fractions are collected "blind," they should be screened by matrix-assisted laser desorption/ionization (MALDI; *UNIT 11.6*) mass spectrometry prior to sequencing.

Time Considerations

Complete analysis times for IEF are ~30 min. Analysis times for protein separations are ~30 min for each step in method development. Peptide separations are normally completed in 40 min and frequently in as little as 20 min. Micropreparative peptide separations using either the multiple or single-separation approach are normally achievable within 90 min, but may take 2 hr or longer. It should be noted that these times are approximate, and sufficient time should be allowed to electrophorese all the components completely from the capillary.

Immunoblot Detection

Immunoblotting (often referred to as western blotting) is used to identify specific antigens recognized by polyclonal or monoclonal antibodies. Protein samples are solubilized, usually with sodium dodecyl sulfate (SDS) and in selected cases with reducing agents such as dithiothreitol (DTT) or 2-mercaptoethanol (2-ME); some antibody epitopes are destroyed if reducing conditions are used. Following solubilization, the material is separated by SDS-PAGE (using either one- or two-dimensional gels; *UNITS 10.1 & 10.4*). The antigens are then electrophoretically transferred in a tank or a semidry electroblotting unit to a nitrocellulose, polyvinylidene difluoride (PVDF), or nylon membrane (*UNIT 10.7*). When nitrocellulose or PVDF membranes are used (*UNIT 10.8*), the process can be monitored by a reversible staining procedure with Ponceau S. After staining, protein bands on the membrane can be photographed and/or the positions of the detected proteins can be marked with indelible ink (e.g., Paper-Mate pen). The membrane is then completely destained by soaking in water for an additional 10 min.

At this point the transferred proteins are bound to the surface of the membrane, providing access for reaction with immunodetection reagents. All remaining binding sites are blocked by immersing the membrane in a solution containing either a protein or detergent blocking agent. After being probed with primary antibody, the membrane is washed and the antibody-antigen complexes are identified using horseradish peroxidase (HRPO) or alkaline phosphatase (AP) enzymes coupled to the secondary anti-immunoglobulin-G (anti-IgG) antibody (e.g., goat anti-rabbit IgG). The enzymes are attached directly (Basic Protocol) or via an avidin-biotin bridge (Alternate Protocol) to the secondary antibody. Chromogenic or luminescent substrates (Support Protocols 1 and 2) are then used to visualize the activity.

IMMUNOPROBING WITH DIRECTLY CONJUGATED SECONDARY ANTIBODY

BASIC PROTOCOL

After electrophoretic transfer to the membrane (*UNIT 10.7*), the immobilized proteins are probed with specific antibodies to identify and quantitate any antigens present. The membrane is first immersed in blocking buffer to fill all protein-binding sites with a nonreactive protein or detergent. Next, the membrane is placed in a solution containing an antibody directed against the antigen (primary antibody). The blot is washed and then exposed to an enzyme-antibody conjugate directed against the primary antibody (secondary antibody; e.g., goat anti-rabbit IgG). Antigens are identified by chromogenic or luminescent visualization (see Support Protocols 1 and 2) of the antigen/primary antibody/secondary antibody/enzyme complex bound to the membrane. Tween 20 is a common alternative to protein blocking agents for use with nitrocellulose or PVDF filters.

Materials

Membrane with transferred proteins (*UNIT 10.8*)
Blocking buffer (see recipe) appropriate for membrane and detection protocol
Primary antibody specific for protein of interest
TTBS (nitrocellulose or PVDF) *or* TBS (neutral or positively charged nylon; see recipes for both solutions)
Secondary antibody conjugate: horseradish peroxidase (HRPO)- or alkaline phosphatase (AP)-anti-Ig (Cappel, Vector, Kirkegaard & Perry, or Sigma; dilute as indicated by manufacturer and store frozen in 25-µl aliquots until use)
Heat-sealable plastic bags
Powder-free gloves
Plastic box

Copyright © 1996 by John Wiley & Sons, Inc.

BCU LIBRARY / CENTRAL UNIVERSITY LIBRARY

Additional reagents and equipment for chromogenic or luminescent visualization (see Support Protocol 1 or see Support Protocol 2)

1. Place membrane in heat-sealable plastic bag with 5 ml blocking buffer and seal bag. Incubate 30 min to 1 hr at room temperature with agitation on an orbital shaker or rocking platform.

   Usually 5 ml buffer is sufficient for two to three membranes (14 × 14–cm size).

   Plastic incubation trays are often used in place of heat-sealable bags, and can be especially useful when processing large numbers of strips in different primary antibody solutions.

2. Dilute primary antibody in blocking buffer.

   Primary antibody dilution is determined empirically but is typically 1/100 to 1/1000 for a polyclonal antibody (Fig. 10.10.1; Cooper and Paterson, 1995; Andrew and Titus, 1991a,b,c, 1993), 1/10 to 1/100 for hybridoma supernatants (Yokoyama, 1991a), and ≥1/1000 for murine ascites fluid containing monoclonal antibodies (Yokoyama, 1991b). Ten- to one-hundred-fold higher dilutions can be used with alkaline phosphatase– or luminescence–based detection systems. Both primary and secondary antibody solutions can be used at least twice, but long-term storage (i.e., >2 days at 4°C) is not recommended.

3. Open bag and pour out blocking buffer. Replace with diluted primary antibody and incubate 30 min to 1 hr at room temperature with constant agitation.

   Usually 5 ml diluted primary antibody solution is sufficient for two to three membranes (14 × 14–cm size). Incubation time may vary, depending on conjugate used.

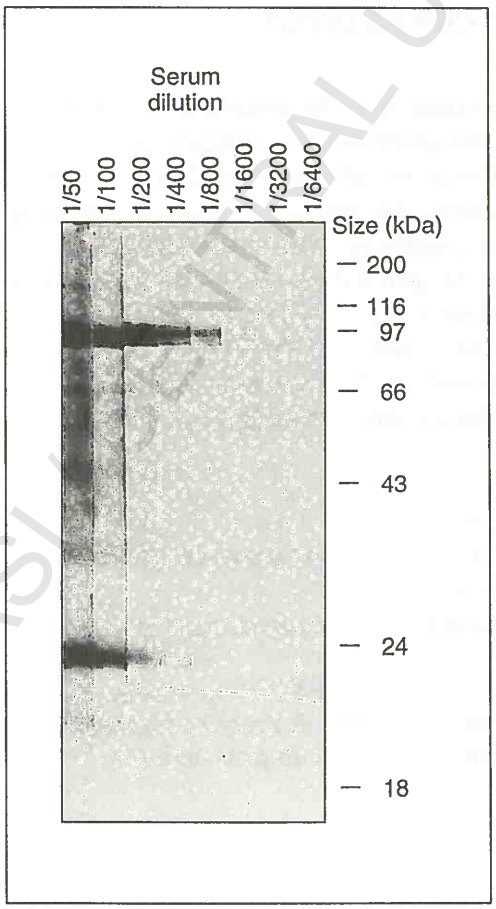

Figure 10.10.1 Serial dilution of primary antibody directed against the 97-kDa catalytic subunit of the plant plasma membrane ATPase. The blot was developed with HRPO-coupled avidin-biotin reagents according to the Alternate Protocol and visualized with 4-chloro-1-naphthol (4CN). Note how background improves with dilution.

BCU IASI CENTRAL UNIVERSITY LIBRARY

When using plastic trays, the primary and secondary antibody solution volume should be increased to 25 to 50 ml. For membrane strips, incubation trays with individual slots are recommended. Typically, 0.5 to 1 ml solution/slot is needed.

4. Remove membrane from plastic bag with gloved hand. Place in plastic box and wash 4 times by agitating with 200 ml TTBS (nitrocellulose or PVDF) or TBS (nylon), 10 to 15 min each time.

5. Dilute secondary antibody HRPO- or AP-anti-Ig conjugate in blocking buffer.

   Commercially available enzyme-conjugated secondary antibody is usually diluted 1/200 to 1/2000 (i.e., 20 µl/ml to 2 µl/ml) prior to use (Harlow and Lane, 1988).

6. Place membrane in fresh heat-sealable plastic bag, add diluted HRPO- or AP-anti-Ig conjugate, and incubate 30 min to 1 hr at room temperature with constant agitation.

   When using plastic incubation trays, see step 3 annotation for proper antibody solution volumes.

7. Remove membrane from bag and wash as in step 4. Develop according to appropriate visualization protocol (see Support Protocol 1 or see Support Protocol 2).

IMMUNOPROBING WITH AVIDIN-BIOTIN COUPLING TO SECONDARY ANTIBODY

ALTERNATE PROTOCOL

The following procedure is based on the Vectastain ABC kit from Vector (*SUPPLIERS APPENDIX*). It uses an avidin-biotin complex to attach horseradish peroxidase (HRPO) or alkaline phosphatase (AP) to the biotinylated secondary antibody. Avidin-biotin systems are capable of extremely high sensitivity because multiple reporter enzymes are bound to each secondary antibody. In addition, the detergent Tween 20 is a popular alternative to protein blocking agents when using nitrocellulose or PVDF membranes.

Additional Materials (also see Basic Protocol)

Vectastain ABC (HRPO) *or* ABC-AP (AP) kit (Vector) containing the following: reagent A (avidin), reagent B (biotinylated HRPO or AP), and biotinylated secondary antibody (request membrane immunodetection protocols when ordering)

1. Equilibrate membrane in appropriate blocking buffer in heat-sealed plastic bag with constant agitation using an orbital shaker or rocking platform. For nitrocellulose and PVDF, incubate 30 to 60 min at room temperature. For nylon, incubate ≥2 hr at 37°C.

   TTBS is well suited for avidin-biotin systems. For nylon, protein binding agents are recommended. Because nonfat dry milk contains residual biotin that will interfere with the immunoassay, its use must be restricted to the blocking step only.

   Plastic incubation trays are often used in place of heat-sealable bags, and can be especially useful when processing large numbers of strips in different primary antibody solutions.

2. Prepare primary antibody solution in TTBS (nitrocellulose or PVDF) or TBS (nylon).

   Dilutions of sera containing primary antibody generally range from 1/100 to 1/10,000. This depends in large part on the sensitivity of the detection system. With high-sensitivity avidin-biotin systems, dilutions from 1/1000 to 1/100,000 are common. Higher dilutions can be used with AP- or luminescence-based detection systems. To determine the appropriate concentration of primary antibody, a dilution series is easily performed with membrane strips. Separate antigens on a preparative gel (i.e., with a single large sample well) and immunoblot the entire gel. Cut 2- to 4-mm strips by hand or with a membrane cutter (Schleicher & Schuell or Inotech) and incubate individual

BOSTON UNIVERSITY LIBRARY

strips in a set of serial dilutions of primary antibody. The correct dilution should give low background and high specificity (Fig. 10.10.1).

3. Open bag, remove blocking buffer, and add enough primary antibody solution to cover membrane. Reseal bag and incubate 30 min at room temperature with gentle rocking.

   When using plastic trays, the primary and secondary antibody solution volume should be increased to 25 to 50 ml. For membrane strips, incubation trays with individual slots are recommended. Typically, 0.5 to 1 ml solution/slot is needed.

4. Remove membrane from bag and place in plastic box. Wash membrane 3 times over a 15-min span in TTBS (nitrocellulose or PVDF) or TBS (nylon). Add enough TTBS or TBS to fully cover the membrane (e.g., 5 to 10 ml/strip or 25 to 50 ml/whole membrane).

5. Prepare biotinylated secondary antibody solution by diluting 2 drops biotinylated antibody with 50 to 100 ml TTBS (nitrocellulose or PVDF) or TBS (nylon).

   This dilution gives both high sensitivity and enough volume to easily cover a large (14 × 14–cm) membrane.

6. Transfer membrane to fresh plastic bag containing secondary antibody solution. Incubate 30 min at room temperature with slow rocking, then wash as in step 4.

   When using plastic incubation trays, see step 3 annotation for proper antibody solution volumes.

7. While membrane is being incubated with secondary antibody, prepare avidin-biotin-HRPO or -AP complex. Mix 2 drops Vectastain reagent A and 2 drops reagent B into 10 ml TTBS (nitrocellulose or PVDF) or TBS (nylon). Incubate 30 min at room temperature, then further dilute to 50 ml with TTBS or TBS.

   Diluting the A and B reagents to 50 ml expands the amount of membrane that can be probed without greatly affecting sensitivity. Azide is a peroxidase inhibitor and should not be used as a preservative for long-term storage of the antibody solution. Casein, nonfat dry milk, serum, and some grades of bovine serum albumin (BSA) may interfere with the formation of the avidin-biotin complex and should not be used in the presence of avidin or biotin reagents (Gillespie and Hudspeth, 1991; see also instructions from Vector).

8. Transfer membrane to fresh plastic bag containing avidin-biotin-enzyme solution. Incubate 30 min at room temperature with slow rocking, then wash over a 30-min span as in step 4.

   Hybridization in a plastic bag requires 5 to 10 ml avidin-biotin-enzyme solution. Membrane strips require 5 to 10 ml/strip, whereas blots from standard-sized gels (i.e., 14 × 16 cm) require 50 ml for convenient handling in a tray.

9. Develop membrane according to the appropriate visualization protocol (see Support Protocol 1 or see Support Protocol 2).

BCU IAS/CENTRAL UNIVERSITY LIBRARY

VISUALIZATION WITH CHROMOGENIC SUBSTRATES

SUPPORT PROTOCOL 1

After incubation with primary and secondary antibody conjugates (see Basic Protocol or see Alternate Protocol), bound antigens are typically visualized with chromogenic substrates. The substrates 4CN, DAB/$NiCl_2$, and TMB are commonly used with horseradish peroxidase (HRPO)–based immunodetection procedures, whereas BCIP/NBT is recommended for alkaline phosphatase (AP)–based procedures (see Table 10.10.1). After incubation with primary and secondary antibodies, the membrane is placed in the appropriate substrate solution. Protein bands usually appear within a few minutes.

Table 10.10.1 Chromogenic and Luminescent Visualization Systems[a]

System	Reagent[b]	Reaction/detection	Comments[c]
Chromogenic			
HRPO-based	4CN	Oxidized products form purple precipitate	Not very sensitive (Tween 20 inhibits reaction); fades rapidly on exposure to light
	DAB/$NiCl_2$[d]	Forms dark brown precipitate	More sensitive than 4CN but potentially carcinogenic; resulting membrane is easily scanned
	TMB[e]	Forms dark purple stain	More stable and less toxic than DAB/$NiCl_2$; may be somewhat more sensitive[e]; can be used with all membrane types
AP-based	BCIP/NBT	BCIP hydrolysis produces indigo precipitate after oxidation with NBT; reduced NBT precipitates; dark blue-gray stain results	More sensitive and reliable than other AP-precipitating substrates; note that phosphate inhibits AP activity
Luminescent			
HRPO-based	Luminol/H_2O_2/ *p*-iodophenol	Oxidized luminol substrate gives off blue light; *p*-iodophenol increases light output	Very convenient, sensitive system; reaction is detected within a few seconds to 1 hr
AP-based	Substituted 1,2-dioxetane phosphates (e.g., AMPPD, CSPD, Lumigen-PPD, Lumi-Phos 530[f])	Dephosphorylated substrate gives off light	Protocol described gives reasonable sensitivity on all membrane types; consult instructions of reagent manufacturer for maximum sensitivity and minimum background (see Troubleshooting)

[a]Abbreviations: AMPPD or Lumigen-PPD, disodium 3-(4-methoxyspiro{1,2-dioxetane-3,2′-tricyclo[3.3.1.1^{3,7}]-decan}-4-yl)phenyl phosphate; AP, alkaline phosphatase; BCIP, 5-bromo-4-chloro-3-indolyl phosphate; 4CN, 4-chloro-1-napthol; CSPD, AMPPD with substituted chlorine moiety on adamantine ring; DAB, 3,3′-diaminobenzidine; HRPO, horseradish peroxidase; NBT, nitroblue tetrazolium; TMB, 3,3′,5,5′-tetramethylbenzidine.

[b]Recipes and suppliers for all reagents except TMB are listed in Reagents and Solutions. Kits containing TMB are available from Kirkegaard & Perry, TSI Center for Diagnostic Products, Moss, and Vector.

[c]See Commentary for further details.

[d]DAB/$NiCl_2$ can be used without the nickel enhancement, but sensitivity is greatly reduced.

[e]First treating nitrocellulose filters with 1% dextran sulfate for 10 min in 10 mM citrate-EDTA (pH 5.0) causes TMB to precipitate onto the membrane with a sensitivity much greater than that seen for 4CN or DAB and equal to or better than that for BCIP/NBT (McKimm-Breschkin, 1990).

[f]Lumi-Phos 530 contains dioxetane, $MgCl_2$, cetyltrimethylammonium bromide (CTAB), and fluorescent enhancer in a pH 9.6 buffer.

BCU ASTON UNIVERSITY LIBRARY

Materials

Membrane with transferred proteins and probed with antibody-enzyme complex (see Basic Protocol or see Alternate Protocol)
TBS (see recipe)
Chromogenic visualization solution (Table 10.10.1; see recipes)

Additional reagents and equipment for gel photography (*UNIT 10.5*)

1. If final membrane wash (see Basic Protocol, step 7, or see Alternate Protocol, step 9) was performed in TTBS, wash membrane 15 min at room temperature in 50 ml TBS.

   The Tween 20 in the TTBS interferes with 4CN development (Bjerrum et al., 1988).

2. Place membrane into chromogenic visualization solution. Bands should appear in 10 to 30 min.

3. Terminate reaction by washing membrane in distilled water. Air dry and photograph (*UNIT 10.5*) for a permanent record.

SUPPORT PROTOCOL 2

VISUALIZATION WITH LUMINESCENT SUBSTRATES

After incubation with primary and secondary antibody conjugates (see Basic Protocol and see Alternate Protocol), antigens can also be visualized with luminescent substrates. Detection with light offers both greater speed and enhanced sensitivity over chromogenic and radioisotopic procedures. After the final wash, the blot is immersed in a substrate solution containing luminol for horseradish peroxidase (HRPO) systems, or dioxetane phosphate for alkaline phosphatase (AP) systems, sealed in thin plastic wrap and placed firmly against film. Exposures range from a few seconds to several hours, although typically strong signals appear within a few seconds or minutes.

Additional Materials (also see Support Protocol 1)

Luminescent substrate buffer: 50 mM Tris·Cl, pH 7.5 (*APPENDIX 2E*; HRPO), *or* dioxetane phosphate substrate buffer (see recipe; AP)
Nitro-Block solution (AP reactions only): 5% (v/v) Nitro-Block (Tropix) in dioxetane phosphate substrate buffer (see recipe), prepared just before use
Luminescent visualization solution (Table 10.10.1; see recipes)
Clear plastic wrap

NOTE: See Troubleshooting section for suggestions concerning optimization of the protocol, particularly when employing AP-based systems.

1. Equilibrate membrane in two 15-min washes with substrate buffer each.

   For blots of whole gels, use 50 ml substrate buffer; for strips, use 5 to 10 ml/strip.

2. *For AP reactions using nitrocellulose or PVDF membranes:* Incubate 5 min in Nitro-Block solution, followed by 5 min in substrate buffer.

   For blots of whole gels, use 50 ml Nitro-Block solution and substrate buffer; for strips, use 5 to 10 ml/strip.

   Nitro-Block enhances light output from the dioxetane substrate in reactions using AMPPD, CSPD, or Lumigen-PPD concentrate. It is required for nitrocellulose and recommended for PVDF membranes. It is not needed for Lumi-Phos 530, AP reactions on nylon membranes, or HRPO–based reactions on any type of membrane. Lumi-Phos 530 is not recommended for nitrocellulose membranes.

3. Transfer membrane to luminescent visualization solution. Soak 30 sec (HRPO reactions) to 5 min (AP reactions).

BCU IASI CENTRAL UNIVERSITY LIBRARY

Alternatively, lay out a square of plastic wrap and pipet 1 to 2 ml visualization solution into the middle. Place membrane on the plastic so that the visualization solution spreads out evenly from edge to edge. Fold wrap back onto membrane, seal, and proceed to step 5.

4. Remove membrane, drain, and place face down on a sheet of clear plastic wrap. Fold wrap back onto membrane and seal with tape to form a liquid-tight enclosure.

   To ensure an optimal image, only one layer of plastic should be present between the membrane and film. Sealable bags are an effective alternative. Moisture must not come in contact with the X-ray film.

5. In a darkroom, place membrane face down onto film.

   Do this quickly and do not reposition; a double image will be formed if the membrane is moved while in contact with the film. A blurred image is usually caused by poor contact between membrane and film; use a film cassette that ensures a tight fit.

6. Expose film for a few seconds to several hours.

   Typically, immunoblots produce very strong signals within a few seconds or minutes; however, weak signals may require several hours to an overnight exposure. If no image is detected, expose film 30 min to 1 hr and, if needed, overnight (see Troubleshooting).

7. If desired, wash membrane in two 15-min washes of 50 ml TBS and process for chromogenic development (see Support Protocol 1).

   It is possible to develop the same membrane with chromogenic substrates after luminescent visualization.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alkaline phosphate substrate buffer

100 mM Tris·Cl, pH 9.5
100 mM NaCl
5 mM $MgCl_2$

Blocking buffer

Colorimetric detection

For nitrocellulose and PVDF: 0.1% (v/v) Tween 20 in TBS (TTBS; see recipe).

For neutral and positively charged nylon: Tris-buffered saline (TBS; see recipe) containing 10% (w/v) nonfat dry milk.

TTBS can be stored up to 1 week at 4°C. Prepare blocking buffer containing nonfat dry milk immediately prior to use, as the milk blocking solution is not stable.

Luminescent detection

For nitrocellulose, PVDF, and neutral nylon (e.g., Pall Biodyne A): 0.2% (w/v) casein (e.g., Hammarsten grade or I-Block; Tropix) in TTBS (see recipe).

For positively charged nylon: 6% (w/v) casein/1% (v/v) polyvinylpyrrolidone (PVP) in TTBS (see recipe).

For each solution: With constant mixing, add casein and PVP to warm (65°C) TTBS. Stir for 5 min, then cool. Prepare each solution just before use.

BOYLAN/CENTRAL UNIVERSITY LIBRARY

Chromogenic visualization solutions

BCIP/NBT visualization solution: Mix 33 µl NBT stock [100 mg NBT in 2 ml 70% (v/v) dimethylformamide (DMF), stored <1 year at 4°C] and 5 ml alkaline phosphate substrate buffer (see recipe). Add 17 µl BCIP stock (100 mg BCIP in 2 ml 100% DMF, stored <1 year at 4°C) and mix. Stable 1 hr at room temperature.

Recipe is from Harlow and Lane (1988). Alternatively, BCIP/NBT substrates may be purchased from Sigma, Kirkegaard & Perry, Moss, and Vector (SUPPLIERS APPENDIX).

4CN visualization solution: Mix 20 ml ice-cold methanol with 60 mg 4-chloro-1-naphthol (4CN). Separately mix 60 µl of 30% (w/v) H_2O_2 with 100 ml TBS (see recipe) at room temperature. Rapidly mix the two solutions and use immediately.

DAB/$NiCl_2$ visualization solution:
5 ml 100 mM Tris·Cl, pH 7.5 (*APPENDIX 2E*)
100 µl DAB stock (40 mg/ml in H_2O, stored in 100-µl aliquots at –20°C)
25 µl $NiCl_2$ stock (80 mg/ml in H_2O, stored in 100-µl aliquots at –20°C)
15 µl 3% (w/v) H_2O_2
Mix just before use

CAUTION: *Handle DAB carefully, wearing gloves and mask; it is a carcinogen.*

Suppliers of chromogenic HRPO substrates (4CN and DAB/$NiCl_2$) are Sigma, Kirkegaard & Perry, Moss, and Vector (SUPPLIERS APPENDIX). For selection of appropriate chromogenic solutions, and for definition of abbreviations, see Table 10.10.1.

Dioxetane phosphate substrate buffer

1 mM $MgCl_2$
0.1 M diethanolamine
0.02% (w/v) sodium azide (optional)
Adjust to pH 10 with HCl and use fresh

Traditionally, the AMPPD substrate buffer has been a solution containing 1 mM $MgCl_2$ and 50 mM sodium carbonate/bicarbonate, pH 9.6 (Gillespie and Hudspeth, 1991). The use of diethanolamine results in better light output (Tropix Western Light instructions).

Alternatively, 100 mM Tris·Cl (pH 9.5)/100 mM NaCl/5 mM $MgCl_2$ can be used (Sandhu et al., 1991).

Luminescent visualization solutions

Dioxetane phosphate visualization solution: Prepare 0.1 mg/ml AMPPD or CSPD (Tropix) *or* 0.1 mg/ml Lumigen-PPD (Lumigen) substrate in dioxetane phosphate substrate buffer (see recipe). Prepare just before use. Lumi-Phos 530 (Boehringer Mannheim or Lumigen) is a ready-to-use solution and can be applied directly to the membrane.

This concentration (240 µM) of AMPPD substrate is the minimum recommended by Tropix. Ten-fold lower concentrations can be used but require longer exposures.

Luminol visualization solution:
0.5 ml 10× luminol stock [40 mg luminol (Sigma) in 10 ml dimethyl sulfoxide (DMSO)]
0.5 ml 10× *p*-iodophenol stock [optional; 10 mg (Aldrich) in 10 ml DMSO]
2.5 ml 100 mM Tris·Cl, pH 7.5 (*APPENDIX 2E*)
25 µl 3% (w/v) H_2O_2
H_2O to 5 ml
Prepare just before use

Recipe is from Schneppenheim et al. (1991). Premixed luminol substrate mix (Mast Immunosystems, Amersham, Du Pont NEN Renaissance, or Kirkegaard & Perry Lumi-

continued

BCU IASI / CENTRAL UNIVERSITY LIBRARY

GLO) may also be used. For selection of appropriate luminescent solutions, and for definition of abbreviations, see Table 10.10.1.

p-Iodophenol is an optional enhancing agent that increases light output. Luminol and p-iodophenol stocks can be stored ≤6 months at –20°C.

Tris-buffered saline (TBS)

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2E*)
0.9% (w/v) NaCl
Store up to several months at 4°C

Tween 20/TBS (TTBS)

0.1% (v/v) Tween 20 in Tris-buffered saline (TBS; see recipe)
Store up to several months at 4°C

COMMENTARY

Background Information

Immunoprecipitation has been widely used to visualize the antigens recognized by various antibodies, both polyclonal and monoclonal. However, there are several problems inherent to immunoprecipitation, including the need to radiolabel the antigen, coprecipitation of tightly associated macromolecules, occasional difficulty in obtaining precipitating antibodies, and insolubility of various antigens (Talbot et al., 1984).

To circumvent these problems, electroblotting (Towbin et al., 1979)—subsequently popularized as western blotting or immunoblotting (Burnette, 1981)—was conceived. Immunoblotting is a rapid and sensitive assay for the detection and characterization of proteins that works by exploiting the specificity inherent in antigen-antibody recognition. It involves the solubilization and electrophoretic separation of proteins, glycoproteins, or lipopolysaccharides by SDS-PAGE (*UNITS 10.1 & 10.4*) or urea-PAGE (*UNIT 10.2*), followed by quantitative transfer and irreversible binding to nitrocellulose, PVDF, or nylon membranes (*UNIT 10.8*). This technique has been useful in identifying specific antigens recognized by polyclonal or monoclonal antibodies, and is highly sensitive (1 ng of antigen can be detected).

Protein blotting has important clinical applications—notably, it is the confirmatory test for human immunodeficiency virus type 1 (HIV-1). SDS-PAGE-separated virus proteins are blotted onto nitrocellulose and processed with patient sera. After washing and incubating (using a Tween 20/nonfat dry milk diluting and washing solution) with an anti-human IgG coupled to horseradish peroxidase (HRPO) or alkaline phosphatase (AP), the antigens are identified by chromogenic development. Typically, the prepared blots and all reagents needed for the test are purchased commercially (Bio-Rad Novapath, Organon Teknika Cappel HIV-1 Western Blot Kit, or Du Pont NEN HIV Western Blot Kit).

Immunoblotted proteins can be detected by chromogenic or luminescent assays (see Table 10.10.1 for a description of the reagents available for each system, their reactions, and a comparison of their advantages and disadvantages). Luminescent detection methods offer several advantages over traditional chromogenic procedures. In general, luminescent substrates increase the sensitivity of both HRPO and AP systems without the need for radioisotopes. Substrates for the latter have only recently been applied to protein blotting (see Gillespie and Hudspeth, 1991; Sandhu et al., 1991; Bronstein et al., 1992). Luminescent detection can be completed in as little as a few seconds; exposures rarely exceed 1 hr. Depending on the system, the luminescence can last up to 3 days, permitting multiple exposures of the same blot. Furthermore, the signal is detected by film, and varying the exposure can result in more or less sensitivity. Luminescent blots can be easily erased and reprobed because the reaction products are soluble and do not deposit on the membrane. Compared to chromogenic development, a luminescent image recorded on film is easier to photograph and to quantitate by densitometry.

AP–based luminescent protocols that achieve maximum sensitivity with minimum background can be complex, and the manufacturer's instructions should be consulted (see Reagents and Solutions). The procedure described in Support Protocol 2 gives reasonable sensitivity on nitrocellulose, PVDF, and nylon membranes with a minimum of steps.

Critical Parameters

First and foremost, the antibody being used should recognize denatured antigen. Nonspecific binding of antibodies can occur, so control antigens and antibodies should always be run in parallel. Time of transfer and dilutions of primary antibody and conjugate should always be optimized.

A variety of agents are currently used to block binding sites on the membrane after blotting (Harlow and Lane, 1988). These include Tween 20, PVP, nonfat dry milk, casein, BSA, and serum. A 0.1% (v/v) solution of Tween 20 in TBS (TTBS), a convenient alternative to protein-based blocking agents, is recommended for chromogenic development of nitrocellulose and PVDF membranes (Blake et al., 1984). In contrast to dry milk/TBS blocking solution, TTBS is stable and has a long shelf life at 4°C. Furthermore, TTBS generally produces a clean background and permits subsequent staining with India ink.

Two types of nylon membranes are used for transfer—neutral (e.g., Pall Biodyne A) and positively charged (e.g., Pall Biodyne B). Although the positively charged membranes have very good protein-binding characteristics, they tend to have a higher background. These membranes remain positively charged from pH 3 to pH 10. Neutral nylon membranes are also charged, having a mix of amino and carboxyl groups that give an isoelectric point of 6.5. Because of their high binding capacity, positively charged membranes are popular for protein applications using luminescence.

Nylon membranes require more stringent blocking steps. Here 10% (w/v) nonfat dry milk in TBS is recommended for chromogenic development. During development of luminescence, however, background is a more significant problem. When compared to dry milk, purified casein has minimal endogenous AP activity (such activity leads to high background) and is therefore recommended as a blocking agent for nitrocellulose, PVDF, and nylon membranes. Positively charged nylon requires much more stringent blocking with 6% (w/v) casein and 1% (v/v) polyvinylpyrrolidone (PVP-40). Because nonfat dry milk and casein may contain biotin, which will interfere with avidin-biotin reactions, subsequent steps are done without protein blocking agents when using these systems. If background is a problem, highly purified casein (0.2% to 6%) added to the antibody incubation buffers may help.

Troubleshooting

There are several problems associated with immunoblotting. The antigen is solubilized and electrophoresed in the presence of denaturing agents (e.g., SDS or urea), and some antibodies may not recognize the denatured form of the antigen transferred to the membrane. The results observed may be entirely dependent on the denaturation and transfer system used. For example, zwitterionic detergents have been shown to restore the antigenicity of outer membrane proteins in immunoblotting (Mandrell and Zollinger, 1984). Gel electrophoresis under nondenaturing conditions can sometimes preserve antigenicity (*UNIT 10.3*).

Other potential problems include high background, nonspecific or weak cross-reactivity of antibodies, poor protein transfer or membrane binding efficiency, and insufficient sensitivity. For an extensive survey and discussion of immunoblotting problems and artifacts, see Bjerrum et al. (1988).

Insufficient blocking or nonspecific binding of the primary or secondary antibody will cause a high background stain. A control using preimmune sera or only the secondary antibody will determine if these problems are due to the primary antibody. Try switching to another blocking agent; protein blocking agents may weakly cross-react. Lowering the concentration of primary antibody should decrease background and improve specificity (Fig. 10.10.1).

Because of the nature of light and the method of detection, certain precautions are warranted when using luminescent visualization (e.g., Harper and Murphy, 1991). Very strong signals can overshadow weaker signals nearby on the membrane. Because light will pipe through the membrane and the surrounding plastic wrap, overexposure will produce a broad, diffuse image on the film. The signal can also saturate the film, exposing it to a point whereby increased exposure will not cause a linear increase in the density of the image on the film.

With the AP substrate AMPPD, nitrocellulose, PVDF, and nylon membranes require 2, 4, and 8 to 12 hr, respectively, to reach maximum light emission. In addition, PVDF is reported to give a stronger signal than nitrocellulose (Tropix Western Light instructions). Positively charged nylon requires special blocking procedures to minimize background (Gillespie and Hudspeth, 1991). These procedures include using a blocking and pri-

RCU IAS CENTRAL LIBRARY

mary antibody solution containing 6% (w/v) casein, 1% (v/v) polyvinylpyrrolidone-40 (PVP-40), 3 mM NaN_3, 10 mM EDTA, and phosphate-buffered saline (PBS), pH 6.8. Prior to use, the casein must be heated to 65°C to reduce AP activity in the casein itself. In addition, maximum sensitivity has been observed when free biotin or biotinylated proteins are removed by pretreating the casein with avidin-agarose (Sigma).

Anticipated Results

Immunoblotting should result in the detection of one or more bands. Although antibodies directed against a single protein should produce a single band, degradation of the sample (e.g., via endogenous proteolytic activity) may cause visualization of multiple bands of slightly different size. Multimers will also form spontaneously, causing higher-molecular-weight bands on the blot. If one is simultaneously testing multiple antibodies directed against a complex protein mixture (e.g., using a patient sera against SDS-PAGE-separated viral proteins in the AIDS western blot test), multiple bands will be visualized.

Time Considerations

The entire immunoblotting procedure can be completed in 1 to 2 days, depending on the transfer time and type of gel. Gel electrophoresis requires 4 to 6 hr on a regular gel and 1 hr on a minigel. Transfer time can be 1 hr (for high-power transfer) to overnight. Blocking, conjugate incubation, and washing each take 30 min to 1 hr. Finally, substrate incubation requires 10 to 30 min (chromogen) and a few seconds to several hours (luminescence).

Autoradiography

Autoradiography is a radioisotope-detection method that records the spatial distribution of radioisotope-labeled substances within a membrane or specimen material. The ionizing radiation (usually β particles) that is emitted from the radioisotope interacts with the silver halide grains within the emulsion of the photographic film, forming a latent image. The latent image is amplified by the action of the developer during processing, thus creating a visible image. The pattern and density of the image are used to locate and quantify the radioactive distribution.

Commercially available autoradiography films are best suited for autoradiography because of their high sensitivity to both light and ionizing radiation. Autoradiography films generally yield higher-contrast images with a shorter exposure time than medical X-ray films and other commercially available photographic films.

The most appropriate choice of autoradiography film depends upon the detection requirements of the experiment and the type and quantity of the radiolabeled isotope. Several autoradiography films are designed and used with very specific exposure methods and radioisotopes—e.g., BioMax MR and BioMax MS (Eastman Kodak). BioMax MR is designed for direct-exposure detection of ^{14}C and ^{35}S radioisotopes and BioMax MS is designed for exposure detection of ^{32}P and ^{125}I radioisotopes with an intensifying screen. The following descriptions of films and exposure procedures will assist in optimizing autoradiography techniques.

TYPES OF FILM

The structure of autoradiography film includes either one emulsion layer or two on a 7-mil (178-μm) polyester support. Double-coated film includes emulsion layers on both sides of the sheet of film. Emulsion layers consist of light-sensitive silver halide grains and gelatin. The polyester support can be either clear or blue-tinted.

Single-Coated Films

Autoradiography films that are single-emulsion coated are optimized for use with medium-energy radioisotopes—e.g., ^{14}C, ^{35}S, and ^{33}P—and direct-exposure techniques (see discussion of Direct Exposure) for a wide range of biological applications such as DNA sequencing. At maximum energy levels of 150 to 170 KeV, the majority of the β particles do not penetrate through the film base, so an additional emulsion on the other side of the film support, such as that found in double-coated films, does not increase sensitivity to ^{14}C and ^{35}S radioisotopes. Single-coated films—e.g., BioMax MR—have greater clarity because they do not have the second emulsion layer. BioMax MR is highly sensitive to direct radioisotope exposure. It is twice as sensitive to ^{14}C and ^{35}S as X-Omat AR film (Eastman Kodak; see discussion of Double-Coated Films). BioMax MR film sensitivity to light has been reduced in order to increase allowable safelight handling time in the darkroom, thus reducing its sensitivity to fluorography or intensifying-screen exposures.

Double-Coated Films

Double-coated films are generally used with intensifying screens (see discussion of Intensifying-Screen Exposure) at reduced temperatures to detect high-energy radioisotopes such as ^{32}P and ^{125}I. High-energy β particles, X rays, and γ rays penetrate and expose both emulsion layers. These high-energy particles are primarily absorbed by an intensifying screen if it is placed on the opposite side of the film from the specimen. Light is emitted by the phosphor grains in the intensifying screen upon absorbing the β particle, and this greatly amplifies detection. Double-coated X-Omat AR film is a widely used film for general autoradiography. This film is highly sensitive to blue light and is used with a blue-light-emitting calcium tungstate ($CaWO_4$) intensifying screen.

The green-light-sensitive BioMax MS film is a double-coated film that gives greatest sensitivity to ^{32}P when used with a BioMax MS intensifying screen or high-energy TranScreen (Eastman Kodak) at –70°C. Both of these screens emit green light when exposed to ionizing radiation. These film/screen systems are approximately four times more sensitive than the X-Omat AR film/$CaWO_4$ intensifying screen system.

Most fluorographic exposures (see discussion of Fluorographic Exposure) emit light in the blue spectrum. X-Omat AR film is a blue-sensitive film that is generally used with scintillants such as PPO (2, 5-diphenyloxazole) and

BIOMEDICAL SCIENCES LIBRARY

sodium salicylate, as well as prepared fluorographic solutions and sprays (Amersham, DuPont NEN). X-Omat AR film is at least two times more sensitive than other blue-sensitive autoradiography films for most fluorographic exposure techniques.

HANDLING OF AUTORADIOGRAPHY FILM

Safelighting

Safe darkroom illumination is dependent upon the type of safelight filter, the wattage of the bulb, and the distance from the safelight bulb to the sheet of film. A red safelight filter (e.g., Kodak GBX-2) is recommended for the majority of autoradiography films. The bulb wattage should not exceed 15 W with direct-illuminating safelight lamps. The minimum safelight-to-film distance is 4 feet.

If one is unsure of the safelight conditions in a darkroom or the safelight sensitivity of a film, it is wise to perform a safelight safety test. In the dark, put the film on the workbench and place a coin on top of the film. Next, turn on the safelight for 1 to 2 min or more, then turn off the safelight and process the film in the dark. If the coin's shadow image is not visible on the film, then the safelight conditions are suitable for the tested exposure time.

If the safelight safety test fails, measures to be taken may include replacing the safelight filter, decreasing the bulb wattage, increasing the safelight-to-film distance, or decreasing the time of exposure to safelight conditions.

Storage and Care of Film

BioMax MS, BioMax MR, and X-Omat AR films are highly efficient detectors of background radiation. With these films, the background fog can be expected to increase with film age. It is advisable to keep down the inventory of these films and order them more frequently to minimize background fog. Most laboratories routinely order just enough film for 3 to 5 months.

Film sheets should be handled carefully to prevent black or white marks and lines that result from pinching and scratching the emulsion. Individual film sheets should be handled only by the edges.

QUANTITATIVE AUTORADIOGRAPHY

A radioactive calibration strip is very effective in autoradiography quantification techniques. Commercially available radioactive standards (e.g., ^{3}H and ^{14}C tissue equivalent standards from American Radiolabeled Chemicals or Amersham), self-prepared radioactive scales, or radioisotope-labeled dilution series are used during an autoradiographic exposure to expose the film or storage phosphor screen to quantitate the image. The autoradiography image (e.g., from a tissue specimen, membrane, or gel) and the calibration strip require digitization or densitometry to convert the information to radioactivity from a plot of radioactivity versus density or pixel value.

A common method of preparing a calibration strip is to serially dilute the radioisotope label by a factor of 2 or more and apply it to a substrate or membrane. It is important to extend the dilution series beyond the estimated range of the radioisotope label concentration. The individual radioisotope-label concentrations are spotted (3 to 5 µl), blotted, or hybridized onto the support material. The shape and configuration of each spot or band should be similar and uniform. The density or pixel value is plotted versus the radioactivity value to obtain the relative radioisotope label calibration curve.

EXPOSURE PROCEDURES

There are many factors to consider when choosing an autoradiographic exposure procedure. The choices include the isotope, the radioactivity level, whether to use double- or single-coated film, film treatment, and exposure temperature. Each researcher needs to determine the best procedure for each particular experimental protocol (see Table 10.11.1).

Direct Exposure

For direct exposure, the radiolabeled specimen is placed in direct contact with autoradiography film and enclosed in a light-tight cassette for a predetermined, or suitable, amount of time. At the end of exposure, the film is removed from the cassette after noting the orientation of the film sheet with respect to the specimen by bending a corner of the film towards the specimen or by marking a corner of the film with a no. 2 pencil. The film is then photographically processed.

Exposing autoradiography film at reduced temperatures (see discussion of Fluorographic Exposure) does not improve the sensitivity with direct β-particle exposures as it does with fluorographic and intensifying-screen exposures. The β particle forms a very stable latent image in the silver grain of the emulsion. This latent image does not significantly fade with time as in the case with light exposures from fluors

BCU IAS (CENTRAL LIBRARY)

Table 10.11.1 Autoradiography Exposure Procedures

Application(s)	Isotope	Priority	Exposure procedure[a]

[a]TranScreen LE is a product of Eastman Kodak (see *SUPPLIERS APPENDIX*).

(scintillants) and intensifying screens (see discussions of Intensifying-Screen Exposure and Fluorographic Exposure).

Direct-exposure techniques are effective with all β-particle-emitting radioisotopes except tritium (^{3}H). Tritium does not have enough energy to penetrate the overcoat layer on top of autoradiography film and expose the silver halide emulsion. ^{14}C and ^{35}S direct-exposure techniques provide the highest imaging resolution when used with a single-coated autoradiographic film such as BioMax MR film (Steinfeld et al., 1994), although longer exposure times are required than for fluorographic exposures with X-Omat AR film.

Wet or moist specimens should be sealed in a plastic bag or wrapped in plastic wrap. Water and other solvents should not come in contact with film. The plastic wrap attenuates radiation from medium-energy β emitters (^{35}S or ^{14}C) by a factor of 2. The effect with ^{32}P is less, but still noticeable. The investigator should be aware of the thickness of the plastic wrap used. Commercially available plastic wraps are acceptable; extremely thin plastic wraps are better but more expensive.

Fluorographic Exposure

Fluorography enhances the detection of low levels of low- and medium-energy radioisotopes such as ^{3}H, ^{14}C, and ^{35}S. The scintillant (i.e., a reagent that emits visible light upon absorbing ionizing radiation) is placed either on or in the radiolabeled specimen. When the scintillant absorbs the β-particle energy it emits blue light, which is detected by autoradiographic film.

In fluorographic exposure, the radiolabeled specimen (e.g., gel, nitrocellulose membrane, or TLC plate) is soaked or sprayed with the scintillant. The specimen is then dried according to the instructions provided by the scintillant manufacturer and published protocols. Next, under safelight conditions, the specimen is placed against autoradiography film in a light-tight cassette. The temperature for optimum exposure sensitivity is between –70° and –100°C.

At the end of the exposure, the cassette is warmed to ambient temperature before opening. The film is carefully removed from the specimen after marking the orientation of the film sheet with respect to the specimen by bending a corner of the film towards the specimen or by marking a corner of the film with a no. 2 pencil. Then the film is photographically processed. If the film and specimen are separated too rapidly, static discharge may occur. This static may appear on the film as many small black dots or as large, branched black streaks.

X-Omat AR film has a spectral sensitivity that is optimal for detecting fluorescence from

BUFFALO GENERAL UNIVERSITY LIBRARY

the scintillant 2,5-diphenyloxazole (PPO), which emits at 388 nm, sodium salicylate, which emits at 420 nm, and other commercially available fluorographic solutions and sprays. Commercially available scintillants and fluorographic products are available from several companies, including Amersham Corporation and DuPont NEN.

The invisible latent image is the forerunner of the visible, metallic silver image that arises from photographic development after exposure to ionizing radiation. This darkening of the photographic film is the result of the latent image, on the silver halide grain, being converted to metallic silver by reducing agents in the developer. Two or more photons of light are required to make a latent image center on a silver halide grain, whereas only one medium-energy β particle (from ^{14}C or ^{35}S) usually forms many latent image centers on numerous silver halide grains. Generally the latent image centers formed from the interaction with two or more light photons are not stable and fade via low-intensity reciprocity failure mechanisms. The latent image centers formed from direct β-particle interactions are very stable and do not exhibit fading from reciprocity failure (Hamilton, 1977).

Detection of light emitted from scintillants is significantly improved by reducing the exposure temperature to –70° to –100°C. At these low temperatures, the latent image center forming in the silver grain becomes more stable, thus reducing latent-image fading. The detection sensitivity increases because the latent image accumulates with additional light exposure (see Table 10.11.2).

Intensifying-Screen Exposure

For use with an intensifying screen, the radioisotope must have sufficient energy to pass through autoradiography film and into the screen, which is located on the other side of film. ^{32}P and ^{125}I are the most common high-energy β and γ emitters that are exposed with intensifying screens.

In this procedure, under safelight conditions, the intensifying screen is placed in the cassette and a sheet of double-coated autoradiography film is placed on top of it. Next, a radiolabeled specimen is placed on top of the film with its radioactive side against the film and exposed at optimum exposure temperature—i.e., –70° to –100°C. At the end of the exposure, the cassette is warmed to ambient temperature before opening it. The film is removed carefully from the specimen after noting the orientation of the film sheet with respect to the specimen by bending a corner of the film towards the specimen or by marking a corner of the film with a no. 2 pencil. Then the film is photographically processed.

Inorganic phosphors in the intensifying screen convert ionizing radiation to blue light or blue and green light, depending on the type of intensifying screen. Generally, the spectral emission of the intensifying screen is matched to the spectral sensitivity of the film to produce optimal sensitivity. X-Omat AR film is spectrally matched with blue-light-emitting intensifying screens and BioMax MS film is spectrally matched to the blue- and green-light-emitting BioMax MS intensifying screen.

TranScreen Intensifying-Screen Exposure

In this method, ionizing radiation is amplified by placing a thin and uniform phosphor coating between the radiolabeled specimen and autoradiography film. The TranScreen ~LE intensifying screen is used to enhance the detection sensitivity with low-energy radioisotopes such as ^{3}H. The BioMax TranScreen LE intensifying screen folder is placed in the cassette and opened. Next, under safelight conditions, a sheet of BioMax MS film is placed inside the

Table 10.11.2 Sensitivity of X-Omat AR Film

Exposure procedure	Temperature (°C)	Sensitivity ($\mu Ci/cm^2$)[a]
Direct	20	8.00
Fluorographic	20	0.30
Fluorographic	–70	0.07

[a]Sensitivity is expressed as the amount of radioactivity required to produce a 0.10 optical density on X-Omat AR film (Eastman Kodak). [^{3}H]Glutaraldehyde bis bisulfite was spotted on Kodak Chromagram sheet and exposed to film for 24 hours (Laboratory and Research Products, 1993).

BCU IASI / CENTRAL UNIVERSITY LIBRARY

folder and the folder is closed on the film. The ^{3}H-radiolabeled specimen is placed on top of the folder and the light-tight cassette is closed and exposed at the optimum exposure temperature—between –70° and –80°C. At the end of the exposure, the cassette is warmed to ambient temperature before opening it. The film is carefully removed from the TranScreen folder after noting the orientation of the film sheet with respect to the specimen by bending a corner of the film towards the specimen or by marking a corner of the film with a no. 2 pencil. The film is then photographically processed.

BioMax MS film is spectrally matched to the BioMax TranScreen LE screen phosphor. The spectral output of the BioMax TranScreen LE is similar to BioMax MS intensifying screen.

Using the TranScreen LE to detect ^{3}H in a protein gel with western blot (10^{-4} cell fraction of a 10-atom label per protein of 30-kDa mass and a 10-μg gel load), the number of total discharges per mm^2 required to produce a 0.10 optical density above background was reduced ~16-fold, from 7.10×10^6 for direct exposure (Vizard et al., 1996) to 0.42×10^6 for TranScreen LE exposure.

PREFLASHING THE FILM

For very-low-light autoradiographic applications, such as with fluorography, detection may be improved by hypersensitizing the film and exposing it at reduced temperature. Hypersensitizing the film is achieved by preflashing it prior to autoradiographic light exposure. For this treatment to be beneficial, light must be the primary source of the autoradiographic film exposure, as in fluorography or intensifying-screen procedures. Preflashing does not provide any advantages with direct β-particle exposure procedures (see discussion of Direct Exposure).

Equipment needed for preflashing includes an electronic flash—e.g., Vivitar Auto 252 Electronic Flash or Sensitize Pre-Flash (Amersham), and light-filtering material. The Vivitar flash requires filtering the light through several sheets of Whatman 3-mm paper, a Kodak Wratten 22 gelatin filter, and a 3.0 neutral-density filter to control intensity. The electronic preflash unit from Amersham will most likely not require any additional filtering material.

The preflash density is the film-density difference between the exposed and the unexposed film. The optimum increase in preflash density is 0.10 to 0.15 optical density units. Preflashing produces the following various effects on photographic film.

1. It increases background density.
2. It lowers the contrast in the low-dose region of the film's characteristic curve (the characteristic film curve is a graph of film response to light exposure as measured by optical density).
3. It increases in net density above background.
4. It produces a more linear density-versus-exposure film response.

Information will be lost if preflashing is not in the optimal range. Thus, it is very important to develop a repeatable and effective preflashing procedure. Amersham provides detailed comprehensive instructions and calibration protocols with their preflashing unit (also see Laskey and Mills, 1975).

FILM-PROCESSING RECOMMENDATIONS

Autoradiography films are processed either in automated medical X-ray film processors or manually in 5-gallon tanks or small trays placed in a sink. With the exception of Direct Exposure Film (Eastman Kodak) and Hyperfilm-βmax (Amersham), most films are processable using the standard cycles on automated medical X-ray film processors. Direct Exposure Film and Hyperfilm-βmax must be processed manually. It is best to standardize film processing by using one processor and one method of processing, because film development in a manual method is slightly different than automated film development in a medical X-ray film processor.

Automated Processing

Automated medical X-ray film processing affords the most reliable and convenient processing of autoradiography films. Generally, the total processing time is <3 min. Besides the ease of use, most low-volume medical X-ray film processors produce high-quality autoradiograms.

Manual Processing

There are two different methods of manual processing for autoradiography films. The difference is primarily in the size and configuration of the containers used to hold the processing reagents. Both methods will yield high-quality autoradiograms. The deep-tank method involves several 5-gallon tanks surrounded by a temperature- and flow-controlled water bath. Film is attached to metal film hangers, and the

BIBLIOTECA CENTRAL UNIVERSITY LIBRARY

Table 10.11.3 Manual Processing Guidelines for Autoradiography Films[a]

Step	Solution	Agitation	Temperature (°C)	Time
Develop	Kodak GBX developer and replenisher	Do not agitate film sheet	20	5 min
Rinse	Kodak indicator stop bath or running water rinse	Use continuous agitation	16 to 24	30 sec
Fix	Kodak GBX fixer and replenisher	Intermittently agitate film 5 sec for every 60 sec	16 to 24	5 to 10 min
Wash	Clean running water with 2 changes every 15 min		16 to 24	10 min
Dry		Let stand in dust-free environment until dry	<50	

[a]For X-Omat AR, BioMax MR, BioMax MS, and BioMax Light films (Eastman Kodak; see *SUPPLIERS APPENDIX*).

hangers are moved from solution to solution by hand. The tray method involves at least three photographic processing trays on a bench or in a sink. The trays must be 2- to 3-cm longer and wider than the film sheet.

The processing chemistries, times, temperatures, and agitation specifications shown in Table 10.11.3 are a guide for manual processing of autoradiography film in either deep tanks or trays. The processing cycle indicated there is appropriate for most autoradiography, medical, and industrial films. Other types of developers and fixers may require different processing times and temperatures.

Autoradiographic imaging that is consistent and quantifiable relies upon consistent and reproducible processing. The developer and fixer solutions must be replenished daily or made fresh every 1 to 2 weeks to maintain solution activity level.

Digital Electrophoresis Analysis

Gel electrophoresis has become a ubiquitous method in molecular biology for separating biomolecules. This prominence is the result of several factors, including the robustness, speed, and potentially high throughput of the technique. The results of this method are traditionally documented using silver halide–based photography followed by manual interpretation. While this remains an excellent method for qualitative documentation of single-gel results, digital capture offers a number of significant advantages when documentation requires quantitation and sophisticated analysis. Digital images of gel electropherograms can be obtained rapidly using an image-capture device, and the images can be easily manipulated using image analysis software.

REASONS FOR DIGITAL DOCUMENTATION AND ANALYSIS

There are several reasons to consider digital documentation and analysis of electrophoresis results. These justifications can usually be categorized into issues of ease of handling, accuracy, reproducibility, and cost.

Ease of Handling

A major advantage of the digital revolution has been in storage and retrieval of information. Storage in notebooks and filing cabinets previously meant that searching for specific data or experiments was a tedious manual process. With digital information, modern search engines can quickly find specific information in a fraction of the time usually required for a manual search. Making backup copies of non-digital data can be difficult, expensive, and time-consuming since it requires copying, retyping, or photographic reproduction. Copies of digital data can be generated more easily and at reduced costs.

Manipulation of information is also easier when it is in a digital format. While the cut-and-paste analogy comes from physical documentation, it takes on a new perspective when applied digitally. Electrophoresis images can be resized, cropped, and inserted into reports. Data can be passed to spreadsheets and statistical packages for analysis and later insertion into notebooks and reports. These reports can be passed out via the Internet to colleagues throughout the world. A single individual can do all this in a few hours.

Digital analysis also provides an easier method for handling the data when comparing large numbers of results or large numbers of separate experiments. Research that requires comparing the banding patterns on 1000 gels containing 50 lanes each can be an undertaking of heroic proportions if the analysis is performed manually. Database software can dramatically speed the analysis and handle the more mundane tasks, leaving the researcher free to interpret the data.

Accuracy

The human eye is an extremely versatile measuring instrument. It can handle light intensities covering a range of nearly nine orders of magnitude and is sensitive to a fairly wide spectrum of light (Russ, 1995). Yet the eye cannot accurately and reproducibly quantitate density and patterns, nor can it deal with large numbers of bands or spots. Accuracy of measurement is a primary reason for using digital analysis on electrophoretically separated proteins and nucleic acids. Two categories of accuracy are key to digital analysis: positional accuracy, which is important for mobility determinations such as molecular weight, and quantitative accuracy.

Positional accuracy is based on both resolution of the recording medium and measuring accuracy. Silver halide–based recording has a theoretical resolution based on ~2000 imaging elements (silver grains) per inch. Measurement traditionally occurs using a ruler, with an accuracy of ~20 to 40 elements (50 to 100 elements per inch). In comparison, typical digital systems have 200 to 600 picture elements (pixels) per inch. The advantage that digital systems have is in measuring accuracy, which can occur at the level of a single imaging element.

Quantitative accuracy is also an issue. The amount of material represented by a band or spot is difficult to determine accurately from an image of a gel unless it is a digital image. On a digital image, the amount present is directly correlated with the derived volume of the band or spot—the volume is calculated using the intensity values of the pixels within the object.

Reproducibility

Any technique or measurement is only as good as its ability to be faithfully replicated. With software-defined routines, measurements

BYU LAW CENTRAL UNIVERSITY LIBRARY

are performed in the same manner every time. Allowing the computer to do repetitive tasks and complicated calculations minimizes the chance for individual errors. This does not imply that such measurements are correct, just that they are reproducible. An incorrect routine or algorithm can also invalidate data.

Cost

A consideration when evaluating any laboratory method is cost. Digital electrophoresis analysis equipment can be expensive. In many cases, however, it offers the only method for achieving acceptable analysis performance. In other cases, equal performance can be achieved using silver halide technology. However, traditional photography can also be expensive when the costs of consumable supplies such as film and developers, as well as other expensive requirements such as developing tanks and dark rooms, are included. Often, digital methods can be a good choice when all costs are considered.

KEY TERMS FOR IMAGING

There are several specialized terms encountered during digital image analysis. The most commonly encountered are contrast, brightness, gamma, saturation, resolution, and dynamic range. They describe controls on how the light detectors report a range of light intensities. Below is a brief description of each.

Contrast

Contrast describes the slope of the light intensity response curve. An increase in the contrast increases the slope of the curve. The result is a more detailed display over a narrowed range of intensities with less detail in the remaining portions of the intensity range. This is depicted in Figure 10.12.1A and 10.12.1B, where a normal, unadjusted image and a contrast-adjusted image are displayed, respectively. The contrast was increased on midrange intensity values in Figure 10.12.1B to highlight band intensity differences at the expense of background information. Images with a narrow range of informative intensities can benefit from increasing the contrast, since that effectively increases the scale and improves detection of minor differences in intensity. Contrast settings should be lowered if information is being lost outside of the contrast range. For example, in Figure 10.12.1B, loss of background information between peaks indicates that this image should not be used for quantitation.

Brightness

While brightness can have many different definitions, only one will be considered here. Brightness shifts the light intensity response curve without changing its slope as is shown in Figure 10.12.1C. Another name for brightness is black level, since it is commonly used to control the number of black picture elements (pixels) in an image. Incorrect brightness levels can lead either to high background and potential image saturation or, as is illustrated in Figure 10.12.1C, to a total loss of background information and partial loss of band information.

Gamma

Nonlinear corrections are often applied to images to compensate for how the eye perceives changes in intensity, how display devices reproduce images, or both. The most common correction is an exponential one, with the exponent in the equation termed the gamma. A typical gamma value for camera-based systems is 0.45 to 0.50, and is illustrated in Figure 10.12.1D. This is a compromise value that compensates for the 2.2 to 2.5 gamma present in most video monitors and the print dynamics of most printers. Since it is a nonlinear correction, special care must be taken if quantitation is desired. Unless directed to by the manufacturer, gamma values other than 1.0 should be avoided when quantitating. More information on gamma correction can be found on Poynton's Gamma FAQ (*www.inforamp.net/~poynton/Poynton-color.html*).

Dynamic Range

Dynamic range describes the breadth of intensity values detectable by a system and is usually expressed in logarithmic terms such as orders of magnitude, decades, or optical density (OD) units. A large dynamic range is important when trying to quantitate over a wide range of concentrations. The most accurate quantitation occurs in the linear part of the dynamic range, which is usually not the complete dynamic range of the system. An additional consideration is the dynamic range of the visualization method. Many popular visualization methods have linear dynamic ranges of 1 to 2.5 orders of magnitude. An imaging system with greater dynamic range analyzing the results of such a visualization method will not improve the dynamic range.

BCU IASH GENERAL UNIVERSITY LIBRARY

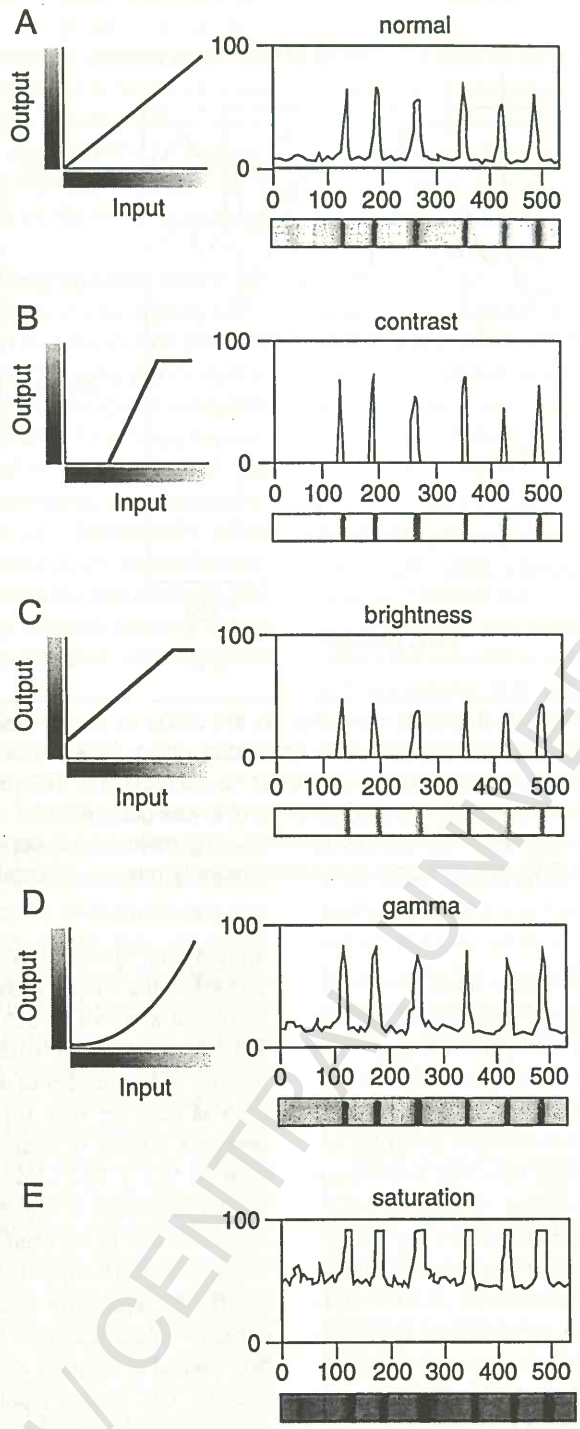

Figure 10.12.1 Examples of how altering image capture settings affects the image and the analysis. The graph on the left displays the light intensity response curve used for image capture while the image and resulting lane profile on the right display how the setting affects the image. The lane profile displays pixel position versus normalized pixel intensity (**A**). In this case, the output has not been altered, giving a straight line with a slope of 1 on the response curve. (**B**) The image acquisition was adjusted to increase the contrast of the displayed image. Although useful for images with a narrow range of informative intensity values, increasing the contrast can lead to a loss of low and high values. (**C**) Decreasing the brightness reduces peak values but also leads to a loss of the weak bands and original background. (**D**) Gamma adjusts raw data to appear more visually accurate. Note that this leads to a loss of fidelity between the adjusted image and the original. (**E**) Saturation indicates that the detector is reporting its maximum value or that the dynamic range for the visualization method has been exceeded.

ASU / CENTRAL UNIVERSITY LIBRARY

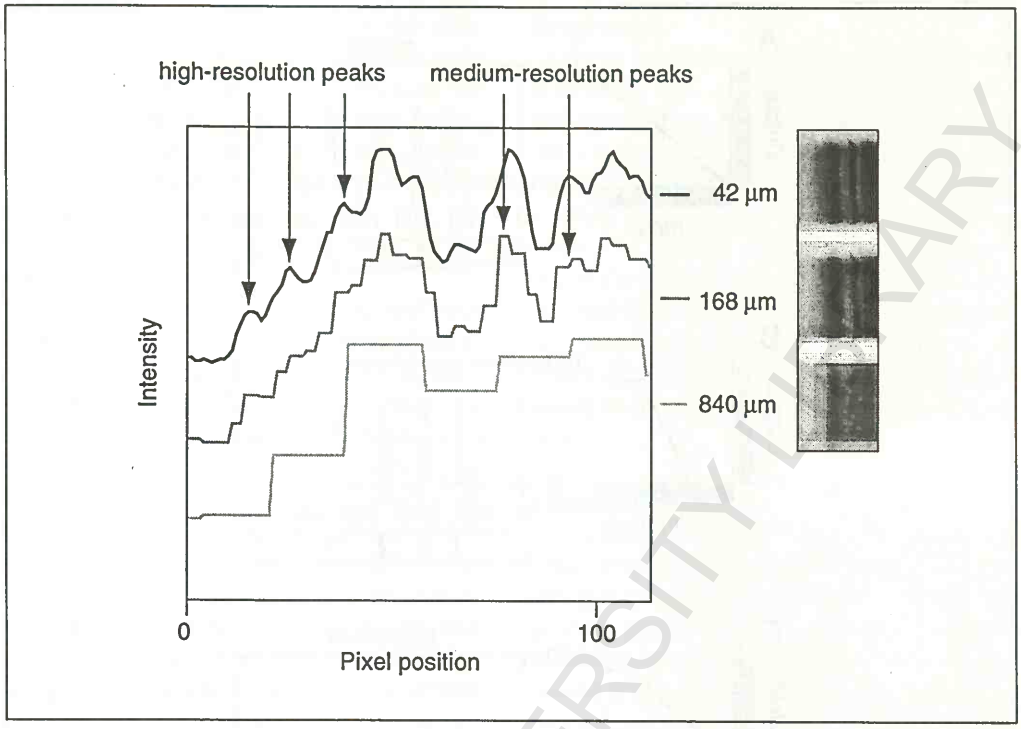

Figure 10.12.2 The effect of spatial resolution on the ability to detect closely spaced objects. Whole-cell protein lysates from *E. coli* were separated using SDS-PAGE and visualized with Coomassie blue staining. An image was captured at 42 µm (600 dpi), 168 µm (150 dpi), and 840 µm (30 dpi) from a segment of the lane, and a lane profile was generated for each image. The lane profiles have offset intensities to allow for comparison. Only major bands can be detected with the low-resolution image (840 µm); at higher resolutions more bands are detectable.

Saturation

Saturation occurs when a detector or visualization method receives input levels beyond the maximum end of the dynamic range. This results in a loss of detail and quantitative information from those data points that are saturated. For fluorescent and luminescent samples, reduction in the sampling time can sometimes correct saturation problems. Optical density-based visualization techniques can also generate saturated images, as is illustrated in Figure 10.12.1E; this can sometimes be avoided with longer sampling times or increased detection source intensities. More often, it will be necessary to perform another electrophoresis with more dilute samples or to alter the visualization process to generate a less optically dense material.

Resolution

Resolution is the ability of a system to distinguish between two closely placed or similar objects. Three types of resolution are important for analysis—spatial resolution, intensity resolution, and technique-dependent resolution.

Spatial resolution is the ability to detect two closely placed objects in one-, two-, or three-dimensional space. It is most accurately described as the closest distance two objects can be placed and still be detected as separate objects. In practice, it is often defined nominally in terms of the number of detectors per unit area such as dots per inch (dpi) or the number of detectors present in total or in each dimension such as 512 × 512 (262,144 total detectors). Actual resolution is less than half the nominal resolution due to the need for two detectors for every resolvable object (one for the object and one for the separation space) and the effects of optical resolution. Figure 10.12.2 demonstrates how spatial resolution can affect detection of objects. The 42-µm resolution image allows detection of closely spaced bands, the 168-µm resolution image detects fewer bands, and the 840-µm resolution image detects only major bands. For instruments with on-line detection systems, a pseudo spatial resolution is often reported in units of time from the start of the separation or the time interval between two objects crossing the detection path.

Intensity resolution is the ability to identify small changes in intensity. It is a function of both the dynamic range of a detector and the number of potential values that detector can

BCU IAST CENTRAL UNIVERSITY LIBRARY

report. Greater dynamic range decreases the intensity resolution of a given detector. The number of potential values a detector reports is described by its bit depth. An 8-bit detector can report 256 (2^8) different possible values, while a 12-bit detector can report 4,096 (2^{12}) values, and a 16-bit detector can report 65,536 (2^{16}) values. The higher the bit depth, the greater the intensity resolution.

Technique-dependent resolution directly affects the spatial and intensity resolution. Electrophoretic separation techniques that generate overlapping objects or that have object separation distances shorter than the spatial resolution will fail to provide reliable data. Many factors, including the amount of sample loaded, gel pore size, buffer constituents, and electrophoresis field strengths, can dramatically affect separation and resolution of biomolecules. Likewise, detection methods that can only generate a small range of discrete intensity values will not benefit from systems with improved intensity resolution.

IMAGE CAPTURE

Devices

Capturing digital images involves a detection beam or source, a sensor for that beam or source, and some method of assembling a two-dimensional image from the data generated. Most systems use a light source for detection. The light wavelengths used range from ultraviolet (UV) to infrared (IR) and can be broad spectrum or narrow wavelength. Broad-spectrum detection is more versatile since it can often be used for more than one detection wavelength. However, when compared to narrow-wavelength sources such as lasers, broad-spectrum detection suffers from reduced sensitivity and reduced dynamic range. While many types of light sensors have been used, including charge-coupled devices (CCDs), charge-injection devices (CIDs), and photon multiplier tubes (PMTs), technology advances in CCDs have led to their dominance. CCDs are semiconductor imaging devices that convert photons into charge. This charge is then read and converted into a digital format via an analog-to-digital converter (ADC).

The method of image assembly depends on the light source and detector geometry. One method is to capture the image all at once using a two-dimensionally arrayed CCD detector similar to the detectors found in digital and video cameras. Typically a camera-type sensor is paired with a light source that evenly illuminates the sample. This same sensor is often used with fluorescent and chemiluminescent detection methods, as its ability to detect light continuously over the entire sample reduces image capture times. Another method of image assembly is to capture the image a line at a time. This typically involves a linearly arrayed CCD scanning slowly across the sample in conjunction with the detection beam of light. The data from each line is then compiled into a composite image. Spatial resolution in this method can be significantly better on large-format samples than the resolution of a camera-based system. This method is also advantageous when OD-based detection is used, since the more focused light beam is usually of higher intensity and can penetrate denser material. A third method of image assembly is to use a point light source and single-element detector on each point on a sample. The image is then compiled from each point sampled. This method is slower than the others but can offer extremely high resolution and sensitivity. A fourth commonly encountered method is that of generating a pseudoimage of electrophoresis results through the use of a finish line type of detection system. This is comprised of a light source positioned at the bottom of the gel (i.e., the end opposite of the site of sample loading) and light detectors positioned next to each lane to detect the transmitted light or emitted fluorescence. A lane trace is generated using time on the *x* axis and light intensity on the *y* axis. The pseudoimage is then generated from this data (Sutherland et al., 1987).

Capture Process

Prior to image capture, electrophoretic separation and any visualization steps are performed. To calibrate the separation process, standards are usually run at the edges of the gel and often at internal positions. If quantitation of specific proteins or nucleic acids is to be performed, a dilution series of standards with similar properties to the experimental samples should also be included. After separation, the protein or nucleic acid is visualized if necessary. Visualization can include binding of a fluorochrome or chromophore such as Coomassie blue, precipitation of metal ions such as copper, silver, or gold, enzymatic reactions, and exposure of film or phosphor screens to radiant sources. These methods can be grouped based on the type of detection into optical density, fluorescence, chemiluminescence, and radioactivity. The suitability of popular detection devices with these methods

BOURNEMOUTH UNIVERSITY LIBRARY

Table 10.12.1 Compatability of Popular Image-Capture Devices with Common Visualization Methods[a]

Visualization method	Image-capture device				
	Silver halide photography	CCD camera	Desktop scanner	Storage phosphor	Fluorescent scanner
Optical density[b]	+	+	++	−	−
Fluorescence	+	+	−	−	++
Chemiluminescence	+	++	−	±	−
Radioactivity	+	−	−	++	−

[a]The device with the highest sensitivity and greatest dynamic range for a visualization method is marked with a ++, other devices that can detect this visualization method are indicated with a +, and devices that are not suitable for a visualization method are indicated with a −. A ± indicates that only some devices of this type can be used with this visualization method.

[b]Optical density methods include Coomassie blue staining.

is described in Table 10.12.1. Once visualization has occurred, image capture consists of the following steps: previewing the image while adjusting capture parameters, capturing the image, and saving the image for later analysis.

During the preview process, capture parameters are optimized for data content and for ease and rapidity of later processing steps. Typically, the first step is to place the sample so that when the image is captured, the rectangular edges of the gel are horizontal and vertical on the monitor and any lanes are either horizontal or vertical. Since band and spot detection will be much easier if the image is properly oriented, this eliminates the need to later rotate the image digitally. Image rotation is time-consuming and can result in spatial linearity errors (a change in the size and shape of objects in image) caused by rectangular image-capture device geometries. The next step for camera-based systems is to adjust magnification and to focus the sample image. For thicker samples, it might be necessary to reduce the aperture on camera-based systems to get a sufficient depth of field to focus the entire sample. Often at this point image imperfections—e.g., dust, liquid, or other foreign objects that will detract from later analysis—are detected, and they need to be removed. Next, image intensity is set. Within the area of interest on the image, band or spot peaks should have values less than the maximum saturated value, and the background should have nonzero values. This is usually accomplished through adjustment of the light-source intensity or the sensor signal integration. If the device allows precapture optimization of other parameters such as spatial resolution, contrast, brightness, gain, or gamma, they are adjusted next. Note that this only applies to controls that affect the response of the sensor or processing of the image prior to a data reduction step and not to controls that affect the image at later stages. The latter process can enhance visualization of specific features but is best left to adjustments in look-up tables (LUTs) in later analysis steps rather than during image capture, since there is a risk of data loss during postacquisition image processing. LUTs are indexed palettes or tables where each index value corresponds to color or gray-scale intensity values present in an image. Many image analysis programs alter LUTs instead of image values directly, since it both is faster and does not change the original image data.

Once all the capture parameters are optimized, the image capture process is initiated. This might take less than a second for images captured with camera-based detectors and up to hours for scanning single-point detectors. When the image has been captured, it should be carefully examined for content. It should fully capture the area of interest and the parameters should have been set so that all necessary information is detectable. Furthermore, it should be in a form that will allow for easy analysis. Extra time spent optimizing the capture parameters will often result in a reduction in total image analysis time and in an increase in data quality. When the best possible image has been captured, it often contains information outside the area of interest. While this is unlikely to cause problems with later analysis, it is often advantageous to crop the image so that the only portion that is saved contains the area of interest. This reduces the amount of disk space necessary to store the image, and the image usually will load and analyze faster with the analysis software.

RCU IAS CENTRAL UNIVERSITY LIBRARY

The last step in image capture is to save the image. Several options are available at this point, including choosing which location to save the image at, what file type or format to use, and whether to use some form of compression.

The location where the image is saved is not as trivial a question as it might seem if the image will need to be transferred to another computer at some point. File sizes can easily exceed 15 megabytes on high-resolution images. This is a manageable size for hard drives but exceeds current floppy drive sizes by an order of magnitude. There are software utilities available that will subdivide files into disk-size chunks and then reassemble them at the next computer, but this is an inconvenient and slow method. If the computer used to help capture the image is connected to a network, the image files can easily be transferred this way or potentially saved on a central server. Alternatively, several types of high-capacity removable media are available (e.g., Zip or Jazz). This usually requires the installation of additional hardware onto two or more computers but does make backing up data easier.

Since image files can be very large, compression techniques are sometimes used to reduce disk space requirements. Compression algorithms use several methods, typically by replacing frequent or repetitive values or patterns with smaller reference values and by replacing pixel values with the smaller difference values describing the change in adjacent pixels. When the file is later decompressed, the compressed values are then replaced with the original information. Not all images compress equally, with simple images containing mostly repetitive motifs compressible by ≥90%, while complex images will benefit much less from compression. Because compression is a much slower method of saving files and will not benefit every file, compression is not used to save all files. Several different forms of compression are available but are separable into two main classes, lossless and lossy. Lossless methods faithfully and completely restore the image when it is decompressed (no loss of data) but offer only moderate file compression; compression values range from ~10% to 90%, depending on the image. Examples of lossless compression include Huffman coding (Huffman, 1952), RLE (Run Length Encoding), and LZW (Lempel, Ziv, and Welch; Welch, 1984). In comparison, lossy methods such as JPEG (Joint Photographic Experts Group), MPEG (Moving Picture Experts Group), or fractal compression schemes can reach compression values of ≥98% (Russ, 1995). The trade-off is that not all information from the original file is recovered during decompression. Lossy compression is sometimes necessary for applications with extremely large image files such as real time video capture, but it usually represents an unacceptable loss of data if used with electrophoresis image capture.

Many different file types have been developed to store digital images. Some of these file types are proprietary or hardware specific. For example, PICT is a Macintosh format and BMP is a PC-compatible format. Each file type has its own structure. Some types do not allow compression, for others it is optional, and for some it is mandatory. File types vary in the types of images they support, particularly in the number of colors or gray levels. Below is a brief description of a few of the more prevalent file types.

TIFF (Tagged-Image File Format) is one of the most commonly used formats. It is particularly versatile since it is an open format that can be modified for specific applications. One reason for its versatility is the ability to attach or tag data to the image. The tags can include information such as optical density calibration, resolution, experimenter, date of capture, and any other data that the application software supports. TIFF images can be monochrome, 4-, 8-, or 16-bit gray-scale, or one of many color-image formats. Compression is optional, with LZW, RLE, and JPEG often supported (Russ, 1995). Since TIFF is supported by both Macintosh and PC computers, it is a good choice for multiple-platform environments. The versatility of TIFF can also be a weakness. Since there are many different tagging schemes and since not all programs support all possible compression and color schemes, it is sometimes not possible for one program to access the information in a TIFF file generated by a different program.

GIF (Graphics Interchange Format) is a file format that is widely encountered on the Internet due to its compactness and standardization. Its compactness is attributable to a mandatory modified LZW compression. Another feature of GIF is the use of a LUT to index the values in the image. One interesting ability of GIF is that it supports storing multiple images within a single file. This can offer some advantages for applications such as time-lapse image capture. A GIF image can contain no

BRANDEIS UNIVERSITY LIBRARY

more than 256 individual color or gray levels and does not support intensity resolutions higher than 8 bit. In addition, since the image is implemented as a LUT, it also is not a true gray-scale image. Due to these limitations and others, alternative formats such as PNG have been developed to replace GIF.

PICT is a file format and graphics metafile language (it contains commands that can be played back to recreate an image) designed for the Apple Macintosh. It can contain both bitmap images and vector-based objects such as polygons and fonts. It supports a ≤256-gray-level LUT, and monochrome images can be RLE compressed. Because it only offers a 256-gray-level LUT, it has the same weaknesses that GIF does with true gray-scale and high-intensity-resolution images. In addition, any vector objects in the image are difficult to translate on a PC since they are designed to be interpreted by Macintosh QuickDraw routines.

BMP is the native bitmap file format present on Windows-based PCs. It supports 2-, 16-, 256-, or 16-million-level images. With images of ≤256 gray levels, it implements a LUT, while the highest-resolution image is implemented directly. RLE compression is optional for 16- and 256-gray-level images. Since compression is prohibited on 16 million-gray-level images and there is no intermediate level supported beyond 256 levels, BMP is not a good choice for images with high-intensity resolution requirements.

ANALYSIS

Once the image has been captured, the data needs to be analyzed and distilled into information about the results of the electrophoresis experiment. Through the use of standards and experimenter input, this software-driven process can estimate mass and quantity of objects in an image and detect relationships between objects within one image and between similar images. The type of software used depends on the analysis to be performed. Images from single electrophonetic separations are examined by one-dimensional analysis software optimized for lane-based band detection. Images from two-dimensional electrophoresis are best handled by specific programs designed to detect spots and to assign two mobility values and a quantity value to the spot. After the initial characterization of bands and spots, comparisons are often made between bands or spots from different experiments through the use of database programs and matching algorithms.

Software for One-Dimensional Analysis

Lane positioning

For one-dimensional analysis, the first activity is to detect the lanes on the image. One of three different methods is commonly employed for this. For images with straight, well-defined lanes with a large number of bands, automatic lane-detection algorithms can quickly and accurately place the lanes. On images with very well-defined lanes, such as pseudoimages from finish-line type electrophoresis equipment, automated lane calling based on image position is possible. For images with "smiling," bent, or irregular lanes, manual positioning of the lanes is often the fastest and most accurate method of lane definition. Regardless of the method of identifying the lanes, the lane boundaries need to be carefully set for accurate quantitation and mass determinations. Lane widths should be wide enough so that the entire area of all bands in that lane are included, but they should not be so wide as to include bands from adjacent lanes. To accomplish this, curved or bent lanes might need to be used in order to follow the electrophoresis lane pattern. Lane length and position also must be adjusted as necessary so that all bands of interest are included. If mass determinations are necessary, the sample loading point should probably also be included in the lane or be the start of the lane. At this point, lines of equal mobility (often called R_f or iso-molecular-weight lines) are added to the image as necessary. These lines allow for correction of lane-to-lane deviations in the mobility of reference bands and generate more accurate measurements of mass. A similar form of correction is also possible for within-lane correction of mobilities. This correction is important for accurate detection and quantitation of closely spaced bands.

Band detection

Once the lanes have been defined, the bands present in each lane need to be detected. There are many methods for detecting bands. One method is to systematically scan the lane profile from one end to the other, identifying regions of local maxima as bands. Another common method is to use first- and second-order derivatives of the lane image or lane profile in order to find inflection points in the change of slope in pixel intensity values (Patton, 1995). Regardless of the method used, it is often necessary to alter the search parameters so that they perform reliably under a given experimental condition.

BCU IASE CENTRAL UNIVERSITY LIBRARY

Typical search parameters include ones for detection sensitivity, smoothing, minimum interband gaps, and minimum or maximum band peak size. Smoothing reduces the number of bands detected due to noise in the image. A minimum interband gap is often used to avoid detection of false secondary bands on the shoulders of primary bands. Limitations on peak sizes, especially for within-lane comparison to the largest band's peak, can be a useful way to allow sensitive detection of bands in underloaded lanes without detecting false bands in overloaded lanes.

Band edges are often detected in addition to band peaks in order to further define bands or to quantitate band amounts. This can be accomplished by using local minima, derivatives of the lane profile, or fixed parameters such as image distances or a percentage of band peak height. The band edges can be applied as edges perpendicular to the long axis of the lane or as a contour of equal intensity circling the band. The perpendicular method is advantageous for bands with uneven distribution of material across the face of the band, while the latter method is better for "smiling" or misshapen bands.

Background subtraction

With nearly all electrophoresis procedures, the most informative images have a low level of signal intensity at each pixel that does not result from protein or nucleic acid. Instead, this background intensity is attributable to the gel medium, the visualization method, electronic noise, and other factors. Since this background tends to be nonuniformly distributed throughout the image, failure to subtract it can make band detection and quantitation less accurate. Many methods of background subtraction are possible. Sometimes it is possible to generate a second image under conditions that do not detect the protein or nucleic acid. The second image is then digitally subtracted from the data-containing image to remove the background. More often, background information must be obtained from a single image. If the background varies uniformly across the image, a line that crosses the variation can be defined at a point where no bands are present. The intensity values at each point on the line can be used as the background value for the pixels perpendicular to the line at that point. Commonly, background is also present as variations in intensity along the long axis within each lane. One simple method is to take the lowest point in the lane profile as the background. Another method is to use an average value of the edge of each band as the background for that band. More complicated methods such as valley-to-valley and rolling-disk use local minima points in the lane profile to define a variable background along the length of the lane. Because there can be many different causes and distributions of background, no single method of background determination can be recommended for all experiments.

Characterization

Once lanes and bands have been detected, it is possible to interpret the mobility of the nucleic acid or protein bands. Depending on the method of electrophoretic separation, information on mass (length or size), pI, or relative mobility (R_f) can be inferred from mobility information. The mobility is characterized using a standard curve with internal standards of known properties. The type of curve depends on several parameters. By definition, with R_f-based separation, a linear first-order curve is used since it represents the linear relationship between mobility and R_f. Similarly, pI and mobility are generally linear in isoelectric focusing separations. For separations based on size, a curve generated from mobility versus the log of the molecular weight provides a relatively good fit as measured by the correlation coefficient (R^2). Several other curves have been suggested for size-based separations, including modified hyperbolic curves and curves of mobility versus (molecular weight)$^{2/3}$ that have good correlation coefficients (Plikaytis et al., 1986). In some cases, no single curve equation can adequately represent the data, and methods of fitting smooth contiguous curves using only neighboring points, such as a Lagrange or spline fit (described in Hamming, 1973), are necessary. This is most common for size separations with a very large range of separation sizes and with nonlinear gradient gels. Care must be taken with multiple-curve techniques since they rely on only a few data points for any one part of the composite curve, and outlying data points can drastically affect the outcome.

For size and R_f determination, a uniform position must be found in each lane as a point from which to measure the mobility of each band. Many software analysis packages use the end of the lane as the measuring start point, so for them it is important to position each lane start point at an iso-molecular-weight or iso-R_f point. A convenient point is the well or sample-loading position since it is usually easily de-

B.C.U. „M. EMINESCU" IAŞI
CHI . IE

BIBLIOTECA CENTRALĂ UNIVERSITARĂ

tectable and at an equal mobility position in each lane. A consistent point on each band must also be chosen to measure mobility. A band's peak is easily defined in digital image analysis and is commonly used. Since peak positions are harder to detect visually than edges on silver halide images, the leading band edge is sometimes used when comparing digital results with silver halide–based results.

Once lanes and bands have been detected, it is also possible to quantify the amount or at least relative amount of nucleic acid or protein present in each band. The amount in a band is related to the sum total of the intensity values of each pixel subtracted by the background value for each pixel in a band. For absorptively detected bands, intensity values are converted to OD values. The total value that is calculated is equivalent to the volume of the band and can be directly compared to other bands that are within the linear range for the visualization method. If standards of known amounts are loaded onto the same gel, they can be used to generate a standard curve that converts band volume into standard units such as micrograms. For greatest accuracy, it is important to be able to generate multiple standard curves when using visualization methods, such as Coomassie blue staining, that are affected by band or spot composition.

Quantitation becomes more complicated when bands are not fully resolved. In this case, material from one band is contributing to the volume measurement of an adjacent band and vice versa. The simplest method for handling this is to partition into each band only the volume within its edges. Alternatively, a Gaussian curve can be fitted to each band and the volume contained within the curve used to estimate the amount of the band. Since most electrophoresis bands have a pronounced skew towards the leading edge of the band, modified Gaussian curves have also been used (Smith and Thomas, 1990). In either case, the curve-fitting process is calculation intensive and can significantly increase analysis times for images with many bands.

Software for Two-Dimensional Analysis

In two-dimensional analysis, the first-dimension separation is performed in a single column or lane and then a second separation is performed perpendicular to the first. The result after visualization is a rectangular image of up to 10,000 spots. The most common two-dimensional gel type is one in which protein is separated first by apparent pI and second by molecular weight, although two-dimensional separation of nucleic acids is also possible. While many of the concepts and analysis techniques used with one-dimensional gels are applicable to two-dimensional gels, the complex nature of most two-dimensional gels requires somewhat different methodology. For example, spots are more difficult to detect since they are not conveniently arranged in lanes and can vary more in shape and overlap than bands. In addition, two-dimensional experiments usually require some method of comparing between two images, whereas one-dimensional images usually contain all of the information from an experiment.

Spot detection

Probably the most difficult aspect of two-dimensional analysis is efficient and accurate spot detection. If it is incorrectly done, it can lead to hours of manual editing. Due to the complexity and computational intensity of some algorithms, the detection process itself can last hours on relatively fast desktop computers. One theoretically effective but computationally intense method is to treat the image as essentially a three-dimensional image with spots treated as hills and background as valleys. A large number of Gaussian curves are then combined to describe the topology of the image. Many other methods make use of a digital-imaging technique known as filtering. In essence, filtering is a way to weight the value of a pixel and its neighbors in order to generate a new value for a pixel. By passing a filter across an image pixel by pixel, a secondary image is generated. Filters can be designed for many tasks, including sharpening an image or removing high-frequency noise. Filters can also be generated to help detect spots by making images that are first and second derivatives of the original image. The derivative images indicate inflection points in the intensity pattern and can be used to detect spot centers and edges. In a different method, called thresholding, filters can be used to detect the edges of objects. Instead of looking for inflection points, threshold filters identify intensities above a set level or at ratios between central and edge pixels above a set value. Since the edges on two-dimensional spots tend to be diffuse, sharpening filters are sometimes used prior to the thresholding filter. In some cases, multiple techniques are used to detect spots (Glasbey and Horgan, 1994).

BCU IAS CENTRAL UNIVERSITY LIBRARY

Unlike one-dimensional detection, detection on images of two-dimensional experiments usually requires secondary processing to get acceptable performance. One example of a secondary process is to discard spots with sizes below a set minimum or above a set maximum. Another is to analyze spots that are oval for possible splitting into two spots. Even after secondary processing, it is likely that a small amount of manual editing will be necessary. When manually editing an image, care must be taken to use as objective criteria as possible, especially if two or more images are to be matched and spot volumes compared.

Characterization

In a two-dimensional system, determination of protein or nucleic acid mobility is complicated by the fact that there are two mobilities to account for and that the second-dimension separation tends to make estimation of the separation which occurred in the first dimension more difficult. One method for dealing with this is to have a series of markers in the sample that, after both separations are completed, are evenly distributed within the gel and image. It is also possible to estimate separation characteristics from calibration points located at the periphery of the gel. For example, distance measurements can be used to pass calibration data from the first dimension separation, and standards can be separated at the ends of the gel to calibrate for mobility in the second dimension. Regardless of the method used, in many instances, a series of related images will be examined and similar spots in each image will be matched. When this occurs, it is possible to calibrate one image and then pass the calibration information via the matches to the related images.

Quantity determination is similar in many regards to that which occurs in one-dimensional analysis, but there are some differences. If spot edges are detected, a simple method of determining spot volume is to take the sum of the intensity value of each pixel in the spot reduced by a background intensity value. Multiple Gaussian curves can also be fitted to the spot to approximate the volume (Garrels, 1989). More difficult is attempting to compensate for a skewed distribution in a size-separating dimension while trying to use a regular Gaussian fit for a pI separation, such as is encountered with the most common form of two-dimensional protein separations. The distribution of background makes quantitation more difficult in two-dimensional gels. There is no lane-dependent component, so it is necessary to use other methods such as image stripes, finding local minimum values or using values derived from the spot edges to determine background values.

Matching

Matching is the process in which proteins or nucleic acids with similar separation properties are linked or clustered together. Matching can occur within one image or between multiple images as long as a frame of reference is established. Matching allows for comparisons between samples. It also makes annotation and data entry easier, since if one spot or band is matched to others and is characterized or annotated, this information is easily passed to all the other matches. An underlying assumption of matching is that objects with similar separation properties are actually similar. Care must be taken to confirm the identity of matched spots or bands by other methods on critical experiments.

A simple form of matching is to link bands or spots at similar positions on the gel images. This works well when separation and imaging conditions are uniform. This is very seldom the case, since slight differences in the electrophoresis, visualization, and imaging conditions across a gel and between gels generates incorrect matching with this method. Since bands on one-dimensional gels are relatively easy to calibrate for mobility, matching can occur along contours of equal mobility. This dramatically decreases but does not eliminate the variability in detecting similar bands. Much of the remaining variability can be attributed to calibration errors. This error can often be compensated for by allowing a small tolerance in mobility values in determining whether a band is matched or not. Because of the difficulties in calibrating mobility in two-dimensional gels, it is often more practical to use matched spots for calibrating mobility than vice versa. Spot matching between two two-dimensional images starts with finding a small number of landmark spots that are used as seeds for subsequent matches (Appel et al., 1991; Monardo et al., 1994). There are many methods for finding the landmarks in both images, including finding the highest-intensity spots, finding spots in unique clusters, and manual positioning. The most common procedure from this point is to derive a vector that describes the direction and extent of the path from one matched spot to the other when the two images are superimposed. The vector is used as the basis for finding more matches near the landmark matches. To allow

BOSTON UNIVERSITY CENTRAL LIBRARY

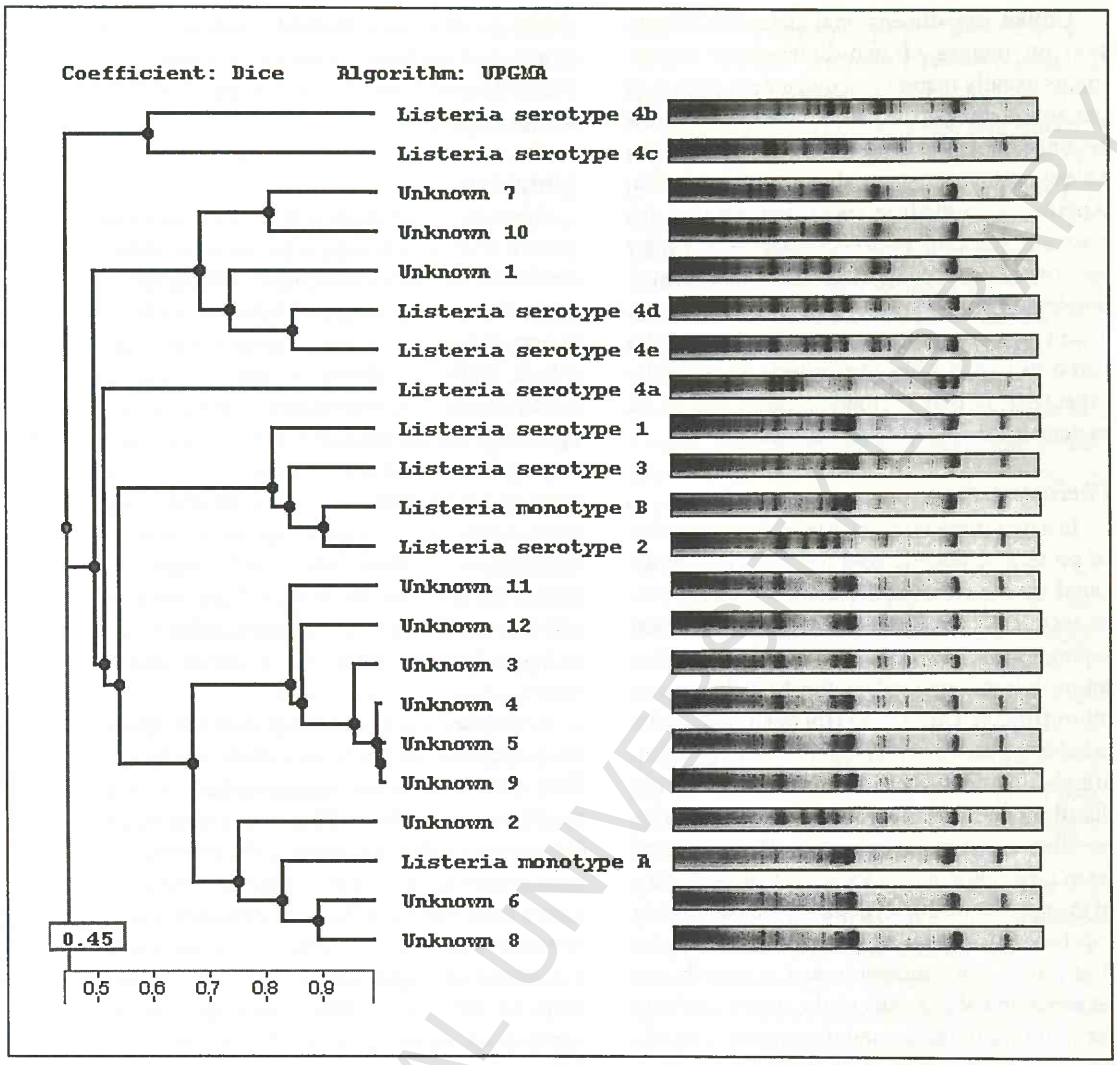

Figure 10.12.3 Example of a dendrogram generated from similarity data on band matching between lanes. DNA samples from 22 isolates of *Listeria* were subjected to Random Amplification of Polymorphic DNA (RAPD) analysis and the resulting electrophoresis image was analyzed with ImageMaster software (Amersham Pharmacia Biotech). Clustering was performed using the Dice coefficient with a tree structure based on the Unweighted Pair-Group Method using Arithmetic Averages (UPGMA). Similarity values between isolates can be determined by locating the node that connects the isolates and reading the value from the scale on the lower left edge of the dendrogram.

for error, the area within a small radius is searched extending from the end of the vector. Once another match is found, its vector is computed and used as the starting point for finding neighboring matches. From this progression, the entire gel is matched. If all vectors are displayed graphically when matching is complete, questionable matches can often be identified as vectors that are significantly different from neighboring vectors.

One specialized use of matching is as an estimator of the similarity and potential genetic relatedness of organisms. For example, on a one-dimensional gel image, a ratio of the matched to unmatched bands for each pairwise combination of lanes can be calculated. This ratio can be used as an indicator of similarity, with values near 1 indicating a pair of highly similar lanes, and values near zero indicating very dissimilar lanes. Assuming that the contents of the lanes are valid samples of the originating organism's genetic makeup, the information on lane similarity can be converted to estimates of genetic similarity. A convenient way to display this similarity data graphically is to generate a dendrogram with similar objects close to each other and less similar objects more distantly placed. An example of such a dendrogram is presented in Figure 10.12.3, where samples from *Listeria* isolates are arranged based on banding pattern.

BCU IACT CENTRAL UNIVERSITY LIBRARY

Databases

In many cases, image analysis is not the last step in the process. The image and analysis data need to be archived in a searchable format. There may be a need to analyze the data from multiple experiments conducted at different sites or in laboratories around the world. Bioinformatic links to diverse data sources might be desired to help develop a unified understanding of the biology behind particular phenomena. When these situations arise, database programs can be utilized to store, link, and search image analysis results.

As the number of images that are captured and analyzed grows, it becomes increasingly more difficult to find particular information from the large number of files that are stored. Relatively simple databases can be used if the major requirement is to find previously analyzed images and associated data. Such databases often display a miniaturized version of each image to aid in visual scanning for the file as well as simple searching for image-specific information such as date of analysis, file name, or other information that was entered at the time of image capture. More powerful database products are also available that can perform complex searches on data generated during the analysis. For an example, a search on a two-dimensional database might include finding proteins exhibiting a specific expression profile and having a molecular weight >20 kDa with a pI between 3 and 5 or 8 and 10 with an amount <50 ng in a series of experiments conducted <1 year ago. Such searches can quickly target potentially interesting molecules for further analysis.

With the increasing ease of transferring data through the Internet as well as local- and wide-area networks, it has become practical to quickly find and examine data from distant locations. Of course, great care must be taken to ensure that similar experimental conditions are employed, as otherwise the results will be difficult to compare. In this manner it is sometimes possible to dramatically increase the sample size and statistical accuracy as well as the probability of detecting rare events. In addition, if one data set is more completely characterized, this extra information can be extracted and applied to the other data set. For example if there is a band in common in two databases and there is sequence information for it in one database, that sequence information can be added to the other database. Currently most public electrophoresis database sites are two-dimensional protein databases. A list with links to many of these Internet database sites can be found at *http://www-lmmb.ncifcrf.gov/EP/table2Ddatabases.html*.

With biological questions becoming more complicated and the answers to the questions often requiring information from a variety of sources, it is becoming increasingly important to be able to move easily between information sources. A relational type of database can help achieve this. Unlike a conventional database with a fixed arrangement of data, relational databases have links between related files that allow for easy movement from one file to another. Another approach to interconnecting electrophoresis data with data from other sources is to generate a series of hypertext links between data sets, similar to what occurs on the Internet. Selecting a specific link moves the search to the related network site and the related information. Regardless of the method, the end goal is similar. An example of what is possible: a researcher selects a protein spot on a two-dimensional gel image, which triggers accessing of related information on this protein. The protein sequence is accessed from mass spectroscopy analysis of the spot on a separate gel. The sequence of the gene and the cDNA that generated the protein is retrieved. The expression pattern of the gene in various tissues and conditions, as well as information on similar genes in other organisms, is incorporated. Citations and annotations to this are retrieved as well. All of this information is compiled automatically into an interactive report about the protein. From this report, the researcher can formulate a more refined hypothesis and plan the most appropriate experiments to test it.

Mass Changes Due to Some Post-Translational Modifications of Peptides and Proteins[a]

Modification	Average Mass Change
Pyroglutamic acid formed from Gln	−17.0306
Disulfide bond formation	−2.0159
C-terminal amide formed from Gly	−0.9847
Deamidation of Asn and Gln	−0.9847
Methylation	14.0269
Hydroxylation	15.9994
Oxidation of Met	15.9994
Proteolysis of a single peptide bond	18.0153
Formylation	28.0104
Acetylation	42.0373
Carboxylation of Asp and Glu	44.0098
Phosphorylation	79.9799
Sulfation	80.0642
Cysteinylation	119.1442
Pentoses (Ara, Rib, Xyl)	132.1161
Deoxyhexoses (Fuc, Rha)	146.1430
Hexosamines (GalN, GlcN)	161.1577
Hexoses (Fru, Gal, Glc, Man)	162.1424
Lipoic acid (amide bond to lysine)	188.3147
N-acetylhexosamines (GalNAc, GlcNAc)	203.1950
Farnesylation	204.3556
Myristoylation	210.3598
Biotinylation (amide bond to lysine)	226.2994
Pyridoxal phosphate (Schiff Base formed to lysine)	231.1449
Palmitoylation	238.4136
Stearoylation	266.4674
Geranylgeranlylation	272.4741
N-acetylneuraminic acid (Sialic acid, NeuAc, NANA, SA)	291.2579
Glutathionylation	305.3117
N-glycolylneuraminic acid (NeuGe)	307.2573
5′-Adenosylation	329.2091
4′-Phosphopantetheine	339.3294
ADP-ribosylation (from NAD)	541.3052

[a]To obtain the molecular mass of a modified peptide or protein, the appropriate mass changes should be algebraically added directly to the molecular mass calculated for the unmodified molecule.

HOW TO USE POST BINDERS

To open: pull tab at bottom of metal locking bar toward you until front cover releases. Pull out post bar to add or remove sheets.

To close: reinsert post bar, engage front cover, and push locking tab in completely.
